Head and Neck Tumor Biology

108

Alec Vaezi *Jennifer R. Grandis*

The treatment of head and neck squamous cell carcinoma (HNSCC) evolved slowly over most of the 20th century, with important breakthroughs including the description of the radical neck dissection by George Crile (1) in 1906 with an improvement of 3-year survival from 19% to 75%, the report of modified radical neck dissection by Suarez et al. (2) in 1963, the introduction of postoperative adjuvant external beam radiotherapy in the 1970s, and the use of adjuvant chemotherapy in the late 1980s. However, the last 20 years have brought considerable advances in the understanding of head and neck cancer tumor biology. Molecular techniques helped epidemiologists identify and characterize human papillomavirus (HPV)-associated HNSCC, which is currently responsible for an epidemic of oropharyngeal HNSCC extending throughout North America and, to a lesser extent, Europe. In addition, with better understanding of the genetic and molecular changes that characterize HNSCC, novel therapeutic agents have been designed and used with success in the treatment of HNSCC, such as the EGFR-blocking antibody cetuximab (Erbitux). Furthermore, novel prognostic and predictive biomarkers are being evaluated in the clinical setting to inform personalized cancer treatments in which the treatment is tailored to the biology of an individual tumor. HNSCC vaccine trials are currently accruing patients, and the role of cancer stem cells (CSCs), angiogenesis, and microRNAs is under study. Very recently, the HNSCC cancer genome has been outlined by sequencing the genomes or exomes of nearly 75 tumors (3). In sum, these times are exciting not only for head and neck tumor biologists but also for clinicians and patients who are already seeing the benefit of scientific discoveries in the clinical setting.

As basic science increasingly merges with clinical medicine, it is important for the clinician to be familiar with the different molecular pathways contributing to HNSCC development. A working knowledge of this biology has become essential for understanding treatment options for HNSCC in the 21st century. This chapter reviews selected major molecular pathways contributing to HNSCC. These include the mitogen signaling cascade, the cell cycle and its regulation, the major DNA repair pathways, and protection against apoptosis. The concept of solid tumor stem cells and angiogenesis is also discussed. For each section, a current model for the pathway is described, highlighting how deregulation of this pathway participates in tumor development. Examples illustrate how each pathway is involved in HNSCC tumor biology, and its clinical relevance. However, it is important to remember that basic science is in constant evolution. What appears meaningful today may be obsolete tomorrow. Every effort has been made to provide models backed by strong evidence that are likely to withstand the test of time.

DIFFERENT SUBTYPES OF HNSCC IDENTIFIED BASED ON RISK FACTORS AND GENETICS

Head and neck cancer is an important cause of death and morbidity worldwide. It is the eighth most frequent type of cancer in the USA with nearly 50,000 new cases diagnosed every year accounting for 11,000 deaths (4). Similar to other cancer types, HNSCC is proportionally even more deadly worldwide, where 510,000 new cases of HNSCC will be diagnosed yearly and more than half of these patients will succumb to their disease (5). Each of these cancers is the result of a multistep accumulation of genetic mutations in a progenitor cancer cell (6–8). Subsequent proliferation of mutated progenitor cells results in clonal expansion. With further accumulation of mutations, the clonal outgrowth becomes unregulated and irreversible. The nascent tumor progressively acquires new phenotypes including the capacity for invasiveness and metastasis. It was previously thought that head and neck cancers resulted from 6 to 10 independent significant genetic mutations acquired

over a period of 20 years (9). However, recent data from head and neck cancer genome sequencing suggest that many more mutations accumulate, although most of these may be of little consequence (i.e., passenger mutations) (3). In HNSCC, on average, 1 to 15 base pairs are mutated for each megabase of exome (3), which suggests there may be at least 6,000 to 90,000 mutations for the 6.4 billion base pairs in the human diploid genome.

Over the past 15 years, it has been increasingly evident that all tumors labeled as HNSCC may not represent the same clinical entity (10). For instance, HNSCC tumors have different prognosis depending on the affected site. A tonsil cancer from a middle-age smoker–drinker behaves differently than a lateral tongue cancer from an elderly woman who never smoked or drank, or a tonsil cancer from a young nonsmoker. Epidemiologic and clinical studies suggest that even HNSCCs with a similar histologic appearance may represent different types of tumors based on molecular heterogeneity, pathogenesis, risk factors, and clinical outcomes.

Exposure to carcinogens present in tobacco or betel quid is a major factor for head and neck cancer that has been recognized for years. Tobacco derivates contain a potent carcinogen, which damage the DNA and mutate the genome of progenitor cancer cell; tobacco smoke contains more than 4,000 toxic compounds including 81 carcinogens (11), and smokeless tobacco contains mutagenic nitrosamines (11). Interestingly, *in vitro*, one of the most potent carcinogens found in cigarette smoke, named benzo[a]pyrene diol epoxide, preferentially mutates p53 at hot spots found in lung cancer (12). It is therefore perhaps not surprising that p53 is the most frequently mutated gene in HNSCC, since tobacco consumption and synergistically excessive alcohol intake are the two major risk factors for HNSCC in the USA; "heavy" tobacco consumption increases the cancer risk by 5.8 times, "heavy" drinking by 7.4 times, and combination of the 2 increases the risk by 38 times in male and 100 times in females (13). In eastern countries, areca nut chewing in betel quid has been identified as a risk factor for HNSCC. The areca nut does not contain a single organic chemical responsible for the cancer formation, but rather a combination of chemicals that affect distinct steps of carcinogenesis. Areca alkaloids have genotoxic effects and participate in tumor initiation, and arecaidine contributes to tumor promotion (14).

After HPV was identified in oropharyngeal cancers (15–19), it became evident that a subset of oropharyngeal HNSCC is not associated with smoking and drinking but rather with promiscuous oral sex behavior and to seropositivity of sexually transmitted HPV16 (18,20). HPV-positive HNSCC found in nonsmokers has a better prognosis than traditional HNSCC found in smoker/drinkers (21,22). That these tumors represent two groups of HNSCC with distinct tumor biology is also evident at a genetic level: considerably fewer mutations are found in HPV-positive tumors from nonsmoker patients (3). Interestingly, retrospective analyses of archived tumors suggest that oropharyngeal HPV-positive tumors represent a relatively recent entity; also, to date, this epidemic has spread more extensively in the USA than in Europe. HPV-positive HNSCC in nonsmokers is now widely recognized as a distinct group of HNSCC (21). With further progress in the genetic and molecular understanding of HNSCC tumor biology, novel groups of HNSCC are likely to be characterized.

Other subtypes of HNSCC may originate on particular genetic backgrounds. Humans are not identical due to a certain genetic variability, or polymorphism, observed within the human population. In certain instances, the polymorphism has a profound effect on the function of a cancer susceptibility gene and induces a cancer-prone syndrome, sometimes an HNSCC-prone syndrome. For instance, patients with a congenital deficiency in one of the multiple genes coding for the Fanconi anemia DNA repair pathway proteins are 500 to 700 times more prone to HNSCC compared to other patients. Fanconi anemia patients, recognized at birth by finger aplasia, abnormal facies, and short stature, develop childhood aplastic anemia due to apoptosis of hematopoietic cells, and myelodysplastic syndrome in adolescence, with an 800-fold increased chance of myeloid leukemia (23). These patients are exquisitely sensitive to genotoxic stress by cross-linking agents (such as mitomycin C) because they cannot efficiently repair mutagenic DNA *inter*strand cross-links; as a consequence, their cells rapidly accumulate mutations when exposed to carcinogens (23). In a similar vein, it has been proposed that polymorphisms in DNA repair genes that mildly affect DNA repair capacity may lead to increased susceptibility to HNSCC due to hypersensitivity to environmental DNA-damaging agents. However, increased HNSCC susceptibility due to polymorphisms in DNA repair genes remains largely unproven (24).

PATHOGENESIS AND FIELD CANCERIZATION

Most of our knowledge about HNSCC pathogenesis comes from oral cancer. Precursor lesions of oral SCC are *oral leukoplakia* and *erythroplakia*. Clinically evident premalignant lesions are prevalent in less than 0.5% of the population where the rate of progression to cancer is estimated to be 1% to 2% per year (25). The leukoplakia is an exclusion diagnosis. It is a clinical term referring to a patch of white mucosa that does not disappear by rubbing. More specifically, a workshop coordinated by the World Health Organization defines leukoplakia as "white plaques of questionable risk having excluded (other) known diseases or disorders that carry no increased risk for cancer" (26). The erythroplakia is a clinical term reserved as an exclusion diagnosis for a red velvety mucosal lesion that cannot be classified otherwise. These are clinical terms based on the macroscopic appearance, the lesion, and not pathologic diagnoses, and inference on the histopathology of the lesion

should not be made. Histologically, most leukoplakia are the consequence of a hyperkeratotic response to an irritant, and only 20% shows evidence of dysplasia or carcinoma on histology (27,28), while 90% of erythroplakia demonstrate changes consistent with premalignancy or early malignancy (29). However, it is now evident that the macroscopically normal mucosa that surrounds the excision site of HNSCC may also represent mucosa in an inconspicuous state of premalignancy, and may be the source of recurrence (10). As early as the 1950s, the concept of field cancerization that the mucosa is diffusely diseased and at higher risk of developing tumor was proposed (30). Scientific advances over the past 20 years have begun to describe the pathogenesis of HNSCC at a molecular and genetic level.

Experimental animal models of tumor formation have identified chemical tumorigenesis as a two-step process. First, a mutagen, such as dimethylbenzanthracene (DMBA) or 4NQO, is applied to the epithelium (31). During this step, called *tumor induction*, genotoxic stress induces DNA damage, which, if not repaired, leads to mutation of the genome of a precursor cancer cell. In this model, mutations are not sufficient to induce cancer. The mutated precursor cancer cell needs to be stimulated to proliferate to progress to cancer. In skin carcinogenesis, application of croton's oil stimulates the protein kinase C (PKC) signaling cascade (see below) and induces epithelial and precursor cancer cell proliferation; this step is called *tumor promotion* (32). With further mutations, clonal outgrowth becomes irreversible and unregulated.

The critical mutations leading to cancer development occur in two major gene categories: *proto-oncogenes* and *tumor suppressors*. Proto-oncogenes are genes involved in normal cellular functions such as cell proliferation or cell death (33). Ras and epidermal growth factor receptor (EGFR) are proto-oncogenes. A proto-oncogene with a mutation that renders it capable of transforming a cell is called an *oncogene*. Since oncogenic mutations represent genetic gain of function, mutation in only one of the two gene copies (alleles) is sufficient to confer a growth advantage. For example, only one mutated copy of an activated EGFR is sufficient to drive proliferation. In contrast, tumor suppressors are genes that prevent carcinogenesis. Mutations of both alleles are required to remove a normal cellular block to cancer development (33). Often one copy is inactivated by mutation, and the other is lost secondary to loss of heterozygosity (LOH). For instance, p53 is a tumor suppressor, as it prevents cell proliferation and induces apoptosis. With a mutation that inactivates only one copy of p53, the cell can still efficiently regulate the cell cycle via the remaining non-mutated copy. If copies are lost or inactivated, the cell cycle block is removed. Ironically, p53 was initially identified in a screen designed to identify oncogenes (34–36). The mutant copy of p53 that was thought to be an oncogene was later recognized to be a dominant negative form, in which the mutated p53 prevented the function of the normal allele (37,38). When this was understood, p53 was recognized to be a tumor suppressor (39,40). A list of putative and confirmed oncogenes and tumor suppressors in HNSCC and their respective chromosomal locations is provided (Table 108.1).

A multistep model of HNSCC progression proposes that mutations may be acquired in a progenitor cancer cell in a successive manner, ultimately leading to carcinoma formation (Fig. 108.1) (7,8,33,41). This model resulted from the analysis of cancers and cancer precursors in which histology was linked to genetic analysis (42). LOH of chromosome 3p and 9p, which contains the tumor suppressor p16, is frequently found in dysplasias, and is thought to be involved early during carcinogenesis (6,8). Loss of 17p, the part of the genome that contains p53, occurs at the transition from a noninvasive to an invasive lesion (6). In contrast, alteration of chromosomes 4q, 11q, and 8 is found

TABLE 108.1 TUMOR SUPPRESSORS AND ONCOGENES IN HNSCC

Tumor Suppressor	Location	Oncogenes	Location
p16 (CDKN2A)	3p21	**Cyclin D1(CCND1)**	**11q13**
p53 (TP53)	17p13	**EGFR**	**7p11**

preferentially in carcinomas and is thought to represent late events in the carcinogenic process (6,7). 11q amplification corresponds to cyclin D1 overexpression.

In LOH and chromosomal amplification, a group of genes located in one region of a chromosome are all lost or amplified at once. Genetic mapping of the lost/amplified portion of the chromosome helps delineate genes potentially involved in tumor formation. In addition, cells with common genetic alterations can be identified on histology and mark clonal expansion of cancer progenitors. By labeling cells bearing these chromosomal markers together with p53 mutations on histologic slides, it was found that in 35% of oral carcinomas the macroscopically normal mucosa surrounding the tumor contained genetic alteration (43). Eradication of the mucosa bearing genetic alterations at the time of surgery is critical to reduce local recurrences (44). These data support the field cancerization theory put forward in the 1950s.

With the principles of carcinogenesis in mind, we can probe into the major molecular pathways that are dysregulated in cancer precursor cells and are instrumental in driving cancer progression. The clonal growth of a cancer precursor cell can be viewed as the product of a steady state equation in which the rate of proliferation is greater than the rate of cell death, leading to a net overgrowth of the clone. At the core of proliferation lies the cell cycle and its tight regulation. Before elaborating on this, it is important to review the major autocrine and paracrine signals that drive the cell cycle.

UPSTREAM OF THE CELL CYCLE: EPIDERMAL GROWTH FACTOR RECEPTOR AND TGFβ

Epidermal Growth Factor

Under physiologic conditions, epithelial cells proliferate in response to mitogens of the epidermal growth factor (EGF) family of ligands that are secreted in autocrine or paracrine fashion, or presented via cell–cell contact and activate the EGF receptor (EGFR) (Fig. 108.2A). For instance, cells are stimulated to proliferate via EGF during wound healing. The signal is initiated by 1 of 11 members of the EGF family. All EGF family ligands exist in pro-form as transmembrane precursor proteins. They are converted to an active diffusible form by extracellular cleavage of the membrane protein. Six members of the EGF family are expressed in most SCC cell lines and activate the EGFR: EGF, transforming growth factor alpha (TGFα), HB-EGF, amphiregulin, betacellulin, and heregulin (45). HB-EGF is particularly interesting. The pro-form may either be cleaved to generate a diffusible factor by matrix metalloproteases (MMPs) that degrade extracellular matrix during cell migration (46), or it may activate EGFR as a transmembrane protein via cell-cell interaction, acting in a juxtacrine fashion. The effects on the target cell are different depending on whether HB-EGF is soluble or membrane bound. (Singh AB, Harris R. Autocrine, paracrine and juxtacrine signaling by EGFR ligands. *Cell Signal* 2005;10:1183–1193.)

Growth factors present in the interstitial space can also act on other receptors of the EGFR family (also called the ErbB family) that include ErbB1 (EGFR), ErbB2 (HER2/c-neu), ErbB3 (Her3), and ErbB4 (Her4) (45). In absence of ligand, most ErbB-family receptors are present at the cell surface of epithelial cells in the form of monomeric inactive transmembrane tyrosine kinase receptors. Binding of bivalent extracellular ligand triggers receptor dimerization, which brings catalytic cytoplasmic tails into close proximity, allowing trans-autophosphorylation of the cytoplasmic tails on tyrosine, serine, and threonine residues (47,48). ErbB receptors present at the cell surface are not a static pool of proteins. The receptors constantly cycle between an endosomal reservoir and the cell surface, where they become exposed to the ligands (49). After being activated, the receptor is endocytosed and either degraded or recycled (47,49).

Upon activation and transphosphorylation, active EGFR triggers three major signaling pathways. First, it activates the Ras–Map kinase pathway. Autophosphorylation sites on the cytoplasmic tail become docking sites for the adaptor protein SHC, which in turn recruits Grb2, which recruits Sos. Sos is a guanosine exchange factor for Ras, a small GTPase bound to the inner leaflet of the plasma membrane where it cycles between GDP and GTP bound forms (50,51). Ras acts as a molecular switch which is turned "on" when bound to GTP (52). The Sos activates Ras by mediating the exchange of GDP for GTP. Active Ras recruits the scaffolding protein Raf to the membrane (53). This leads to activation of the map kinase cascade, ultimately leading to ERK

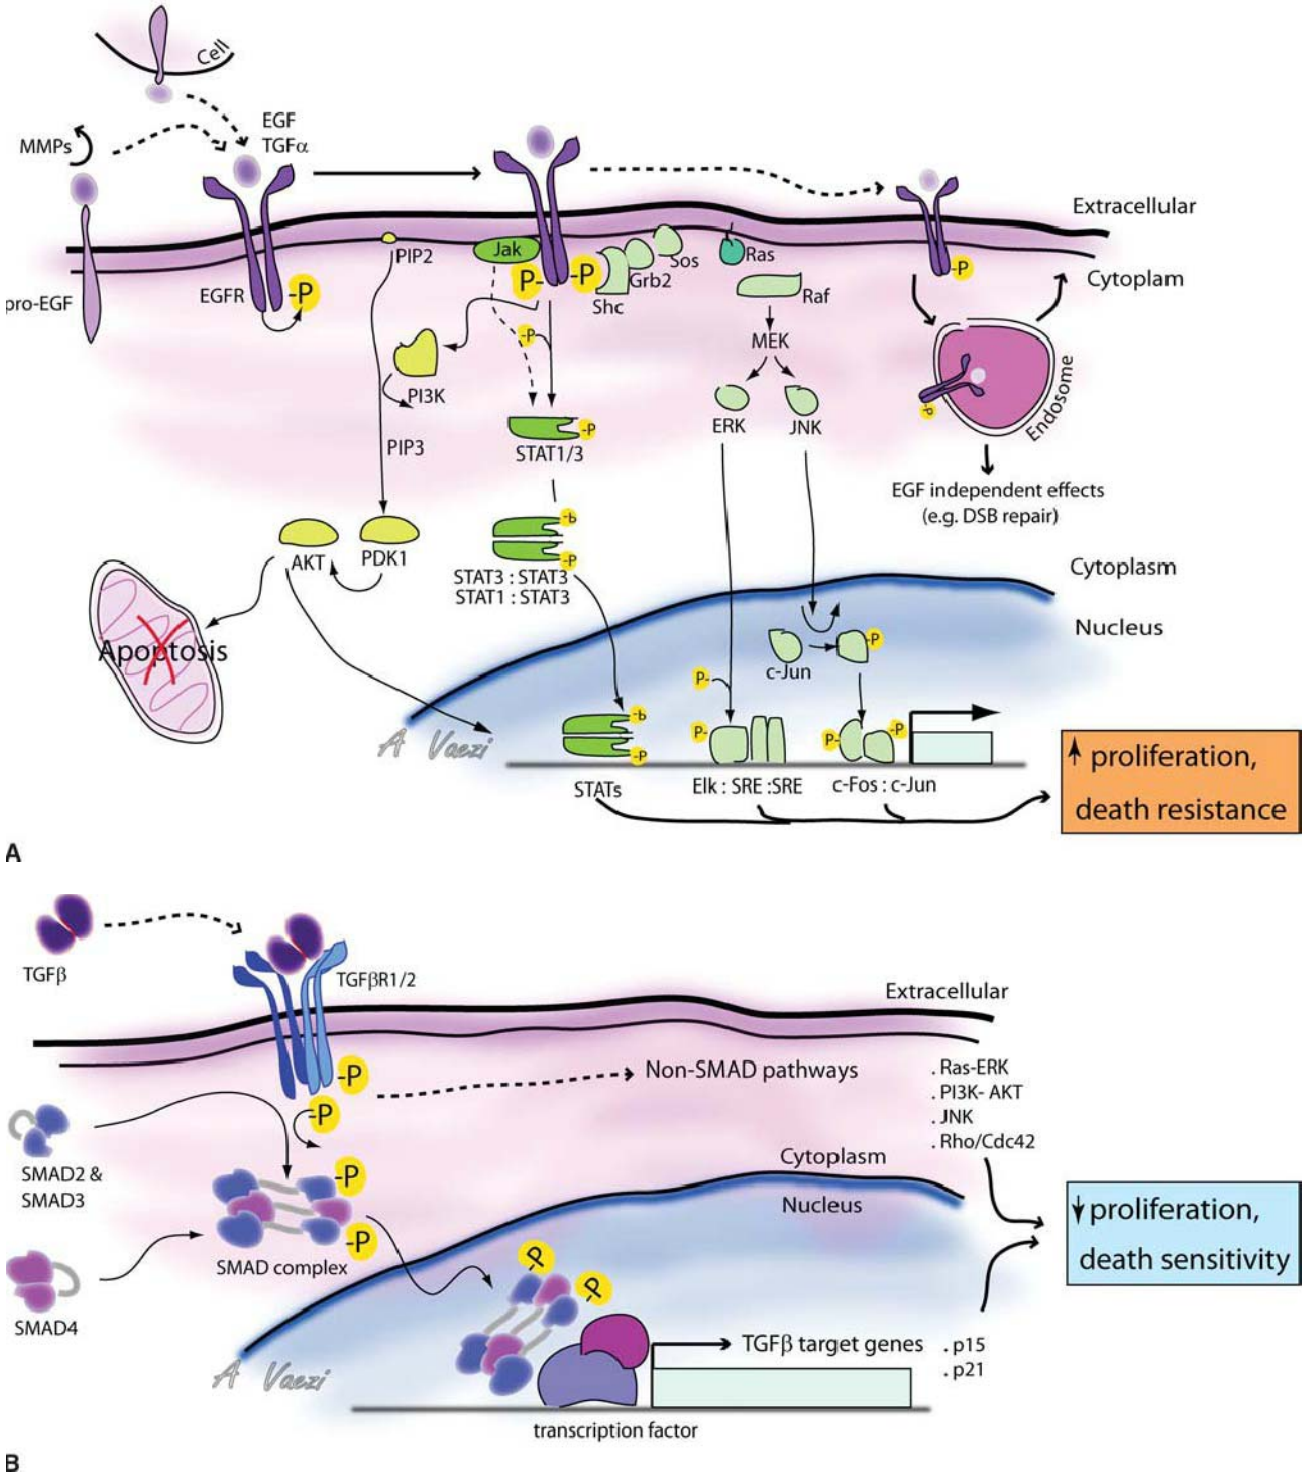

Figure 108.2 Signaling upstream of the cell cycle. Model for EGFR **(A)** and TGF-β **(B)** signaling pathways are represented. See text for details.

and Jun kinase (JNK) phosphorylation and activation (54). JNK is a serine/threonine kinase, which phosphorylates the c-Jun transcription factor. Phosphorylated c-Jun forms a heterodimer with phosphorylated c-fos, which together constitutes the AP-1 early response transcription factor that drives cell proliferation (55). ERK can also phosphorylate and activate transcription factors responsible for cell proliferation and cell migration.

The second signaling pathway activated by EGFR is the Jak/STAT pathway. Inactive STAT (signal transducer and activator of transcription) proteins are located in the cytoplasm. Activated EGFR recruits and activates the transcription factor STAT3 via two mechanisms: via Janus kinase (Jak) or via direct interaction with STAT3. Jak is a tyrosine kinase that binds to the juxtamembrane intracellular portion of activated receptors. Active Jak then phosphorylates

and activates STAT1 or STAT3 proteins (56). An alternate mode of activation of STAT3 is via direct interaction with EGFR (57). STAT3 is recruited to active EGFR, where it binds to specific phosphotyrosine residues of the receptor via its Src homology domain (SH2). STAT3 is then directly phosphorylated by the receptor on critical tyrosine and serine residues. Phosphorylation of STAT3, either via Jak or via EGFR, leads to its dimerization, either as STAT3 homodimers or as STAT3:STAT1 heterodimers (58). Activated STAT transcription factor dimers translocate either to mitochondria where they regulate metabolism characteristic of cancer cells (59,60) or to the nucleus where they regulate growth factor/cytokine-directed gene expression (56) and increase cell motility (61,62).

Finally, EGFR also activates the PI3 kinase/Akt pathway that promotes cell survival by suppressing apoptosis. Activated EGFR recruits and activates phospholipase-Cγ, which directs the hydrolysis of the phosphatidylinositol biphosphate (PIP2) at the plasma membrane. This hydrolysis generates an insoluble diacyl glycerol, which activates PKC, and a soluble phosphatidyl (1,4,5) triphosphate in the cytosol (32). There, IP3 (1,4,5) releases Ca^{2+} stores from the endoplasmic reticulum. Activated EGFR can also recruit and activate PI3 kinase, via the SH2 domain of the kinase. PI3 kinase then phosphorylates PIP2 to generate phosphatidylinositol-(3,4,5) triphosphate (PIP3) that remains membrane bound (63). Proteins with a pleckstrin homology (PH) domain such as Akt and PDK migrate to and associate with PIP3 located at the plasma membrane (63). Close proximity of Akt and PDK leads to Akt phosphorylation and activation. Akt renders the cell more resistant to apoptosis and increases proliferation. In addition, Akt also induces a motile and invasive cell phenotype. PTEN, an important tumor suppressor that is frequently mutated in cancers, counteracts Akt effects (64,65). PTEN's sequence resembles serine, threonine, and tyrosine phosphatases, but it acts principally as a lipid phosphatase converting PIP3 into PIP2 (64). Thus, PTEN tempers the effect of PI3K activation by limiting PIP3-mediated signaling. PI3 kinase lipid signaling pathway is a major pathway linking EGFR activation to increased cell proliferation and motility and decreased cell death, and is often involved in carcinogenesis.

Clinical Implications of EGF Pathway in HNSCC

EGFR is frequently upregulated in HNSCC (66–68), and in general EGFR upregulation correlates with a worse prognosis (68–70), including more rapid disease progression and the presence of lymphatic metastasis, through its effect on proliferation, motility, and angiogenesis (71). The mechanisms leading to EGFR overexpression in HNSCC are still unclear. Genome sequencing suggests that EGFR is not mutated in HNSCC, in contrast to other tumor types (3). It is rarely amplified (less than 10% of HNSCC). However, a peculiarity of HNSCC is the common overexpression of a truncated mutant of the receptor (EGFRvIII) in 40% of HNSCC (72). EGFRvIII, which is constitutively active and has degradation prolonged half-life, is found exclusively in tumors, making it a prime target for anticancer therapy with specific monoclonal antibodies. Because of the high frequency of EGFR upregulation HNSCC, EGFR-targeting strategies have been extensively investigated. Both small molecule EGFR tyrosine kinase inhibitors and monoclonal antibodies have been tested for activity against HNSCC. Cetuximab, an EGFR-blocking antibody, demonstrated activity against HNSCC, with improved locoregional control and survival compared to radiotherapy alone (73) and with improved response rate and survival when used in combination chemotherapy (74). Cetuximab (Erbitux) is now used routinely to potentiate radiotherapy. To date, while tyrosine kinase inhibitors targeting EGFR (such as gefitinib and erlotinib) have activity in HNSCC, they have not demonstrated prolonged survival in Phase III clinical studies (75). This discrepancy suggests that EGFR-blocking antibody has effects other than inhibition of the signaling pathway; the antibody could have an effect on immunity (76,77), or on EGF-independent effects such as DNA repair (78,79).

In addition to targeting EGFR itself, considerable effort has been invested in inhibiting downstream targets. STAT3 homodimers, which have oncogenic properties, are overexpressed in HNSCC and are the target of anticancer therapies (80). Specifically, STAT3 inhibitory strategies using dimerization-disrupting agents or competitive inhibitors of the DNA-binding domain of STAT3 have been proposed to combat HNSCC (80–82); the latter was used in a clinical trial with promising results. HNSCC genome sequencing found that 5% of tumors display H-Ras mutations, leading to constitutive activation of the small GTPase (3). Whether Ras is mutated or simply subject to sustained activation by EGFR, it is a seductive therapeutic target. Ras may be inhibited via blocking farnesylation of the protein (63), an essential posttranslational modification required for its targeting to the plasma membrane where it mediates its effects. In addition, the PIP3 lipid pathway is also relatively frequently mutated in HNSCC. PTEN is mutated in 7% of HNSCC with some cancers bearing both H-Ras and PTEN mutations (3,83). The inactivation of PTEN promotes PIP3 accumulation and activation of downstream targets such as Akt. PI3KCA, a catalytic subunit of PI3 kinase, is also mutated in HNSCC (3,84). These mutations underscore how frequently the inositol lipid pathway is the target of carcinogenic mutations. While the contribution of these mutations to protein function or prognosis is yet unknown, they will likely be the subject of exciting HNSCC tumor biology discoveries in the near future. To date, therapeutic strategies targeting the PI3K/Akt pathway in HNSCC remain mostly limited to the preclinical setting (63). Pharmacologic inhibitors being developed include a water-soluble form of wortmannin, an inhibitor of PI3K.

Importantly, mTOR, a downstream target of Akt, can be inhibited with rapamycin, the RAD001(Everolimus), and CCI-779 (Temsirolimus) compounds and is the focus of innovative anti-HNSCC therapeutic strategies that are already being tested in Phase I and II clinical trials (85).

Transforming Growth Factor Beta

The transforming growth factor beta (TGF-β) superfamily of ligands regulates both embryologic processes and adult tissue homeostasis. These ligands act as tumor suppressors by inhibiting proliferation of epithelial cells, and by sensitizing cells to apoptosis; in that respect, TGF-β effects are opposite to those of EGFR. It is therefore not surprising that TGF-β signaling is also the target of carcinogenic mutations.

The TGF-β superfamily includes TGF-βs (TGF-β 1, 2, and 3), bone morphogenic protein, growth and differentiation factors, nodal, activin (involved in embryogenesis and bone formation), and anti-mullerian hormone (86,87). TGF-β is secreted as inactive precursors that are proteolytically activated by extracellular proteinases (86,88). The biologically active cytokine is present in the interstitial compartment; the signal is triggered when TGF-β binds a dimeric *Type II* TGFβ receptor. TGF-β receptors are single-span transmembrane receptors with serine/threonine kinase activity (Fig. 108.2B). Upon activation, dimeric type II receptors recruit and associate with dimeric *Type I* receptors, another transmembrane serine/threonine kinase receptor, to form a tetrameric receptor complex (86–88). Both receptors are then in close proximity, leading to the phosphorylation and activation of the Type I receptor by the Type II receptor. In turn, activated Type I receptor recruits an adaptor protein named SARA (Smad anchor for receptor activation) that mediates transient binding between the Type I receptor and SMADs, a family of transcription factors present in the cytoplasm. The SMAD family of proteins has eight members, SMAD 1–8, which come in three types: receptor-activated SMADS (R-SMADS), co-SMADS, and inhibitory SMADS (I-SMADS) (89). R-SMADS involved in TGF-β signaling are SMAD2 and SMAD3. SARA brings SMAD 2 and 3 in close proximity to the catalytic site of the Type I receptor, which then phosphorylates the R-SMAD C-terminus (87,88). This posttranslational modification induces a conformational change that allows interaction with a co-SMAD (SMAD4). The newly assembled SMAD:co-SMAD complex translocates to the nucleus where it interacts with other transcription regulators, to control expression of genes involved in apoptosis, and cell cycle repressors including p15 and p21(87). However, TGF-β signaling does not necessarily involve SMADs, and SMADs are not necessarily activated by Type I receptors. Recently, important cross talk between the MAP kinase pathway and SMADs has been revealed: ERK has been shown to phosphorylate SMADS (90). Reciprocally, TGF receptors can regulate important targets in a SMAD-independent manner, including the Map kinase pathway (90) and the Rho family of small GTPases (91), which are "molecular switches" similar to Ras, but are involved in the regulation of actin dynamics, cell migration, and metastasis (51). This represents one way in which TGF-β regulates cell morphology and migration.

The TGF-β pathway is negatively regulated at three levels. First, at the level of the extracellular matrix, the small proteoglycan decorin inhibits TGF-β receptor signaling (92). Decorin has antitumoral activity *in vitro*. Second, intracellular I-SMADs prevent binding of R-SMADs to the activated Type I receptor, and thus negatively impact SMAD signaling. Third, both the receptor and SMADs can be targeted for proteasome-mediated degradation, regulated by E3 ubiquitin ligases SMURF1 and SMURF2 (93,94). Interestingly, SMURF1 not only downregulates the TGF-β signaling pathway but also enhances cancer cell migration and invasion by targeting the GTPase Rho A for degradation, thereby reducing stress fibers and enhancing cell protrusions and motility (91). In summary, TGF-β signaling is at the crossroads of cell proliferation, cell death, and migration, and it is involved in many aspects of carcinogenesis.

Clinical Implications of TGF-β Pathway in HNSCC

The role of TGF-β signaling in tumorigenesis is multifaceted. While TGF-β has tumor suppressive effects, cancer cells can circumvent the suppressive component of the pathway and use TGF-β stimulation to their advantage to promote invasion and secretion of mitogens and pro-metastatic cytokines. This explains why TGF-β signaling is inhibited in certain cancers and upregulated in others. HNSCC is no exception. For instance, TGF-β receptor and SMADS are often downregulated in HNSCC (95). The downregulation may occur via loss of heterozygosity of chromosome q18, which contains TGFβRI and SMAD genes, or via DNA methylation-mediated gene repression (88). In addition, inactivating mutations in TGFβRI or II and SMADs have been reported in HNSCC, and may be present in up to 20% of neck metastasis (TGFβRI) (96–98). However, exosome sequencing of 80 HNSCC primary tumors found no mutations in TGF-β pathway, indicating that inactivating mutations are probably not a frequent event (3). An elegant demonstration that the downregulation of TGF-β signaling participates in HNSCC formation comes from a genetic mouse model in which the loss of TGFβRII, in the presence of an activating Ras mutation, induces head and neck tumors that closely resemble human HNSCC.

As above, TGF-β1 is actually frequently overexpressed in HNSCC, by about five times the normal levels in 40% of HNSCC (99). TGF-β1 is not only upregulated in the tumor but also in the surrounding normal-appearing tissue, suggesting that the tumor microenvironment contributes to tumorigenesis. This hypothesis was confirmed in a

transgenic animal model where the induction of TGF-β1 overexpression in oral mucosa led to mucosal hyperproliferation and angiogenesis (99). This suggests that TGF-βR ligand stimulation may be upregulated in HNSCC and have a profound effect on tumorigenesis and tumor biology. In addition, modulation of TGF-β signaling mediators downstream of the receptor also contributes to HNSCC tumorigenesis. For instance, SMAD2 and 4, but not SMAD3, are frequently downregulated in HNSCC, correlating with a worse prognosis (100,101). Here again, a genetic animal model in which SMAD4 is deleted demonstrates that loss of SMAD4 interferes with DNA repair pathways and results in the spontaneous development of invasive head and neck tumors (101). In a similar vein, TGF-β inhibitors interfering with SMAD signaling also contribute to tumorigenesis. The overexpression of SMURF2, which enhances cell migration and invasion *in vitro*, is a marker of bad prognosis in esophageal SCC (102); whether SMURFs have prognostic value in HSNCC has not yet been tested.

THE CELL CYCLE ORCHESTRATES CELL PROLIFERATION

Multiple extracellular mitogenic signals such as EGF, the sensing of neighboring cells via cell–cell interactions, or tissue oxygenation are integrated via distinct signaling pathways that converge to regulate the cell cycle. The integration of these signals informs the cell of the decision to proliferate. The cell cycle-regulating machinery is a prime target for oncogenic mutations, since cancer is a disease of unregulated cell proliferation.

In the resting state, the cell is quiescent, termed the G0 phase of the cell cycle. In this dormant stage, the pocket family proteins (Rb, p107, and p130) act as transcriptional cofactors that inhibit expression of proliferation-related genes (103). Among other effects, Rb inhibits the transcription factor E2F that drives the expression of proliferation genes (33,103). However, in the presence of growth factors, the Ras/Raf/ERK pathway becomes activated, leading to the phosphorylation and activation of transcription factors driving expression of proliferation genes, including cyclin D (Fig. 108.3) (104). Cyclin proteins are expressed for a limited period during the cell cycle and are rapidly degraded via ubiquitin-mediated protein degradation, leading to oscillating concentration during the cell cycle (105). There are several members of the cyclin family, each specific for a phase of the cell cycle. Cyclins have no intrinsic enzymatic activity, but associate with and partially activate cyclin-dependent kinases (Cdk), whose expression levels remain constant during the cell cycle. A second posttranslational modification, such as phosphorylation of the cyclin:Cdk complex by a Cdk-activating kinase (CAK or cylinH:Cdk7) at a specific threonine site (Thr 160) (106) or dephosphorylation of an active site by cdc25 (107), is also required for full activity of the complex.

Early in the G1 phase, cyclin D is synthesized as a consequence of ERK activation (104). Cyclin D accumulates as long as the growth factor is present, but in the absence of growth stimuli, the protein is quickly degraded, and progression through the cell cycle stops. Cyclin D associates with Cdk4/6, the effector kinases of the G1 phase of the cell cycle. Active cyclinD:Cdk4/6 complex acts in a positive feedback loop during the G1 phase to promote cyclin D expression. The active kinase complex mediates the inhibitory phosphorylation of pocket proteins, which repress E2F. As a result, E2F-dependent transcription is derepressed, and cyclin D synthesis increases (104). The same mechanism is responsible for the accumulation of cyclin E later in G1.

As cyclin E levels increase in somatic cells, it associates with Cdk2 to form an active complex that governs the G1/S transition. This cyclin:Cdk complex has distinct functions to prepare cell for DNA synthesis and mitosis. First, it induces duplication of the centrosome (108), a membraneless organelle responsible for microtubule network and mitotic spindle assembly. Second, it renders the cell competent for DNA synthesis, but does not start DNA synthesis (109). Third, it phosphorylates and inactivates a cell cycle inhibitor named p27 (110). The transcription of cyclin A thus far inhibited by p27 is now induced. Cyclin E is present at high levels only at the G1/S transition in somatic cells and is targeted for ubiquitin-mediated degradation in early S phase. As cyclin E levels decrease, the free pool of Cdk2 instead associates with the increasingly abundant cyclin A. The active cyclin A:Cdk2 then stimulates DNA replication by activating the replication complex, completing the transition from G1 to S phase (104,109).

After completion of DNA replication, cyclin A changes kinase partner, now associating with Cdk1, which drives the G2 and M phases. G2 is a phase of preparation for mitosis that is incompletely understood. G2 is not an absolute requirement for division, as cancer cells may skip this stage and directly progress to mitosis. In early G2, cyclin B accumulates. As the cell progresses through G2, cyclin A is targeted for ubiquitin-mediated degradation, increasing the pool of free Cdk1 available for association with cyclin B. With rising cyclin B:Cdk1 activity by the end of G2, nuclear breakdown occurs, chromosomes condense, and the cell enters mitosis (111).

Mitosis is a highly orchestrated phenomenon. During this phase, 46 duplicated chromosomes need to be distributed equally between two future daughter cells. Faulty distribution results in aneuploidy, which is most often incompatible with cell survival, at least under physiologic conditions (112). The central regulator of proper cell division, ensuring correct distribution of genetic material between daughter cells, is an ubiquitin ligase complex called the anaphase-promoting complex (APC). APC targets mitosis regulatory proteins for degradation. The specificity of APC for its targets is dependent on Cdc20; if Cdc20 is inhibited, APC cannot degrade regulators essential for progression through mitosis, and the cell cycle is stalled before anaphase (105).

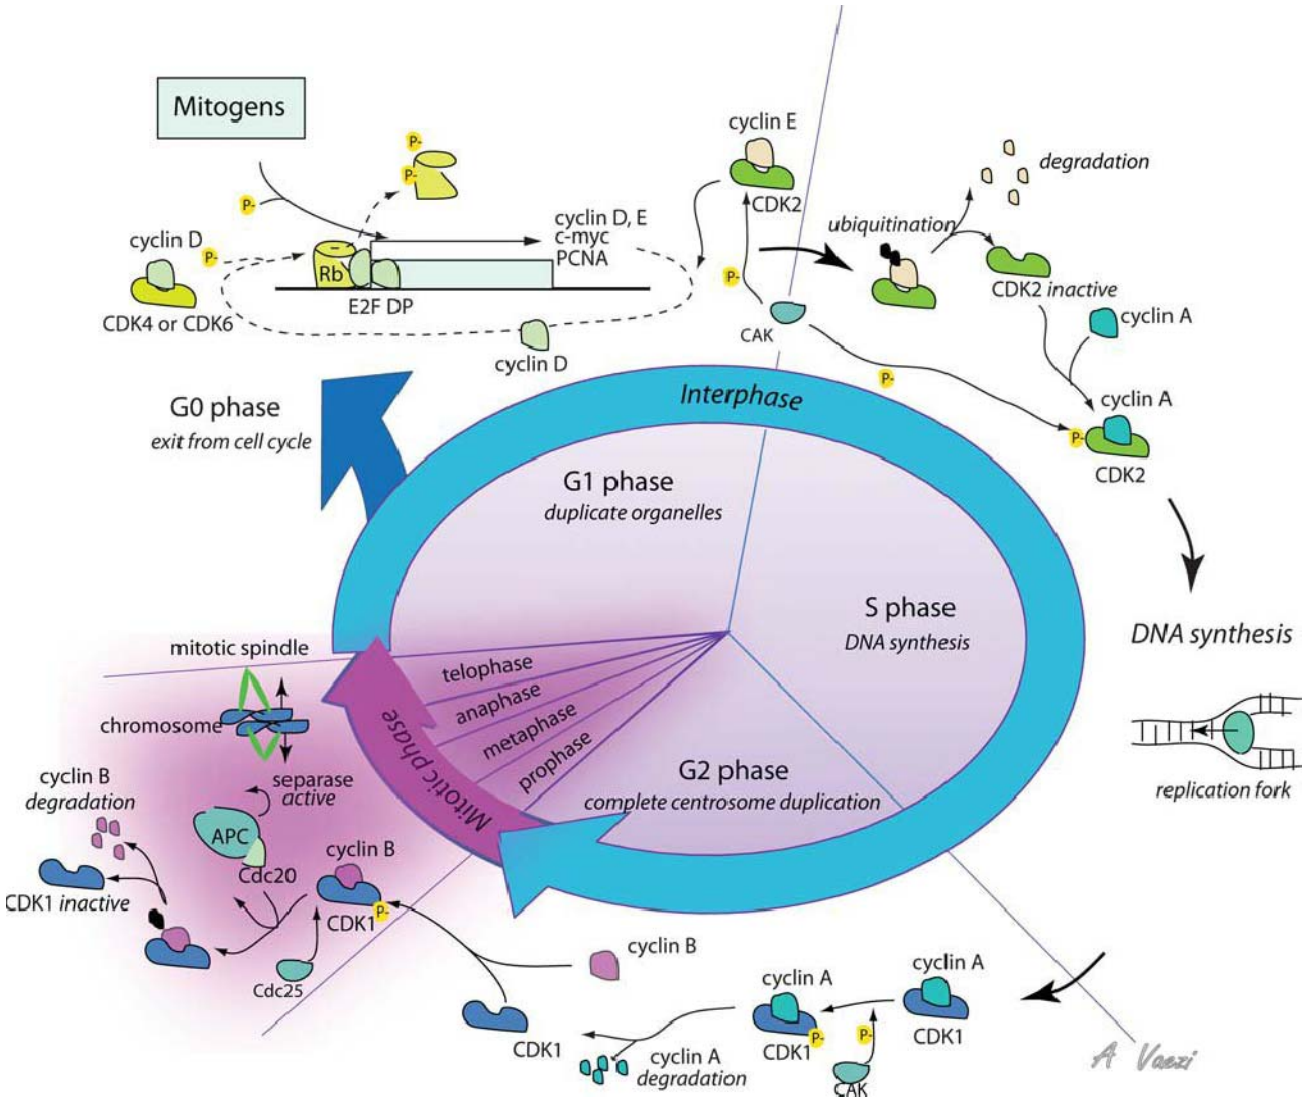

Figure 108.3 Cell cycle proteins regulate cell replication. Cyclin:Cdk complexes orchestrate progression through the cell cycle. Mitogen signals triggering proliferation are represented on the top left; regulation of cyclin:Cdk complexes is represented on the rest of the figure. See text for details.

During mitosis, chromosomes condense, the nuclear envelope breaks down, a bipolar mitotic spindle forms, and each chromosome attaches to the mitotic spindle at the chromosome center, or kinetochore. To ensure symmetry, the "mitotic checkpoint" ensures that no cell division starts before each and every chromosome is attached to both mitotic spindles (113). The molecular mechanism responsible for preventing premature division is only partially understood. Uncaptured kinetochores bind to protein complexes formed by Bub and Mad proteins (114,115). These complexes generate, through an unknown mechanism, an inhibitory signal that represses Cdc20. Thus, only when all kinetochores are captured by the spindle, and therefore the division is expected to unfold symmetrically, does the inhibitory signal stop. Cdc20 can then direct APC to target mitotic regulators for degradation (105). APC instructs the degradation of securin, which is essential to prevent the premature separation of sister chromosomes. Securin binds to and inhibits separase, a protease that cleaves cohesin, the "glue" that holds the two sister chromatids together. When securin is degraded, active separase cleaves cohesin, freeing the sister chromatids from each other and allowing the chromosomes to be freely pulled in opposite directions by each mitotic spindle (116). By this elegant mechanism, symmetrical segregation of genetic material is ensured. APC:Cdc20 also targets cyclin B for degradation, which inactivates Cdk1; this constitutes a major signal to start anaphase and complete cell division.

Clinical Implications of Cyclins and Cdks for HNSCC

Since cyclins and Cdks drive the cell cycle, they are obvious targets for oncogenic mutations. In HNSCC, cyclin D gene or protein expression level was identified as a prognostic

factor in HSNCC in most but not all studies (117–122) and has been proposed to be an early event in tumor progression. Interestingly, cyclin D is part of an amplicon present in 30% of tumors, which may explain why HNSCC overexpresses this cyclin (123–125). Conceptually, the presence of the amplicon may be of no consequence if the amplified chromosome does not translate to elevated levels of protein expression. In some but not all studies, the presence of the amplicon correlated with increased cyclin D expression, establishing a possible link between the genetic abnormality and elevated protein expression (126–128). In addition, a particular genetic polymorphism in cyclin D that increases the protein half-life predisposes its carrier to HNSCC and predicts response to treatment (129); the cancer predisposition results were confirmed by an extensive meta-analysis analyzing genetic polymorphisms in DNA repair genes associate with risk for cancer (24).

Cdks are being targeted by pharmacologic inhibitors, such as seliciclib. Preclinical studies and Phase I clinical trials point to promising effects in nasopharyngeal cancer (130). However, the antitumoral efficacy of a nonspecific modulator of G1 cyclins/Cdk (small molecule E7070) in a Phase II trial was disappointing (131). The drug was effective in reducing Rb phosphorylation, but the trial was aborted early due to lack of antitumoral effect.

Spindle checkpoint abnormality induces mis-segregation of genetic material during mitosis and induces chromosomal instability in animal models. In head and neck cancer, the level of expression of a mitotic checkpoint protein named BubR1, which is involved in pairing kinetochores with spindles, has been identified as a potential biomarker for HNSCC clinical outcome (132,133). Low expression, which may mark a defective spindle checkpoint, correlated with worse outcome. This may suggest that in the presence of an abnormal checkpoint, the segregation of chromosomes is not maintained, leading to chromosomal instability, a hallmark of aggressive cancers. Most importantly, taxanes are microtubule stabilizing drugs that interfere with the normal function of the mitotic spindle and prevent anaphase. Taxanes are increasingly used in HNSCC treatment.

CELL CYCLE REGULATORS: A CHECK ON PROLIFERATION

Cell Cycle Inhibitors: INKs, KIPs, and Wee1

Unregulated proliferation has disastrous consequences for living organisms, not only for a complex multicellular organisms at risk for cancer but also for unicellular organisms that must match their growth rate to the availability of nutrients present in their environment. There is therefore strong evolutionary pressure to regulate the cell cycle. In cancer, these mechanisms are almost invariably deficient or altered.

Active cyclin:Cdk complexes are the terminal signaling event that drives progression through the cell cycle. Cell cycle regulators modulate activity of the cyclin:Cdk complexes using different molecular strategies. Conceptually, cell cycle inhibitors can be categorized in three families: the inhibitors of cyclin-dependent kinases (INKs), the kinase inhibitor proteins (KIPs), and Wee1 (Fig. 108.4A) (134,135). Each family has a different mechanism of repression, blocks different phases of the cycle, and inhibits a different range of cyclins or cyclin:Cdk complexes. The INK family includes p15 (INK4b), p16 (INK4a), p18 (INK4c), and p19 (INK4b). These inhibitors are specific for the G1 phase and suppress Cdk4 activity (Fig. 108.4A). INKs act by physically binding to Cdk to prevent interaction with cyclin D. When cellular levels of p16 are persistently elevated, cells permanently withdraw from the cell cycle, a process known as cellular senescence. p16 is an important tumor suppressor; it is frequently the target of repression in cancer via microRNA or gene methylation,

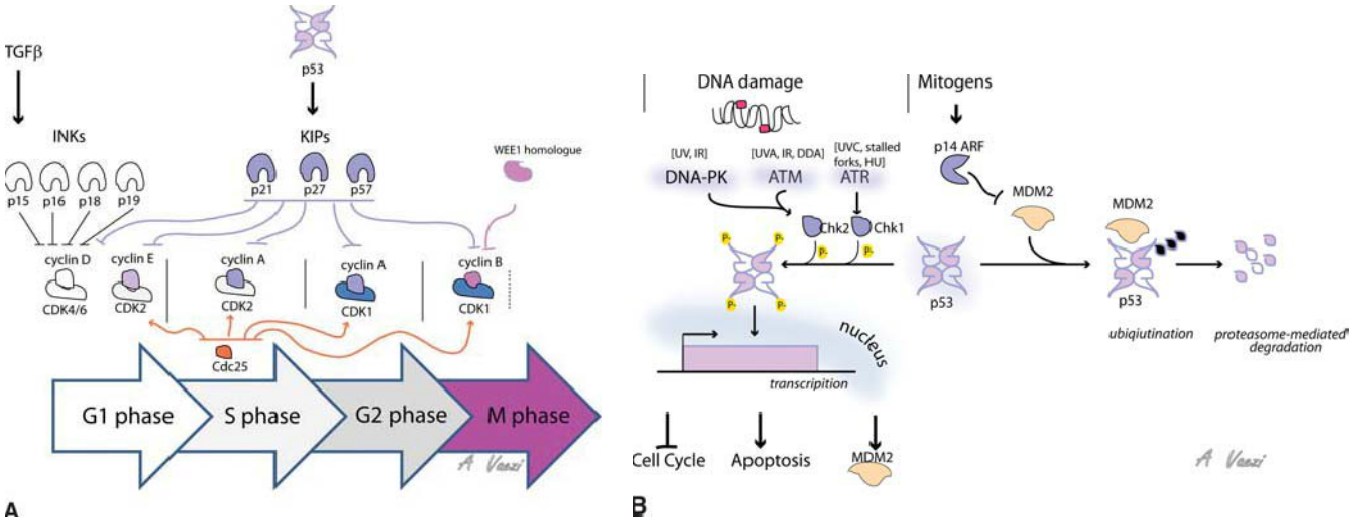

Figure 108.4 Activators and repressors of the cell cycle. **A**: INKs, CIP/KIP, and Wee1 repress cyclin:Cdk complexes and the cell cycle, while CDC25 activates them. **B**: p53 stabilization in response to cellular stress represses the cell cycle and stimulates apoptosis. See text for details.

and overexpression of p16 in mice confers a protective effect against cancer development (136).

KIPs have a wider scope of action. The KIP family consists of p21, p27, and p57. In contrast to INKs, these proteins counteract active cyclin:Cdk complexes after cyclins are already loaded on the kinase. KIPs also principally inhibit G1 phase Cdks, but are not restricted to this phase of the cell cycle, as KIPs also inhibit both cyclin:Cdk2 and cyclin:Cdk1 complexes involved at the G2/M transition (135). p27 represses cyclin A expression in G1, and inactivation of p27 by phosphorylation mediated by cyclinE:Cdk2 permits cyclin A synthesis. However, the actions of KIPs are more complex as in addition to their negative effect on cyclin E-, A-, and Cdk complexes. They act as positive regulators of cyclinD:Cdk4/6 and can also affect apoptosis, transcription, and cell motility (137).

The Wee1 family of proteins prevent cells from entering mitosis by inactivating cyclinB:Cdk1. Wee1 phosphorylates Cdk1 on critical threonine residues located in the ATP-binding loop necessary for Cdk function, keeping the kinase in check (138). Wee1 action is opposed by Cdc25 phosphatases, which permit entry into mitosis. Cdc25 activates Cdks throughout the cell cycle, including G1 and S phase. It is therefore not surprising that Cdc25 is overexpressed in many cancers (107). Overexpression of Cdc25 in animal model induces tissue proliferation, suggesting a tumor promoter effect, but mutagens are required to induce cancer.

P53, A Master Regulator of Cell Proliferation

The tumor suppressor p53 plays a major role in preventing progress through the cell cycle under conditions in which mitosis might be deleterious for the cell, such as DNA damage or sustained proliferation stimuli. p53 blocks proliferations and induces apoptosis. p53, a transcription factor that exists mainly as a homotetramer, has a high turnover rate, constantly being synthesized and degraded (Fig. 108.4B). p53 activity is regulated at two levels: (a) by inactivation through degradation and (b) by stabilization through phosphorylation (139). At steady state, the murine double-minute protein (MDM2) oncogene, an E3 ubiquitin ligase, binds to and ubiquitinates p53, targeting it for proteasome-mediated degradation (139). When p53 levels are low, the cell cycle can progress. However, in the setting of potentially hazardous events for the cell such as constant mitogen stimulation or DNA damage, degradation of p53 is blocked, and the transcription factor accumulates in the cytoplasm. p53 then shuttles to the nucleus where it increases transcription of KIPs to block the cell cycle, and of proapoptotic factors that trigger cell death. This selectively activates transcription of down targets depending on the level and type of posttranslational modifications such as phosphorylation, acetylation, neddylation, or sumoylation (139). Specifically, during persistent proliferation signals caused by sustained exposure to mitogens or by oncogenic stimulation, constant Ras or myc activation induces the expression of p14ARF, which is coded by a single gene locus with alternate reading frames responsible for expression of two INKs (p15 and p16) and p14ARF (136). p14ARF inhibits MDM2, which prevents ubiquitin-mediated degradation of p53, thus stabilizing p53. Through this pathway, p53 level rises and the cell is protected from sustained mitogenic activation.

DNA damage is sensed through different mechanisms depending on the type of damage encountered, but severe DNA damage also leads to p53 stabilization. For instance, irradiation generates severe oxidative stress that provokes DNA lesions. DNA double-strand breaks (DSBs) are particularly toxic as they may lead to genetic rearrangement events. DSB leads to activation of the gigantic ataxia telangectasia mutated (ATM) kinase (350 kD) (140). Upon activation, ATM induces a rapid and robust phosphorylation of proteins (141). On the one hand, it phosphorylates proteins involved in DNA repair pathways as explained in detail below. On the other hand, it activates the effector kinase Chk2, which in turn phosphorylates p53 (142). The addition of the phosphate group prevents association between p53 and MDM2. p53 then ceases to be degraded and accumulates, leading to cell cycle arrest or apoptosis if the damage is severe (141). Other types of DNA damage, such as when alkylating chemicals covalently modify DNA, prevent the replication fork from processing. A stalled replication fork is an unstable and dangerous event for the cell since it may result in DNA DSBs that are very toxic. Stalled replication forks are recognized by and activate another kinase named ATM- and Rad3-related (ATR) protein kinase. ATR is believed to stabilize p53 via activation of Chk1 protein kinase, which like Chk2 prevents association of p53 and MDM2, leading to accumulation of p53 (141,142). The ATM and ATR pathways leading to p53 accumulation and cell cycle arrest constitute the major DNA damage checkpoints of the cell cycle: cell proliferation is prevented until the DNA is repaired, ensuring conservation of genetic information. Since cancer escapes the DNA damage checkpoints, and proliferates despite persistent mitogenic stimuli, it is not surprising that p53 mutations have been found in most cancers.

Clinical Implications of Regulators of the Cell Cycle for HNSCC

The p16 INK is frequently lost early in SCC carcinogenesis, whether secondary to promoter methylation of genetic rearrangements (143). LOH in 9p is found in dysplastic mucosa (144), and in 20% to 75% of HNSCC (143–146). Loss of p16 locus is a biomarker of poor prognosis in some but not all studies, underscoring the importance of p16 in preventing head and neck cancers (124,143,147). Furthermore, p16 positivity, which occurs more frequently in HPV-related tumors, is a marker of better prognosis (21,148–153). p16-positive tumors in nonsmokers have a far better prognosis than p16-negative tumors when treated with chemoradiation therapy (21). At this juncture, it is not possible to determine whether p16 positivity

simply correlates with outcome or whether p16 is directly responsible for a biologic activity that generates a favorable prognosis.

Cdc25A and B, the phosphatases that activate cyclins/Cdk complexes and promote progression through the cell cycle, are upregulated in 96% (Cdc25A) and 57% (Cdc25B) of laryngeal tumors (154). The proportion of overexpressing tumors increases with progression. However, overexpression does not correlate with clinical prognosis and upregulation of this phosphatase does not necessarily translate to increased phosphatase activity. The meaning of this upregulation needs to be determined (107).

p53 is heavily mutated upon exposure to tobacco smoke, and 50% of HNSCC tumors harbor mutations in p53 (3,155). Because of a high prevalence p53 mutations that negatively impact protein expression level, p53 expression is low in HNSCC, which in turn correlates with poor prognosis in large studies (155). The multistep HNSCC carcinogenesis model proposes that LOH in p53 may represent a genetic event that marks the transition from a noninvasive to an invasive cancer (6). In fact, p53 mutations may occur earlier, in normal-appearing mucosa; loss of p53 is now accepted as an early genetic event in HNSCC tumorigenesis (156,157). Using an elegant technique to detect mutations in p53, it has been shown that p53 mutations exist in normal-appearing mucosa present near tumor margins (44). This is an important finding as excision of these mutated cancer progenitors is essential to prevent locoregional recurrence. p53 is thus a prime candidate for cancer screening methods in HNSCC.

The elevated rate of p53 mutations observed in HNSCC opens therapeutic opportunities for preferential pharmacologic targeting of cells lacking this tumor suppressor. Despite the strong rationale, clinical success has been limited. Exposure of tumors (by intra-tumoral injection or mouthwashes) to Onyx virus, which supposedly replicates in and preferentially kills cells lacking p53, showed efficacy (158,159). For instance, virus mouthwashes transiently reduce precancerous lesions (160). However, the specificity of the virus for p53 mutated cancers has been questioned, stopping progression to Phase III trials, except in China.

p53 downregulation is intimately linked with HPV infection. While the mechanism by which HPV 16 causes tumors is not completely elucidated, HPV produces early genes E6 and E7. E6 protein associates with a cellular ubiquitin ligase that targets p53 for proteosomal degradation, but it also interferes with p53 acetylation required for some of its function (161). In addition, E7 not only competes with Rb for binding to E2F transcription regulatory sequence but also neutralizes p21 and p27. As a result, Rb is displaced and E2F is derepressed, triggering synthesis of proliferation genes such as c-myc and cyclin D and E (161). In the presence of both E7 and E6, the cell receives a constant proliferative stimulus, but has lost the protection conferred by p53. Proliferation continues contributing to carcinogenesis. Interestingly, cancer exome sequencing confirmed that nonsmokers with HPV-positive tumors have fewer p53 mutations, underscoring the interrelation between HPV and p53 in HNSCC (3).

DNA REPAIR PATHWAYS MAINTAIN GENOME INTEGRITY

p53 stabilization is a major event inducing cell cycle arrest in response to DNA damage. The delay in cell cycle progression provides time for DNA repair to occur. Failure to repair damaged DNA leads to mutations, a change in genetic sequence, which propagate in progeny of each additional cell division. Appearance of mutations occurs because the damaged DNA cannot be replicated properly during DNA synthesis. The replication machinery may, for instance, incorporate a mismatched base opposite to the damage. The replication fork may also be stalled when the damage is encountered, leading to its collapse and creation of secondary chromosome breaks and rearrangements (162). The resulting mutations are not detected as being abnormal by the cell and will be replicated and propagated as normal genome with each cell division.

DNA repair pathways are multiple and complex, and common components are often shared between pathways, adding a level of complexity. A comprehensive description of all the pathways involved in DNA repair is beyond the scope of this chapter; selected repair pathways are discussed. An essential concept in DNA repair is that the type of DNA repair is specific to the type of DNA damage encountered. For example, a DSB is repaired by a different pathway than a single-strand break (SSB) or a bulky DNA adduct that distorts the double helix. Often the repair pathway is able to correct the damage and restore the original DNA sequence, but not always (163). Certain types of damage are repaired without preservation of the genome fidelity, via "error-prone" repair mechanisms. Why cells adopt error-prone repair is not completely understood, but it is believed that the introduction of a mutation may be preferable for the cell or the organism, rather than maintaining a hazardous DNA lesion that is incompatible with cell survival.

Nucleotide Excision Repair and Interstrand Cross-Link Repair

Bulky chemical DNA adducts such as those caused by cisplatin result in intrastrand cross-links and distortion of the double helix (164,165). Such lesions are recognized and repaired via nucleotide excision repair (NER) (Fig. 108.5). This efficient mechanism is faithful; genome sequence is conserved at the end of the repair. In NER, the distortion of the DNA double helix is detected by XPC-hHR23B complex, in some cases with the assistance of XPE–DDB. Xeroderma pigmentosum (XP) proteins (e.g., XPE, XPF, XPG, XPD) were found to be congenitally mutated in patients diagnosed with XP, a syndrome characterized by a high propensity for skin cancer and exquisite sensitivity

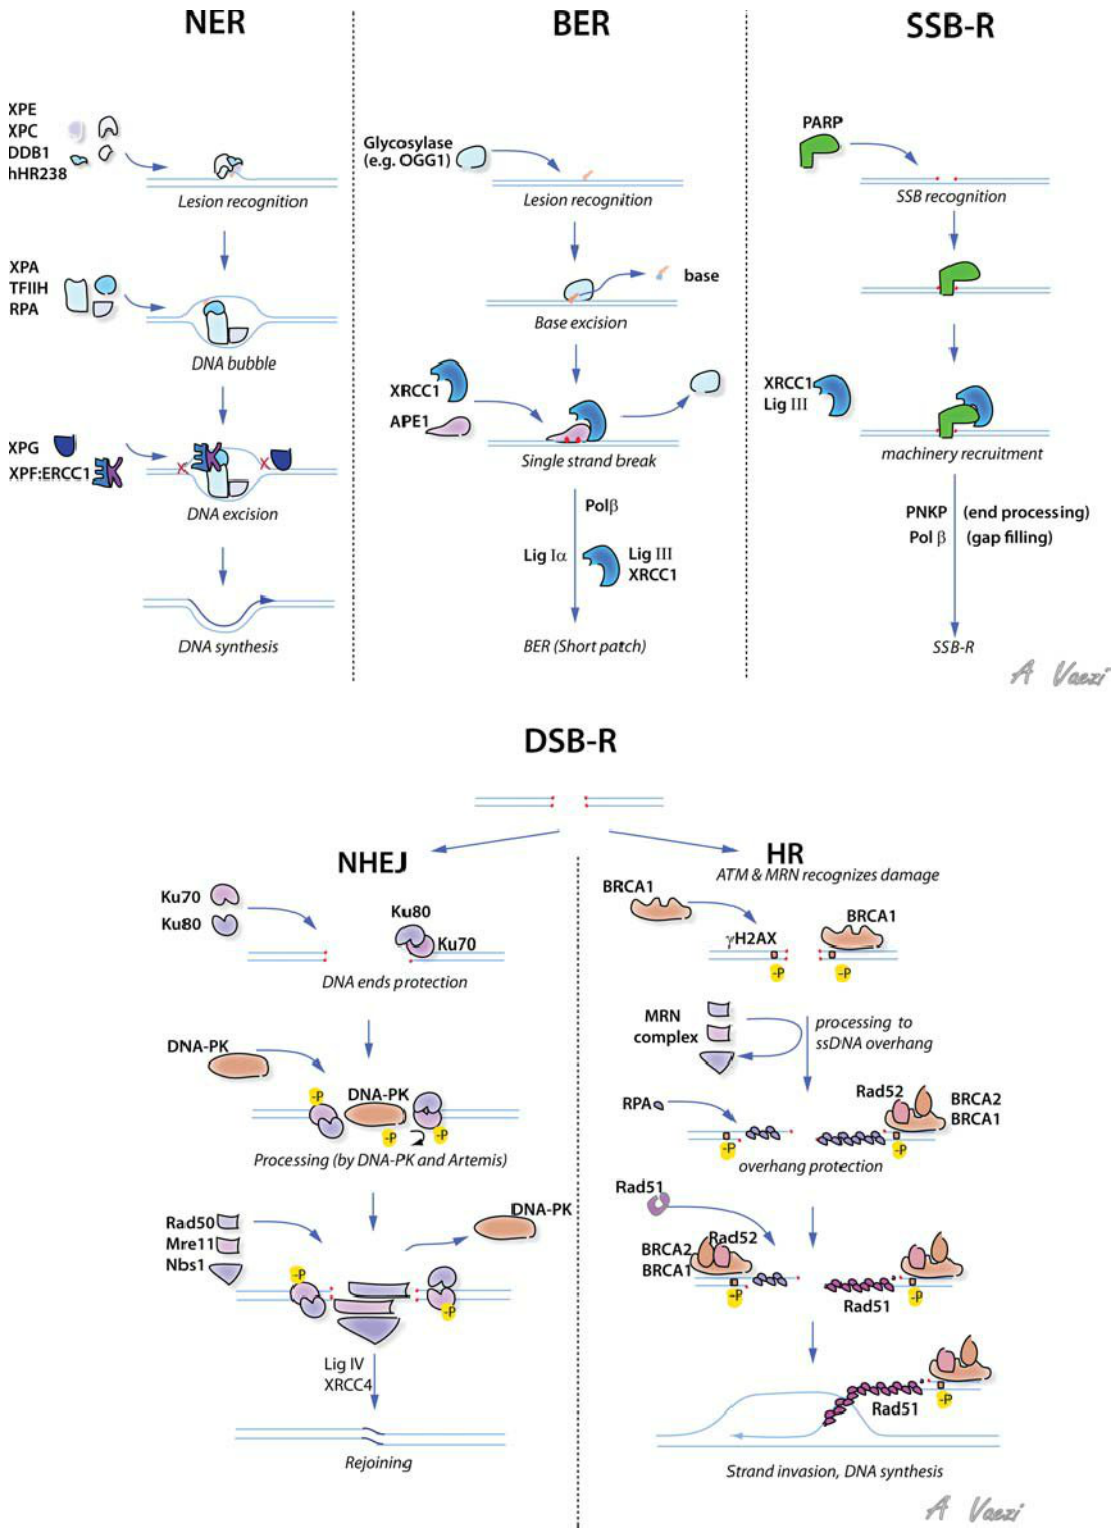

Figure 108.5 DNA repair pathways. Model of selected DNA repair pathways. From top right to bottom left, nucleotide excision repair (NER), base excision repair (BER), single strand break repair (SSB-R), and double-strand break repair (DSB-R) with non-homologous end joining (NHEJ) and homologous recombination (HR) are represented.

to DNA-damaging agents. The XPE:DDB protein complex signals the damage by binding to the damaged DNA. The complex recruits TFIIH, which unwinds the DNA around the adduct, creating a single-stranded DNA bubble centered on the damage. XPA and RPA, which bind ssDNA, stabilize the open complex and recruit the ERCC1:XPF endonuclease. XPF:ERCC1 is a bipartite endonuclease that cuts the damaged strand 5′ to the adduct. TFIIH recruits

a second endonuclease, XPG, which cuts 3′ of the lesion. The damaged base is removed as part of a single-stranded oligonucleotide. The replication machinery uses the 3′-OH created by ERCC1-XPF incision to prime DNA synthesis to fill the gap. After ligation, the integrity of the DNA is fully restored (166,167).

In addition to intrastrand cross-link and bulky DNA adducts, cisplatin also creates interstrand cross-link (ICLs), in which both strands are covalently linked by the chemical. The consequence of this lesion is catastrophic for the cell, as it prevents transcription and constitutes an absolute block for DNA replication machinery at the replication fork. The stalled replication fork collapses and creates DSB. The fork cannot progress until the DNA is repaired. ERCC1-XPF cuts near the ICL to release it from one strand, allowing bypass of the adduct by a trans-lesion polymerase such as REV1/Polζ (164,165). This type of repair is error-prone. An error-free repair has also been documented, which involves the formation of a DSB followed by homologous recombination (HR) (see below). The importance of intact NER and ICL repair to prevent cancer is illustrated by the genetic disorder XP, and alteration in these pathways could be an important carcinogenic event.

Base Excision Repair

Physiologic metabolism generates oxidative reactive species, which cause an estimated 1,000 to 1,000,000 DNA lesions per day. Oxidative stress, like alkylating agents or ionizing radiation, generates small genotoxic oxidative base lesions, which do not distort the DNA double helix, and are principally repaired through the base excision repair (BER) pathway. In BER, damaged bases are recognized and excised by glycosylases, such as OGG1, which removes the abundant oxidative lesion 8-oxodeoxyguanosine. Excision of the damaged base leaves an abasic (AP) site, while leaving the DNA backbone intact. The backbone adjacent to the AP site is then incised by APE1 endonuclease to create an SSB. XRCC1, a platform protein with no enzymatic activity that is critical for the scaffolding of proteins involved in BER is recruited to the site of damage. The recruitment is mediated either by the glycosylase/AP1 complex or by PARP1, which recognizes and binds SSBs. DNA polymerase β (Polβ) then fills the gap. XRCC1 subsequently forms a complex with ligase 3 (LIG3). The ligase seals the SSB created during the repair process to complete BER in an error-free fashion (165,168).

Single-Strand Break Repair

Energy release by free radicals generated by ionizing radiation disrupts phosphodiester bonds in the DNA backbone and can cause either SSB or DSB, the latter being very toxic. SSB is repaired by the single-strand break repair (SSB-R) pathway which shares many components with BER; this is not surprising since the BER mechanism creates an SSB intermediate product. In SSB-R, the severed DNA strand is detected by PARP that binds to the lesion to protect the ends against processing. It then recruits the scaffolding protein XRCC1. The XRCC1:PARP complex recruits PNKP, a bifunctional polynucleotide kinase/phosphatase, which processes the ends of the broken DNA. Once the gap has been tailored, it is filled by Polβ, using the intact complementary DNA strand as template. The newly completed DNA strand is then ligated to complete SSB-R. DNA integrity is restored with maintenance of the genetic sequence via an error-free repair mechanism (162,169,170).

Double-Strand Break Repair

Ionizing radiation or stalled replication forks are very hazardous for a cell. Both create double-strand DNA breaks that can lead to genome rearrangement if left unrepaired. Here we discuss two mechanisms directed to the repair of double-stand breaks: nonhomologous end-joining (NHEJ) and HR repair. These pathways are different in multiple aspects. NHEJ occurs at all stages of the cell cycle, but during the repair, the broken ends have been processed before being rejoined, which leads to loss of DNA. On the other hand, HR is faithful as the processed broken DNA ends are copied from intact DNA from a sister chromatid, but the repair is restricted to S phase and G2.

In NHEJ, the site where both strands of the double helix are severed is recognized by two proteins of the Ku family (Ku70 and 80). Ku70/80 dimers rapidly bind to the free end of the broken DNA to prevent processing of the ends. These protein foci located at DSB recruit the large protein DNA-dependent serine/threonine protein kinase (DNA-PK). The kinase autophosphorylates itself and also phosphorylates the Ku proteins. As a consequence, the Ku proteins translocate slightly away from the broken DNA end, giving space for DNA-PK and a protein named Artemis to process the free ends of the broken DNA double helix; Artemis resolves DNA hairpins formed due to sequence homology in the broken DNA. After this first step of end processing, a complex of three proteins (Mre11, Rad50, and Nbs1) named MRN is recruited at the DSB foci. MRN catalyzes further the ends processing and produce single-stranded ends. XRCC4 is then recruited to the site of damage, and in tight association with ligase IV, it reseals the broken ends together. During end processing, DNA is lost: This repair is error-prone (162,171). However, the pathway as described here is simplified and does not account for all the observations. For instance, cells are able to undergo NHEJ in the absence of Ku/DNA-PK, demonstrating the presence of an alternative pathway, which may be error-free and involve the protein breast cancer 1 (BRCA1) (172).

An alternate way to repair DSB involves HR with intact DNA borrowed from sister chromatids or homologous chromosomes. This type of repair happens preferentially when the DNA has been duplicated in S or G2 phase. Initially, the DSB is detected by ATM and the MRN complex. ATM rapidly

phosphorylates the Chk2 kinases involved in stabilizing p53 to activate the DNA damage checkpoint as described above. ATM also phosphorylates histone H2A at the site of damage, on a serine (Ser139); the phosphorylated histone is called γH2AX. Within 1 hour of damage, BRCA1, which was identified as being mutated in familial breast cancers, is recruited to sites of DSB containing γH2AX. The MRN complex also localizes early at the site of DSB, where it processes the broken DNA ends to form single-stranded overhangs on each side of the lesion. The single-stranded DNA ends are rapidly covered by replication protein A (RPA), which forms a filament and prevents the formation of secondary DNA structures. RPA also activates ATR, leading to p53-mediated DNA damage checkpoint. At this stage, BRCA1 recruits two other proteins, BRCA2 and Rad52, which load the recombinase Rad51 onto the single-stranded overhang. RPA is dislodged by Rad51 polymer, which forms a filament composed of protein and DNA named the presynaptic filament. Rad51 then searches for homologous sequences via strand invasion of the sister chromatid or the homologous chromosome. The DNA is copied from the undamaged DNA and results, after resolution of complex DNA intermediate structures, in HR and in faithful repair of DNA (162,171–173).

Clinical Implications of DNA Repair Pathways for HNSCC

HNSCC are generally treated with DNA-damaging agents such as ionizing radiation and platinum-based chemotherapy, either in a primary or adjuvant setting. Tumors with an altered capacity to repair DNA respond differently to these treatments. During treatment with DNA-damaging agents, genotoxic lesions accumulate both in normal tissue and in cancer cell DNA. In this context, cancer cells with a low level of DNA repair machinery accumulate damage and mutations more rapidly, and are thus more sensitive to DNA-damaging agents. Hence, therapeutic compounds that inhibit DNA repair pathways are relatively cytotoxic for tumors and may sensitize cancers to DNA-damaging agents. For instance, a novel class of antitumor drugs, PARP inhibitors, showed promising results in preclinical studies and are currently being tested in Phase I and Phase II clinical trial in breast and other cancers (174). Other compounds showing promising results in the preclinical setting include the Chk1/2 inhibitors (175), DNA-PK (175), ATM kinase (175), RPA (176), and MGMT (177) inhibitors, although results of MGMT inhibition in clinical trials were disappointing (177,178). It is with great hope that we follow the evolution of these new therapies as they are tested in clinical settings in HNSCC.

Abnormalities in DNA repair pathways of a given tumor may predict sensitivity to DNA-damaging agents and inform the head and neck oncologist on the most appropriate treatment to administer for a given tumor. In the growing field of personalized oncology, there is great interest in estimating the DNA repair capacity of HNSCC prospectively. The tumor expression level of ERCC1 and XPF generally correlates with survival in HNSCC treated with DNA-damaging agents, although the results are not uniform (165,179–183). Platinum-based compounds such as cisplatin and carboplatin are the most commonly used chemotherapeutic agents for HNSCC. These genotoxic drugs form bulky chemical adducts and cause intrastrand and interstrand cross-links, which are repaired via NER and ICL repair. The bipartite endonuclease ERCC1:XPF is the only DNA repair protein involved in the repair of all DNA damage generated by cisplatin, and cells deficient in ERCC1:XPF are exquisitely sensitive to DNA-damaging agents such as cisplatin. This explains why a low level of ERCC1:XPF correlates with enhanced sensitivity to cisplatin and ionizing radiation, and predicts clinical outcome in HNSCC. Surprisingly, when the level of expression of more than 30 genes involved in DNA repair was evaluated in HNSCC, Ku80, which is involved in NHEJ, was the only gene studied associated with prognosis (184). Another DNA repair protein identified as potential biomarker is XRCC1 (BER pathway), for which the expression level associates with clinical outcome in HNSCC (185). With further validation through independent prospective clinical trials, these biomarkers will instruct the personalized treatment of HNSCC to maximize survival and minimize unnecessary toxicity.

It has also been proposed that polymorphisms in DNA repair genes may correlate with altered capacity for repairing DNA, and therefore may indicate risk for HNSCC. Single nucleotide polymorphisms (SNPs) are defined as single-base changes that occur in more than 1% of the population. Depending on the location of the SNP, it may alter protein expression level or activity. A meta-analysis of HNSCC cancer risk in relation to SNPs in DNA repair genes revealed that XRCC1 codon 194 is associated with cancer risk (24). Mutation in DNA repair genes, such as the numerous genes in involved in Fanconi anemia, causes a high risk of HNSCC. It is therefore possible that genetic variants in the same or other DNA repair genes may have a more subtle clinical phenotype to increase HNSCC risk, response to treatment, or treatment toxicity.

APOPTOSIS COUNTERBALANCES PROLIFERATION

Proliferating tissues such as skin and the mucosa of the gastrointestinal, respiratory, and aerodigestive tracts are in constant turnover. Some cells proliferate, while others die, often through programmed cell death, but under physiologic conditions, the overall number of cells within the tissue remains constant. In cancer, this balance is lost and net gain of cells occurs; this results from both unregulated proliferation and impaired programmed cell death. The molecular pathways leading to programmed cell death, or apoptosis, can be divided in two categories: the extrinsic pathway, which is triggered by the activation of death receptors at the cell surface, and the intrinsic pathway, which is

activated by radiation, cytotoxic drugs, cellular stress, or growth factor withdrawal (186). Both pathways are mediated through activation of a cascade of intracellular proteases called caspases that cleave multiple intracellular targets (187). The hallmarks of apoptosis are DNA fragmentation as a result of DNA cleavage between nucleosomes and nuclear disintegration into small vesicles, which leads to the characteristic appearance of apoptotic cells. Caspases are zymogens that are activated by cleavage and can be grouped in two categories: *initiator* or apical caspases, which transduce the apoptotic signal, and *effector* caspases, which break down the cell and execute apoptosis (187).

In the extrinsic apoptotic pathway (Fig. 108.6), caspases are activated by a protein platform called death-inducing signaling complex (DISC), which forms at the plasma membrane. Death receptors of the TNF receptor superfamily, which include the FAS receptors and the CR4 and CR5 receptors, are used by neutral killer cell to kill cancer cells. FAS ligand binding to FAS receptor or Apo2L/TRAIL binding to CR4/CR5 initiates clustering of the receptors and DISC formation (186). The transmembrane receptors homo-trimerize and recruit an adaptor protein (FADD) to form an active DISC. The protein platform then recruits and activates procaspase 8 or procaspase 10 (187). The active caspase is released from the DISC and remains in the cytosol where it cleaves and activates effector caspases, in particular caspase 6, 7, and 3, which execute cell autodestruction. The extrinsic pathway is also connected to the intrinsic pathway as described below.

The mitochondria play a central role in mediating apoptosis via the intrinsic pathway. In the intrinsic pathway, proapototic proteins located in the mitochondrial membrane trigger the release of cytochrome C from the mitochondrion. The cytochrome C is located in the space between the mitochondrial inner and outer membranes and is sequestered from the cytoplasm in the absence of a death signal. Cytoplasmic release of cytochrome C, instrumental in activating caspases and apoptosis in the intrinsic pathway (188,189), is regulated by proteins of the BCL-2 family. The BCL-2 family contains 21 proteins, which can be divided into 3 classes: multidomain anti-apoptotic (including BCL-2, BCL-XL, MCL-1), multidomain proapototic (including BAX and BAK), and single-domain proapoptotic activators (including BID, BIN) or sensitizers (including BAD, NOXA, PUMA); the single domain of the activators/sensitizers resembles a portion of BLC-2 and is termed Bcl-2 homology 3 (BH3) domain that is important in drug development (190). Under physiologic conditions, in the absence of death signals, the multidomain anti-apoptotic BCL-2 and proapoptotic protein BAX are constitutively inserted in the outer leaflet of the mitochondrial outer membrane (MOM), where they neutralize each other. Upon activation by death signals, apoptotic activators such as BIN disrupt this interaction, via their BH3 domains. The freed pool of BAX then oligomerizes into channels that permeabilize the MOM, leading to leakage of cytochrome C. BAK, on the other hand, is mainly

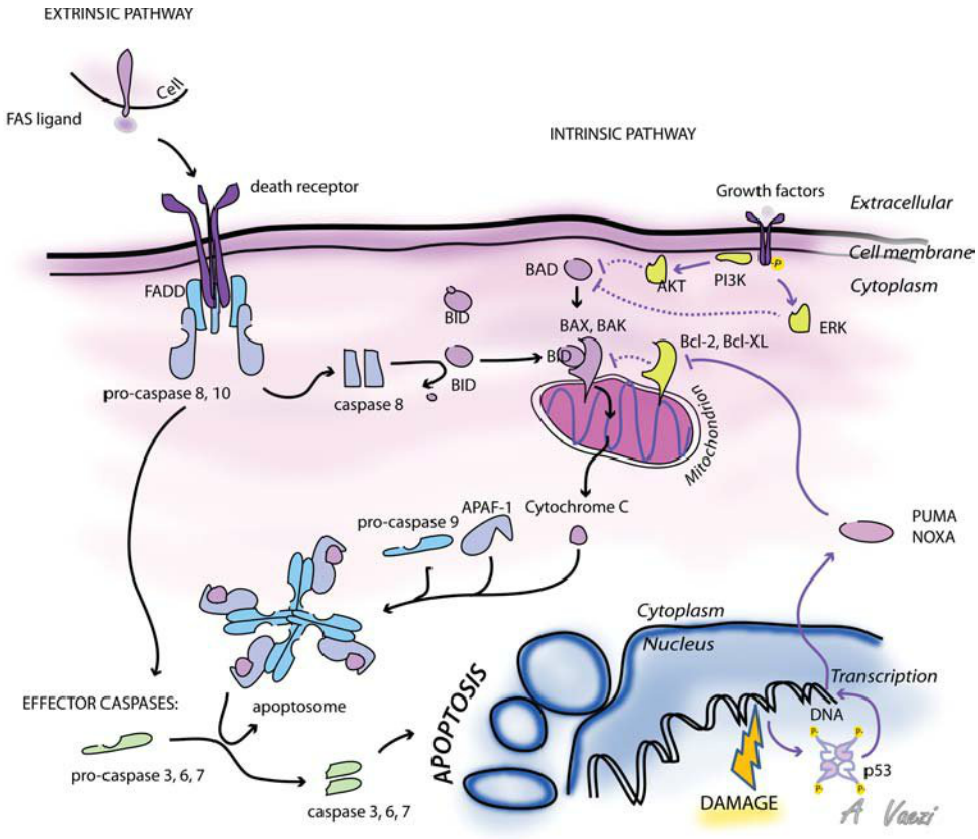

Figure 108.6 Pathways to apoptosis. Model of the extrinsic (**left**) and intrinsic (**right**) apoptosis pathways and their cross talk is represented. See text for details.

cytoplasmic; activation by apoptotic signals induces a conformational change in the protein that leads to its insertion into the MOM. Upon binding and activation by the cytosolic proapoptotic activator or sensitizer, BAK forms pores and releases cytochrome C from the mitochondrion, like BAX (190). Once in the cytoplasm, cytochrome C permits the formation of a large multiprotein platform called the apoptosome. This propeller-like structure is composed of APAF1, procaspase 9 dimers, and cytochrome C (190). It acts as an effector caspase activator platform, where procaspase 9 is activated and cleaves the *effector* caspases 6, 7, and 3 (187).

The extrinsic pathway and the intrinsic pathway interact. In the cytoplasm, the initiator caspase of the extrinsic pathway, caspase 8, cleaves the self-inhibitory portion of the single-domain proapoptotic activator BID (187). BID then translocates to the mitochondrial membrane where it binds BAX and BAK, triggering the intrinsic pathway and the release of cytochrome C. Of interest, mitogenic pathways also have cross talk with the intrinsic pathway. Growth factors enjoy both positive effects on cell proliferation and pro-survival effects by inhibiting apoptosis. Growth factor receptors, such as EGFR, activate PI3 kinase. The formation of PI3P (3,4,5) in inner leaflet of the plasma membrane creates docking and activation sites for PH domain proteins, in particular Akt (63). Activated Akt phosphorylates BAD, a single-domain proapoptotic protein (191,192). Phosphorylated BAD is unable to activate BAX or BAK, rendering the cell increasingly resistant to apoptosis. EGFR signaling also counteracts apoptotic signals via the MAP kinase ERK, which activates RSK kinase, which, similar to Akt, inhibits BAD (193). Finally, p53 activates apoptotic pathways in response to DNA damage. Phosphorylated p53 increases transcription of PUMA (194) and NOXA (195), two apoptotic sensitizers. PUMA is the more potent apoptosis activator, inhibiting all multidomain anti-apoptotic proteins including Bcl-2, Bcl-X_L (194), and MCL-1, while NOXA inhibits only Bcl-X_L and MCL-1.

Defective apoptotic pathways, for instance when Bcl-2 is overexpressed, are beneficial for a cancer cell, because they are resistant to death signals from TNF or FAS ligand induced by contact with a cell responsible for immune surveillance. In addition, it will also be more protected against apoptotic signals triggered by oncogenic activation of Ras or Myc. In this case, the cancer cell may progress through the cell cycle despite DNA damage, leading to accumulation of further mutations. This also renders apoptosis-deficient cells resistant to chemotherapy by DNA-damaging agents. Escape from apoptosis clearly favors carcinogenesis.

Clinical Implications of Apoptosis for Prognosis and Treatment of HNSCC

Cancer results from a disequilibrium between cell proliferation and cell death, and HNSCC is not an exception. The apoptotic pathways are frequently impaired in HNSCC, with repercussions on tumor behavior and resistance to treatment. For instance, the anti-apoptotic proteins Bcl-2 and Bcl-X_L of the intrinsic pathway are often overexpressed in HNSCC (196). Overexpression of Bcl-2 or Bcl-X_L conferred resistance to apoptosis and associated with a worse clinical prognosis in some but not all retrospective analysis (149,196,197). Curiously, Bcl-2 overexpression had opposite effects in two studies, where it associated with better clinical response to hyperfractionated radiotherapy and laryngeal preservation strategies (196,198). Probably higher level of clinical evidence via prospective analysis or meta-analysis is needed to clarify the role of Bcl-2 family of protein as biomarkers in HNSCC. In addition, the apical caspase of the extrinsic pathway, caspase 8, is mutated in 8% of HNSCC, as identified by HNSCC exome sequencing (3). The majority of the mutations identified are nonsense mutations, coding for a premature stop codon. Interestingly, caspase 8 appears to be the only apoptotic gene mutated in the 80 tumors sequenced; the reason for this peculiarity remains to be understood. Taken together, these results underscore how frequently the intrinsic and the extrinsic apoptosis pathway are altered in HNSCC, suggesting an important role of apoptosis suppression in HNSCC carcinogenesis.

The frequent resistance to apoptosis in HNSCC, conferred in part by Bcl-2 overexpression, renders HNSCC an attractive target for new generation Bcl-2 inhibitors (199,200). While four Bcl-2 family targeting agents are currently being studied in a preclinical setting, four are already being used in Phase I, II, or III clinical trials, although for cancers other than HNSCC (200). An important compound being tested in Phase III trial is oblimersen sodium, an antisense oligonucleotide that interferes with Bcl-2 mRNA. Oblimersen shows survival benefit in melanoma (201) and to a certain degree in chronic lymphocytic leukemia (CLL) (202); however, the positive effect may be only partially related to Bcl-2 inhibition, as oblimersen appears to stimulate local immunity independently of its effect on Bcl-2 (200). Another class of agents that deserves attention is BH3 mimetic compounds. BH3 mimetics bind to and sequester Bcl-2, thereby facilitating oligomerization of Bax and Bak and related cell death induction. Gossypol (AT-101), a toxin isolated from cotton seed half a century ago, is under clinical investigation, but is toxic for the GI tract limiting its use (200). A novel BH3 mimetic ABT-737 recently showed promising effects in a clinical trial as a radiosensitizer or chemosensitizer in hematogenous malignancies and solid non-HNSCC tumors (200); ABT-737 oral counterpart ABT-263 is under current investigation (203,204). Therefore, the overexpression of Bcl-2 family proteins or mutations in caspase 8 observed in HNSCC may serve to identify tumors that are most likely to benefit from Bcl-2 targeting therapies.

Triggering the extrinsic apoptotic pathway is another angle to attack cancer. Two approaches are employed. On the one hand, soluble human recombinant death receptor ligands are administered systemically. Interaction between ligand and CR4 and CR5 receptors triggers receptor clustering and leads to activation of the extrinsic pathway. Phase

II clinical trials are under way in non-small cell lung cancer using soluble recombinant human Apo2L/TRAIL (186). An alternative approach consists of monoclonal antibodies directed against death receptors. Antibodies such as mapatumumab, lexatumumab, and apomab induce DISC formation and cell death (186). Phase II trials are under way for cancers other than HNSCC.

CANCER STEM CELLS CONTRIBUTE TO TUMOR HETEROGENEITY

The dysfunction of the signaling pathways described above explains how a single cell may grow in an unregulated manner, resulting in clonal expansion of the diseased cell. The expected product of the clonal expansion of a single cell is a homogenous mass of cells. However, tumors are extraordinarily heterogeneous, and multiple theories attempt to reconcile this paradox. The stochastic genetic mutation theory proposes that mutations occur randomly in the initial clone, leading to the generation of subclone populations. However, another concept, now widely accepted in hematopoietic malignancies, may also be true for solid tumors. The hierarchical CSC theory proposes that only a small pool of self-renewing cancer cells have the exclusive ability to maintain the tumor. It is still unclear whether CSCs originate from mutated tissue stem cells or whether CSC come from more differentiated cells which acquire stem cell properties via a dedifferentiation process. In any case, by definition, the CSC must (a) have an unlimited self-renewal capacity to maintain the pool of CSC and (b) divide asymmetrically to provide a differentiated progeny that accounts for heterogeneity and the bulk of the tumor (205,206). For instance, in hematopoietic malignancies, a progenitor may acquire transforming mutations responsible for clonal expansion of itself while maintaining the ability to produce partially or completely differentiated cell progeny. On a blood smear, the abundant differentiated progeny will account for the vast majority of cancer cells seen; however, only a few cells, the cancer progenitors, sustain continuous proliferation and are responsible for maintaining the tumor (205). All the other tumor cells, despite their abundance, are incapable of recreating a hematopoietic malignancy when transplanted into immunodeficient animals, the gold standard test of isolation of CSC (207). Thus, novel CSC therapies are aimed at eradicating the CSC responsible of tumor maintenance and recurrences, irrespective of whether the tumor bulk is affected initially. The goal is to kill the cancer at its roots (Fig. 108.7).

In 2003, Clarke et al. applied the concept of CSC to solid tumors and isolated the first solid tumor CSCs in breast cancer (208). CSCs have now been isolated from brain, colon, prostate, pancreas, melanoma, and HNSCC tumors (206). Interestingly, there is, to date, not a single marker common for all CSCs. Often, however, solid tumor CSCs express a molecular signature of gene products involved in epithelial–mesenchymal transition (EMT) (209,210). EMT denotes a change in cell phenotype seen during gastrulation in which epithelial cells acquire a mesenchymal phenotype. Cell–cell adhesions are lost, the cytoskeleton is remodeled with adoption of a spindle cell morphology, and cells acquire an invasive phenotype. Specifically, the cell–cell adhesion molecule E-cadherin is downregulated, while mesenchymal markers such as α-smooth muscle actin and MMPs are upregulated; TGF-β via SMAD3 and 2 and tyrosine kinase receptors induce EMT (211).

The concept of EMT may be reversible in CSC, leading to the theory of migratory CSC.

This model proposes that CSC could be divided into stationary (sCSC) and migratory CSC (mCSC) (212). The sCSCs would be entrenched to the core of the tumor, while mCSC are located at the periphery and represent CSCs that underwent EMT. mCSCs are responsible of locoregional and distant metastasis. Since EMT appears reversible in cancer, it has been proposed that the mCSC cells undergo EMT reversal, or mesenchymal–epithelial transition, at the site of metastasis (212). The exciting field of CSC is in rapid evolution, and the future will tell what proportion of this theory will prove correct.

Like tissue stem cells, CSCs live in stem cell niches poor in oxygen content, where they are protected from oxidative stress. While this has advantages for genome protection, radiation therapy, which is more effective in well-oxygenated tissues, is less effective against CSC. This may account for radioresistance and locoregional failure. Not only are CSCs relatively protected from free radicals by their location in the tissue, but they also overexpress free radical scavengers such as the glutathione reductase system (213). In addition to being resistant to oxidative stress, CSCs are also resistant to chemotherapy agents. They express drug evacuation channels such as multidrug resistance gene 1 (MDR1), which is an ATP-binding cassette transporter which lowers the intracellular concentration of chemicals and chemotherapeutic agents including taxol (214).

However, there are also differences between tissue stem cells and CSCs. Tissue stem cells are rare, but CSCs may be abundant. While the CSC population in leukemia represents a rare portion (<1%) of cancer cells (205), in HNSCC, they may represent between less than 1% and 45% of the tumors (215). It is therefore conceptually important to understand that in some tumors up to half of the cells have tumor-maintaining capacity. Another level of complexity is the tumoral environment. The gold standard test used to define CSC populations, the xenograft model, has limitations: Tumor stroma and associated cells including supporting cells, endothelial cells, and immune cells are missing. It is therefore possible that cells that act as stem cells in the native tumoral environment may lose tumor-forming ability when deprived of their native environment (205). Thus, the concept of CSC continues to evolve, but it opens new perspective for treatment.

The models of CSC, stochastic mutations, and field cancerization in HNSCC may coexist (Fig. 108.7A).

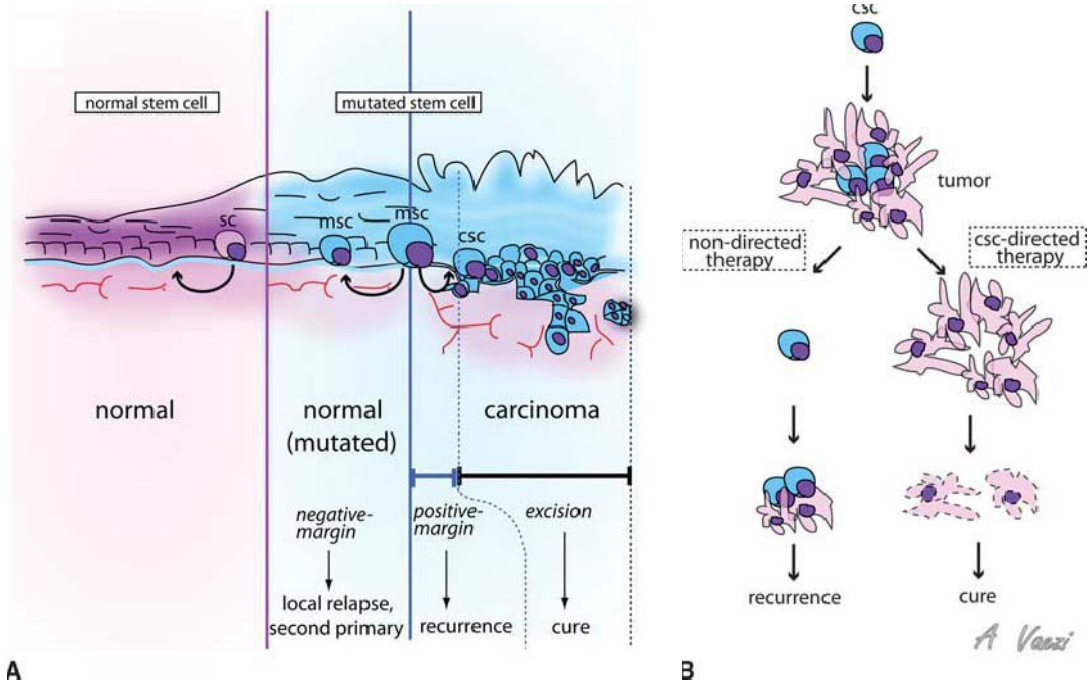

Figure 108.7 Cancer stem cells. **A**: Model integrating the concept of CSC and field cancerization, with emphasis on consequences for surgical margins. (Inspired from Leemans CR, Braakhuis BJ, Brakenhoff RH. The molecular biology of head and neck cancer. *Nat Rev Cancer* 2011;11:9–22.) **B**: Model of CSC-targeted therapies.

Transforming mutations due to alcohol and tobacco consumption in aerodigestive tract progenitors may lead to clonal expansion of CSC progenitors. It has also been proposed that transforming mutations occur in a more differentiated cell that undergoes dedifferentiation as a result of the mutation, thereby acquiring stem cell features (212). Both alternatives are possible and could lead to expansion of CSC precursors, which could lead to progressive replacement of large portions of the normal mucosa by the cancer progenitor and its differentiated progeny: the fields of cancerization. With further mutations acquired by a stochastic mutation model, CSCs arise in a cancer progenitor cell. The tumor may be the consequence of both (a) differentiation of the CSC and (b) novel mutations acquired stochastically within the clone. CSCs become mCSCs at the tumor periphery, detaching from the primary tumor to form metastatic seeds. Metastatic cells may be detected in the lymph and the circulation, but will not necessarily cause metastasis. When mCSCs home to a favorable distant site, they may grow into a metastasis (212). Resection of the primary tumor may leave either CSC or CSC progenitors at microscopically negative and possibly normal-appearing margins (10). Failure to resect these progenitors may increase the chance of recurrence.

Clinical Implications of Cancer Stem Cells in HNSCC

Little is known about HNSCC stem cells, but knowledge is increasing rapidly. In 2007, Prince et al. (215) reported CSC isolation in HNSCC for the first time. The population was initially isolated by FACS sorting with two markers; CSCs were enriched in the $CD44^{+}CD24^{-}$ cell population. The CSCs were found to express an oncogene BMI-1 (215), a polycomb family protein involved in chromatin remodeling and gene regulation, including p16. However, CD44 was found to be widely expressed in HNSCC; other markers have now been identified. For instance, aldehyde dehydrogenase 1 (Aldh1) expression can be used to narrow the CSC population (216). In laryngeal cancer, CD133 was identified as a sorting marker for CSCs (217,218). In addition, a less specific marker of CSC is exclusion of nuclear dye by cells with stem cell proprieties; the efflux of dye is mediated via a membrane channel of the same family as multidrug resistance gene 1 (MDR1), which also evacuates chemotherapy drugs (219). This test can be used to detect a cell population enriched in stem cells, which, as predicted, is resistant to chemotherapy.

CSCs are functionally different, and more radioresistant, than non-CSCs. CSCs are relatively resistant to chemotherapy and ionizing radiation. This explains why, while ionizing radiation is effective at reducing the global volume of head and neck tumors in xenograft models, it resulted in a relative enrichment in CSCs (213); radiation therapy and chemotherapy may select for and enrich CSCs that are resistant to treatment. As a corollary, the HNSCC CSC marker high CD44+ predicts response to treatment and is associated with increased local recurrence after radiotherapy in laryngeal cancer (220).

Novel treatment strategies target CSCs specifically. The primary goal of treatment is to attack the cancer at its regenerating roots, rather than simply reducing the tumor bulk (Fig. 108.7B). However, these strategies have not yet been translated to HNSCC clinical trials. Specific attempts to target CSCs in HNSCC include immunotherapeutic strategies targeted to CSC markers, either using anti-CD133 antibodies (221) or tumor vaccines targeting Aldh1+ cells. To date, however, no antibody specific for HNSCC CSC has been found. Another therapeutic approach is the downregulation of BMI-1, the transcription factor essential in maintenance of the self-renewal proprieties of CSCs, via siRNA strategies (217). Much hope is being invested in CSC-targeting therapies.

ANGIOGENESIS AND VASCULOGENESIS FEED TUMOR GROWTH

Tumor cells are dependent on their microenvironment and their supporting cells. For instance, independent of the existence of CSC, the tumor cannot grow without blood vessels to bring oxygen and nutrients vital for survival of the cell, and evacuation of catabolic products toxic for the cell. In absence of blood vessels, tumors cannot grow more than 1 to 2 mm in diameter (222). New blood supply is provided either through the formation of new blood vessels arising from preexisting vessels in a process termed *angiogenesis* or via the recruitment of bone marrow-derived cells and *de novo* formation of blood vessels through the process of *vasculogenesis* (223).

Angiogenesis occurs in orchestrated steps, in which a preexisting capillary sprouts new endothelial tubes which appear as finger projections of proliferating endothelial cells. Initially, endothelial cells differentiate into a motile "tip cells" that lead a trail of proliferating endothelial cells and the "stalk cells," constituting the core of the finger projection, through the hypoxic tissue (224). The endothelial tube then encounters and fuses with other capillaries, forming a complex vascular network. The immature newly formed endothelial vessels are stabilized after association with pericytes originating either from the preexisting capillaries or from the bone marrow (225). In cancer, the mature capillaries are different than normal capillaries, being more tortuous and leaky.

The molecular mechanisms involved in angiogenesis are partially understood. Capillary endothelial cells are sensitive to tissue hypoxia. In response to the lack of O_2, hypoxia-inducible factor 1α (HIF-1α) accumulates in the endothelial cell (222). HIF-1α is a transcription factor that is continuously degraded via ubiquitin-mediated degradation dependent on oxygen. Hypoxia blocks the degradation of HIF-1α, leading to its accumulation (226). HIF-1α partners with HIF-1β to induce expression of hypoxia genes including the vascular endothelial growth factor A (VEGF-A) and the VEGF receptor 2 (VEGFR2) (222). VEGF-A is a potent endothelial mitogenic factor that acts on tyrosine kinase receptors of the VEGF family. A VEGF-A gradient induces differentiation of a pioneering "tip cell," which acquires a proteolytic phenotype and degrades laminin in the basement membrane. With erosion of the basement membrane, interstitial collagen is exposed, leading to a change in cell morphology with appearance of cell protrusions and finger-like cell projections known as filopodia, which sense the VEGF gradient in the hypoxic tissue and direct the growth of the endothelial chords (222). VEGF also induces expression of the receptor notch and its ligand delta present on "stalk cells," which counteract the proliferation and migration of the endothelial chord (222). Later, association with the pericytes induces the production of metallo-protease inhibitors in both pericytes and endothelial cells, which terminates the proteolytic phenotype of the endothelial cells.

Angiogenesis is a particularly attractive target for anticancer therapy, because the cells responsible for the formation of blood vessels vital for the tumor are not transformed. They have fewer mechanisms in place to evade radio- or chemotherapy.

Vasculogenesis occurs during embryogenesis and in tumors. It involves the migration of endothelial progenitor cells (EPC) originating from bone marrow into hypoxic tissue, where EPC contribute to new vessel formation. EPC are characterized by surface markers including CD34, endothelial surface makers, and CD11, a cell substratum adhesion molecule (223). In response to tumor hypoxia, EPC home in the tumor bed in a process involving HIF-1α. HIF-1α induces secretion of stromal cell-derived factor 1 (SDF-1) in the hypoxic tissue, which activates CXCR4, a cytokine receptor present on the EPC cell surface. SDF-CXCR4 constitutes the recruiting signal for EPC into hypoxic tissue (227). Experimental evidence supporting the presence of EPC in cancer comes from animal models where EPC are genetically labeled with a color marker. In xenograft experiments, EPC contributed to 25% of the tumor vasculature within a week of tumor implantation, but the number decreased to 1% by 1 month (228). Whether or not EPC is an artifact seen in animal models is debatable, but in one study of patients who received gender mismatched bone marrow transplants showed that EPC do contribute to tumor vasculature in patients. EPC contributed to 1% to 12% of the tumor vasculature depending of the tumor type (229). The role played by EPC in tumor regrowth after irradiation was elegantly demonstrated in animal model. Blocking EPC migration through HIF-1α, or SDF-CXRCC4 inhibitors, prevented homing of EPC at the site of tumor xenograft and blocked regrowth of tumors after radiation (227).

Clinical Implication of Hypoxia, Angiogenesis, and Vasculogenesis in HNSCC

Tumoral hypoxia has long been recognized as a resistance factor for radiation therapy, and tumor tissue with oxygen tension under 0.5 mm Hg is considered resistant to radiation. Tumor hypoxia measured in pretreatment tissue specimens is an independent prognostic factor for survival, but measurements are not done routinely in clinic. HIF-1 was

proposed to be a predictive biomarker for clinical outcome (230–234), but clinical results for this marker are equivocal (235–237). Another hypoxia biomarker is carbonic anhydrase IX (CA-IX), a target of HIF-1 that regulates local pH, is elevated in hypoxic regions of HNSCC, and is a confirmed marker of tumor hypoxia (231,232). Unfortunately, the prognostic value of CA-IX is disappointing. In a large retrospective analysis of a prospective study of HSNCC treated with radiotherapy with or without the hypoxia sensitizer nimorazole, CA-IX had no prognostic value, even for tumors treated with nimorazole (238). In contrast, tumoral VEGF expression as a biomarker is promising. VEGF, also a HIF-1 target, correlated with worse prognosis in several studies, and the results were confirmed in a meta-analysis (239).

Therapeutic strategies have been used to target the hypoxic regions of HNSCC. For instance, tirapazamine becomes activated in a cytotoxic radical only in hypoxic cells and was proposed as a radiosensitizer of choice to target hypoxic-resistant cells. Unfortunately, after a promising Phase II trial, the drug showed no benefit over standard cisplatin plus radiation therapy in a Phase III, multiinstitutional trial (240). Another therapeutic angle is to neutralize tumor angiogenesis. Anti-VEGF therapies are used clinically to combat HNSCC. The compound SU5416 (semaxanib), a pharmacologic inhibitor of VEGF receptor 2, was tested in HNSCC with limited efficacy (241). In contrast, some Phase III HNSCC clinical trials using bevacizumab (Avastin), a monoclonal anti-VEGF antibody, have been completed, and other Phase II trials are under way in combination with other drugs. In a double-blind, placebo-controlled, randomized trial of non-small cell lung cancer salvage therapy with erlotinib with or without bevacizumab, the addition of the VEGF-blocking agent did not improve overall survival, despite an encouraging but nonsignificant improvement in disease-free survival (242). However, in HNSCC, Phase I/II showed encouraging results (243), and promising Phase II trials testing the activity of bevacizumab and the antimetabolite pemetrexed in HNSCC are actively accruing patients. It is conceivable that only tumors expressing high levels of VEGF are sensitive to bevacizumab, and tumoral VEGF expression could be used as predictive biomarker to select patients who would benefit from antiangiogenic therapy. Novel therapeutic agents are in the preclinical study pipeline, such as PG545, which is a heparan sulfate mimetic that sequesters tumor angiogenic factors in the interstitium (244). This is another example where the understanding of the biology of angiogenesis led to the development of innovative therapies.

CONCLUSION

The information on biology of head and neck cancers is vast. In this chapter, we have focused on a description of basic concepts with an emphasis on the clinical implications of each pathway. It is crucial for the clinician to understand the molecular pathways contributing to tumorigenesis of HNSCC in order to understand and participate actively in the development of novel anticancer therapies.

The pathways described herein are interconnected. The mitogenic signal starts with growth factors of the EGF family, which lead to activation of the Map kinase, PI3K, and STAT signaling pathways leading to cell proliferation and promotion of cell survival, as well as increased motility. In contrast, TGF-β counterbalances EGF effects by restraining the cell cycle and enhancing cell death. However, TGF-β has dual effects; it also appears important in EMT and possibly metastasis. These two essential pathways appear to be essential for HNSCC carcinogenesis.

The cell cycle, activated by mitogenic signals, is ultimately orchestrated by the oscillating expression of cyclins, and activation of Cdks, the effector kinases responsible of signaling progression through the cell cycle. Multiple checkpoints must be passed in order for the cell to proliferate, and multiple inhibitors including INKs, KIPs, and Wee1 proteins stall the cell cycle to ensure appropriate proliferation. Malfunction(s) in the series of molecular events linking mitogens to cell division is an opportunity for uncontrolled cell proliferation and cancer formation.

However, tumor biology is more complex than an imbalance between proliferation and cell death leading to the clonal expansion of one cell. The tumor, like an organ, depends on supporting cells, blood vessels, and subject to an immune surveillance. Cancer cells are not homogenous within the tumor. This may be explained by the presence of solid CSCs, which may self-renew, may maintain the cancer, and may differentiate into other subpopulation of cancer cells found in the tumor. However, CSC is a model that is not mutually exclusive. The traditional stochastic mutation model with development of subclone population probably also contributes to the tumor heterogeneity. Furthermore, the HNSCC should be viewed as an abnormal organ in which cancer cells of epithelial origin interact with the stroma and blood vessels, essential for its growth.

Any of the molecular mechanisms leading to or supporting the tumor growth are potential anticancer treatment targets. Understanding the basic concepts of tumor biology is crucial to the development of rationale therapies.

HIGHLIGHTS

- Tumors labeled as HNSCC are not homogenous, but represent different clinical entities based on their pathogenesis, such as smoker–drinker, HPV infection, or genetic defects in DNA repair genes.
- HPV16 is a sexually transmitted disease causing oropharyngeal HNSCC; these cancers are p16 positive and have a favorable clinical outcome in non-smokers when treated with chemoradiation therapy.

- EGFR, tyrosine kinase transmembrane receptors of the ErbB family that drive proliferation, resistance to apoptosis, and migration, is upregulated in HNSCC. EGFR acts via Ras/Raf/MapKinase as well as PI3K/Akt and STAT pathways. Agents targeting the EGFR pathway have clinical utility against HNSCC (cetuxumab, erlotinib).
- TGF-β signaling is frequently deregulated in HNSCC. Cancer cells can circumvent tumor suppressor components of this pathway and use TGF-β stimulation to promote invasion, EMT, secretion of mitogens, and pro-metastatic cytokines.
- Cell cycle progression is regulated by cyclin proteins. Cyclin family members, each specific for a phase of the cell cycle, have no intrinsic enzymatic activity, but associate with and activate Cdk. *CCND1*, the gene coding for cyclin D1 that regulates progression through G1 phase, is frequently amplified in HNSCC.
- Cyclin:Cdk complexes are inhibited by INKs, CIP/KIPs, and Wee1 homologues and are activated by CDC25 phosphatases. CIP/KIPs are upregulated in response to cellular stresses, via p53. p53, the gatekeeper of the human genome that mediates cell cycle arrest in response to DNA damage, is inactivated in 50% of HNSCC.
- DNA repair processes are important to prevent conversion from damage to mutation. Impaired DNA repair predisposes to HNSCC cancer (e.g., Fanconi anemia) but also renders tumors more sensitive to DNA-damaging agents such as ionizing radiation and cisplatin. Reduced levels of DNA damage proteins are emerging as predictive biomarkers in HNSCC.
- Apoptosis, or programmed cell death, is mediated via the extrinsic pathway involving TNF superfamily death receptors, or via the intrinsic pathway involving release of cytochrome C by the mitochondrion. Caspases are proteases that are the machinery of apoptosis. Proapoptotic drugs are part of the new armamentarium of oncologists.
- The concept of CSC is gaining traction in solid tumors including HNSCC. CSCs have unlimited self-renewal capacity and divide asymmetrically to provide differentiated progeny that make up the bulk of the tumor. CSC are the target of novel anticancer therapeutic strategies.
- Blood supply is critical to tumor growth. New blood vessels form from preexisting capillaries (angiogenesis) or via the formation of new blood vessels from bone marrow-derived cells (vasculogenesis). Hypoxic tumor cells are resistant to radiation, and are therefore the target of anti-hypoxic adjuvant therapeutic agents.

109 Principles of Patient Care

Rohan R. Walvekar *Marcie C. Tauzin* *Neelima Tammareddi*

Principles of care for the head and neck patient can be defined by understanding of the concepts of quality health care and the methods and processes necessary to secure it. An appropriate definition of quality care must be agreed upon in order to implement it. There are several mechanisms that have been introduced in current medicine as ways to measure, implement, and audit quality health care and ensure an equitable and ethical practice of medicine. *Clinical guidelines* and *critical pathways* are used to direct medical decision making. The appropriate evaluation of clinical outcomes through evidence-based research provides a reasonable justification for everyday clinical decision making. Multidisciplinary team (MDT) approaches ensure complete and efficient care for the patient. In addition, safety, standardization of care, and associated costs can be examined to allocate health care resources in an equitable fashion.

PURPOSE

The aim of this chapter is to highlight the importance of quality care, particularly with regard to the head and neck cancer patient. We define the different components of quality care and describe the various tools used to improve it. Reviews of current literature are used to support the importance of this topic and offer examples of implementation. The goal is to emphasize the need for high-quality medical care and to provide a resource that explains how it can be incorporated into the care of a head and neck cancer patient.

QUALITY OF CARE

Historical Background

Beginning in the 1990s and rising over the last two decades, there has been an increasing focus on the quality of medical care in the United States. It has prompted the development of several organizations to assess and improve health care, including the Agency for Healthcare Research and Quality (AHRQ), which oversees the National Guideline Clearinghouse (NGC), the Patient-Centered Outcomes Research Institute, and the National Quality Forum (NQF). In addition, there was rapid growth of existing programs such as the Institute of Medicine (IOM), which is the health arm under the National Academy of Sciences, dating back to the 1860s. Some of these initiatives are government-based, some are nonprofit, and others are professionally associated. The Clinical Guidelines Task Force established by the American Academy of Otolaryngology (AAO) and the Quality of Care Committee created by the American Head and Neck Society (AHNS) are organizations specific to otolaryngology. The emphasis on quality improvement also coincided with a new shift toward the use of evidence-based medicine (EBM). It has become increasingly important in all aspects of health care, especially those that affect the quality of health care delivery.

Defining Quality Care

In 2001, the IOM published a report entitled "Crossing the Quality Chasm: A New Health System for the 21st Century," which highlighted the disparity between optimal care based on the best evidence and the quality of care that is delivered. In this report the IOM proposed six critical goals to redefine health care: improved safety, effectiveness, timeliness, efficiency, individualization, and equality of delivery of health care. It defined quality as "the degree to which health services for individuals and populations increase the likelihood of desired heath outcomes and are consistent with current professional knowledge" (1). The AHRQ simplified this definition as "doing the right thing, at the right time, in the right way, for the right person—and having the best possible results" (2,3).

The three general aspects studied in assessing quality of care are structure, process, and outcomes. *Structure* refers

to health system characteristics. *Process* refers to the role of the health care provider. *Outcome* refers to what happens to the patient (3,4). These three concepts are intertwined and must all be addressed for effective quality improvement. This involves analysis of how organizations and systems fail and the practice of devising, testing, and evaluating tools and techniques to address those deficiencies.

Organizations For Improved Quality

The national initiatives dedicated to the improvement of quality health care all work together but also focus on different aspects of the same goal. The AHRQ focuses on research that promotes improvement of health care quality, safety, efficiency, and effectiveness. The IOM identifies key health care areas that need to be addressed more urgently. The Patient-Centered Outcomes Research Institute commissions research focused on evidence-based information as well as specific values and interests of patients. The NQF was formed in 1999 to identify and enforce performance measures and disseminate quality measures. Currently, there are 55 of these performance quality measures pertaining to oncology; however, none that explicitly pertain to head and neck cancer.

The Clinical Guidelines Task Force of the AAO was formed for the development of rigorous evidence-based guidelines in head and neck surgery. There are several published treatment guidelines available such as those for hoarseness (5), otitis externa (6), and acute sinusitis (7). These focus on improving quality of care and standardizing clinical protocols and algorithms for patients with specific otolaryngologic diagnoses based on best current evidence. They describe accurate diagnosis, treatment options, and prevention measures.

The Quality of Care Committee, formed in 2007 by the AHNS, works to establish consensus quality measures in head and neck cancer care and to promote compliance with these standards as a framework for measuring quality of care in head and neck surgery. Currently, there are quality measures for the two most common head and neck cancers: oral cavity and laryngeal cancer, approved by the AHNS in 2007 and 2009, respectively. Pretreatment measures include histopathologic confirmation of diagnosis, appropriate Tumor Node Metastasis (TNM) staging (8), and tobacco cessation counseling. Treatment-related measures involve referrals to radiation oncology, medical oncology, and speech pathology when necessary. Appropriate follow-up for symptom management and cancer surveillance encompasses the posttreatment measures (4).

Outcomes of Care

Another important aspect of quality health care is assessing the outcomes of care received. The IOM defines three general categories of outcomes: clinical status, functional status, and patient satisfaction. *Clinical status* is defined as the biologic outcome of disease, for example, 30-day mortality rates. *Functional status* is the patient's physical, emotional, and cognitive activity levels as the disease affects them, for example, Karnofsky score (4). Quality of life has become an important goal for head and neck oncology outcomes, in addition to cancer control and overall survival. Attempts to measure health-related quality of life have led to an increase in production of formal assessments to evaluate physical, mental, and social function for a variety of clinical topics. A frequently used example of such a tool is the University of Washington Quality of Life Revised Version 4 (9). Finally, *patient satisfaction* is a measure of patients' opinions about the care they receive, for example, Likert scale (10). It should be noted that patient satisfaction and high-quality care have not been shown to be correlative, and thus, it may not be the best means of measuring quality of care (4). Quality of care can be improved by considering these three aspects of clinical outcomes.

CLINICAL GUIDELINES

Clinical practice guidelines present systematically and precisely developed evidence-based recommendations for diagnostic procedures and medical treatment options that are used for standard patients (11). They use EBM to help set national standards and aid in decisions regarding appropriate health care for specific clinical circumstances. While there is increasing integration of evidence-based practice into clinical decision making, most clinical practice is still not based on the best available evidence. Guidelines are tools used to ensure that this evidence is put into current practice. They serve not only as references for clinical decision making and best practices but also as criteria for performance evaluation (12).

The general goals of developing clinical guidelines are to improve the quality of clinical care by helping physicians and patients in decision making and to support the delivery of cost-effective care by reducing unwarranted variations in clinical practice (13). In addition to promoting improved decision making, they can be used to initiate improvement strategies, prioritize research goals, and support reimbursement for particular services.

However, physicians must be careful in the use of guidelines. A flawed guideline can impair the whole health care system through the same pathways that an effective one makes improvements. There is a potential threat to individualized patient care if guidelines are used without proper evaluation. Every clinician must remember that in medicine every patient and every situation is slightly different. Guidelines must be developed in a very strict fashion to prevent inappropriate use (12,14).

Many review articles, consensus statements, practice parameters, and policy recommendations are labeled as "guidelines," without possessing the diligent methodology to merit such a designation (12). A variety of tools such

as the Conference on Guideline Standardization (COGS) checklist, the Grading of Recommendations Assessment, Development and Evaluation (GRADE) approach (11), and the Appraisal of Guidelines Research and Evaluation (AGREE) instrument exist to measure the quality of guidelines. The AGREE instrument is a widely used generic measure of guideline quality characterized by the attributes outlined in Table 109.1 (15).

Clinical guidelines for a variety of otolaryngologic issues can be found through several different databases. The NGC database, an initiative of the AHRQ, is a repository that includes national guidelines that meet specific criteria. As of the publication date, the NGC database contains a total of 151 published guidelines with the search term "head and neck" and 71 with the search term "otolaryngology." A few resources for finding guidelines are listed in Table 109.2.

TABLE 109.1 AGREE INSTRUMENT PRINCIPLES

1. Scope and purpose
   a. Overall objective(s) of the guideline described
   b. Clinical questions detailed
   c. Intended target patient population identified
2. Stakeholder involvement
   a. Guideline development group of individuals from all relevant professional groups
   b. Incorporation of patients' views and preferences
   c. Clear definition of target users
   d. Pilot testing of guideline for further validation
3. Rigor of development
   a. Systematic methods used to search for evidence
   b. Criteria for evidence selection described
   c. Methods used to formulate of recommendations described
   d. Recommendations account for health benefits, side effects, and risks
   e. Explicit link between recommendations and supporting evidence
   f. External review of guideline
   g. Process for updating guideline provided
4. Clarity of presentation
   a. Specific and unambiguous recommendations
   b. Different options of management presented
   c. Key recommendations easily identifiable
   d. Supported with tools for application
5. Applicability
   a. Potential organizational barriers in applying recommendations discussed
   b. Potential cost of applying recommendations considered
   c. Key review criteria for monitoring or audit purposes
6. Editorial independence
   a. Editorially independent from funding body
   b. Conflicts of interests acknowledged

CLINICAL PATHWAYS

Clinical pathways are manifestations of guidelines, typically set up by a single institution, to specify care through protocols and to provide action plans with the appropriate support systems in place. Also known as critical pathways, they are developed by MDTs and establish the optimum timing of essential care in the management of patients who have specific conditions or undergo specific procedures. The development of these pathways through critical analysis has become a way to further streamline the clinical workup, treatment, and follow-up of head and neck cancer patients (16). By utilizing evidence-based interventions and reducing variations in care, the development of pathways can benefit patients by reducing complications, providing better quality of life, improving survival, and allowing more cost-effectiveness (17).

Several institutions have described experiences with critical pathways in head and neck oncology, reporting on associations between the implementation of a pathway and lengths of stay (LOS) in the hospital. Some studies compare observational cohorts of critical pathway patients to prepathway historical cohorts for the same or similar procedure. Others controlled for changes in medical care over time by comparing pathway cohorts with nonpathway counterparts during the same time frame. Pathway implementation does appear to decrease LOS, but the effect is confounded by temporal trends such as increased utilization review, more cost-conscious care, and better-educated medical providers regarding the importance of minimizing hospitals stays (17).

Chen et al. examined the implementation of a clinical pathway for unilateral neck dissection. Pathway patients were compared with historical controls and with a nonpathway contemporaneous cohort. Significantly decreased LOS and median costs were seen in pathway patients. Interestingly, LOS and median cost of care for the nonpathway contemporaneous control group was in between that of the pathway patients and historical controls. This suggests that care was made more efficient and cost-effective through both changes over time as well as through the clinical pathway (18).

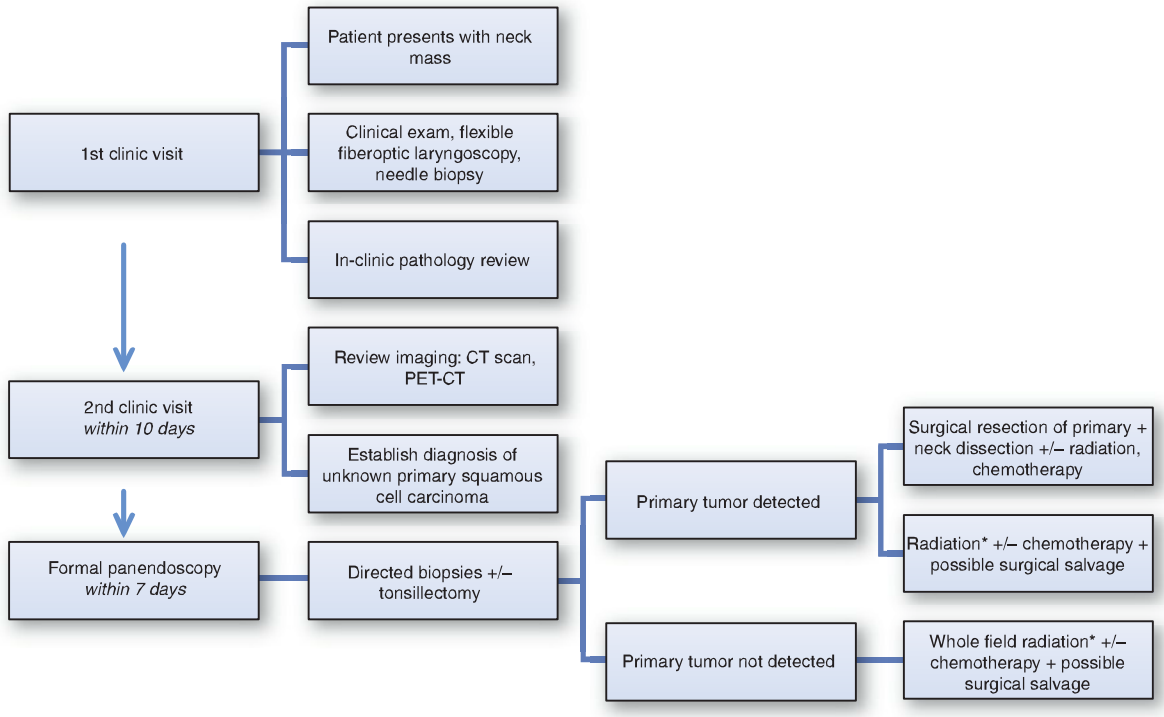
Gendron et al. examined the effect of a clinical pathway for head and neck cancer patients on health care efficiency. Several aspects of hospital courses were reviewed for 3 years. Intensive care LOS, incidence of postoperative pneumonia, 30-day readmission rates, and median total costs decreased across the 3 years with implementation of the pathway. Median total LOS and nonintensive care LOS decreased over the first year but remained stable through year three (3,19).

Yueh et al. critically evaluated the impact of critical pathways on LOS after laryngectomy. This study compared a hospital that implemented a critical pathway for laryngectomy and a contemporary control group that did not utilize a critical pathway at a separate institution. After controlling for temporal trends and clinical variables, the direct impact of a clinical pathway on LOS in relatively low-volume procedures such as laryngectomy was noted to be limited. However, the simple process of thinking about and developing a pathway can help patients, whether they are managed using it or not, by encouraging those involved to more critically evaluate the care that is provided (17).

Clinical pathways ideally function to maximize quality of care in a resource-effective manner and may serve as a working model to readily implement clinical guidelines. An example of a pathway for the care of a patient with an unknown primary associated with squamous cell carcinoma of the neck is illustrated in Figure 109.1. In general, the aforementioned findings suggest that successful clinical pathway implementation confers, either directly or indirectly, sustained efficacy and continual potential for improvement of health care quality (3).

MULTIDISCIPLINARY TEAM APPROACH

Even with medical advances, the 5-year survival rate of head and neck cancer patients has not substantially improved during the last 30 years. There has been a movement toward centralized multidisciplinary clinics and tumor conferences and cancer treatment programs in an effort to provide high-quality individualized patient care, which encompasses medical, surgical, social, emotional, and rehabilitative needs of the head and neck cancer patient. In addition, the goals of these centralized services are to improve and standardize treatment outcome, improve access to clinical trials, and improve survival outcomes (20). The variability of head and neck cancer presentation along with the complexity of cancer care warrants multidisciplinary coordination and centralization of care to optimize treatment.



** Radiation therapy can be tailored to inclusion of the primary tumor and nodal basins most likely to be involved if Primary tumor is detected. When no primary tumor is detected, the radiation field should include all potential epicenters of cancer from the skull base to the clavicles and include all nodal basins.*

Figure 109.1 Clinical pathway example for neck mass with unknown primary tumor.

The purpose of a MDT meeting is to ensure the quality of the health care provided to patients with head and neck cancer. The team includes physicians such as otolaryngologists and radiation oncologists, as well as allied health professionals who provide adjunctive care to head and neck cancer patients. Table 109.3 lists the essential components of this team.

The main goals of a MDT meeting are to define the true anatomical extension of the tumor, assign accurate TNM staging, and offer appropriate treatment recommendations. Proposed benefits of MDTs include more standardized care, better coordinated continuity of care, cost-effective care, improved communication among health professionals, improved clinical outcomes, and increased recruitment into clinical trials (16).

Multidisciplinary Team Presentations

Every patient with a newly diagnosed head and neck cancer, all patients who have undergone initial surgery, and all patients with newly identified recurrent or metastatic disease should be presented to a MDT meeting. Adequate preparation and complete workup of the patient prior to meeting are essential to the working process of establishing a multidisciplinary accurate diagnostic TNM stage and treatment plan.

To ensure accurate TNM staging, satisfactory documentation of head and neck tumors should include a verbal description, precise measurement, illustrative representation, photographic recording, and appropriate radiographic imaging techniques such as computerized tomography (CT), magnetic resonance imaging, positron emission tomography (PET), and finally pathology reports and demonstrative histologic slides (21). Simo et al. presented their experience utilizing concise integrated multimedia Microsoft PowerPoint presentations including all of the aforementioned data, which could later be integrated into a centralized database. Figure 109.2 shows a good example of effective and complete MDT presentation using the format from Simo et al. as a guideline. The highlighted advantages include comprehensive and complete information available for each member to give expert opinion, educational benefit to medical and nonmedical team members, comparative baseline multimedia presentation in cases of recurrence, and a valuable adjunct to long-term clinical monitoring (21).

TABLE 109.3 MULTIDISCIPLINARY HEAD AND NECK ONCOLOGY TEAM

Physicians
- Otolaryngologist/head and neck surgeon
- Subspecialty surgical consultants
  - General surgeon
  - Plastic and reconstructive surgeon
  - Oral maxillofacial surgeon
- Radiologist—interventional and diagnostic
- Radiation oncologist
- Medical oncologist
- Internal medicine physician
- Anesthesiologist
- Pathologist

Nurses
- Head and neck surgery clinic
- Operating room
- Postanesthesia care unit
- Intensive care unit
- Postsurgical unit
- Rehabilitation, long-term care, or nursing home
- Home health care

Allied health members
- Dentist
- Prosthodontist
- Speech–language pathologist
- Audiologist
- Physical therapist
- Occupational therapist
- Nutritionist or dietician

Other core members
- Social worker
- Religious or spiritual counselor
- Mental health specialists

Efficacy of Multidisciplinary Teams

Despite more than 30 years of experience with MDTs in several countries, such as Sweden, the evolution to centralization and multidisciplinary care is supported mostly by lower power and anecdotal evidence with an obvious lack of fully high-quality evidence (16). There are few studies specifically focusing on the quality, efficacy, and efficiency of MDTs for head and neck that warrant discussion.

In a literature review, Westin et al. focused on the management of head and neck cancers using MDT meetings, evaluated whether this entity is beneficial to patients and treating staff, and determined if it is cost-effective. The review concluded that MDTs provide quality assurance for patients on an individual basis. They provide a forum for up-to-date individualized treatment plans, facilitate coordinated and timely treatment, and enhance the personal competence of clinical members. Additionally, MDTs within cancer care networks likely lead to improved patient outcomes and cost-effectiveness (16).

Stalfors et al. evaluated the quality and effectiveness of MDTs by collecting data prospectively from tumor board presentations on 329 consecutive patients. They found that 236 of 324 patients (73%) had their diagnosis and treatment plans established at the first meeting and were thus regarded as successes. However, 27% of patients were presented before all the necessary data were available, and the need to have more complete routine workup of patients prior to the MDT was emphasized. After presentation at the MDT, the TNM classification was only changed in 1.4% of patients. This attests to the high quality of decisions

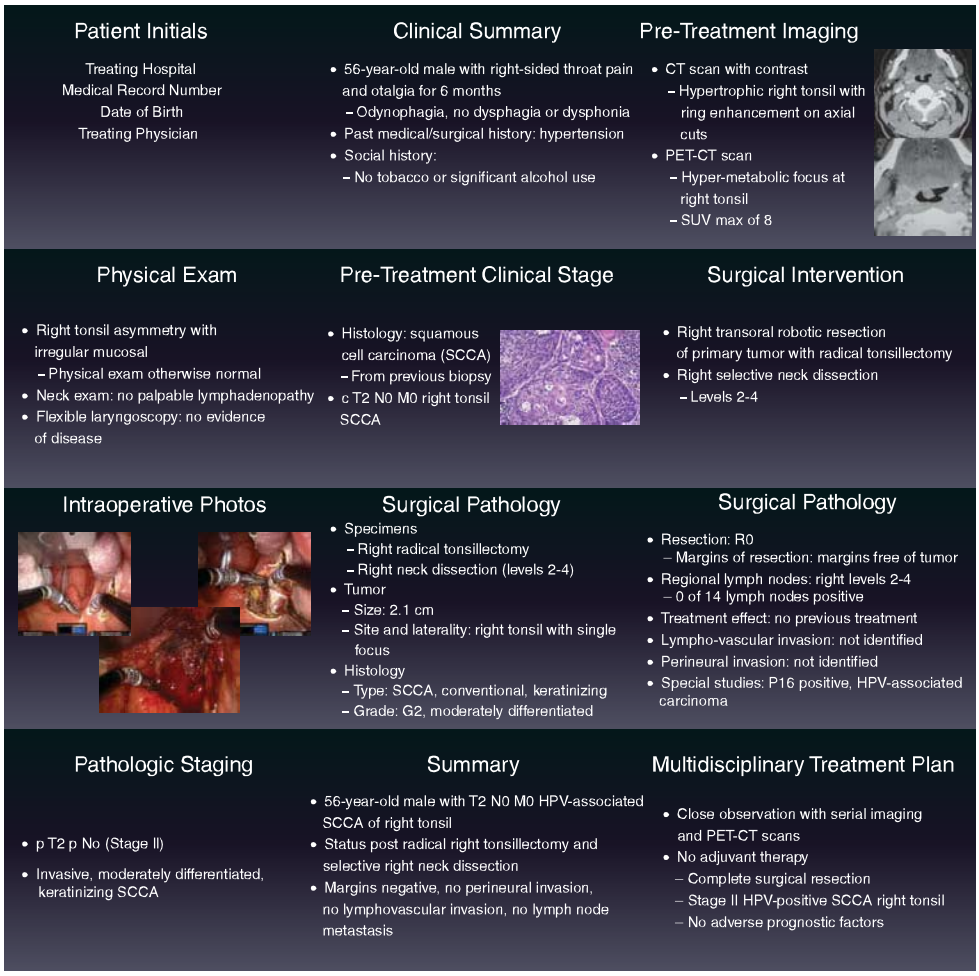

Figure 109.2 Integrated media presentation for MDT. (From Simo R, et al. Integrated media presentation in multidisciplinary head and neck oncology meetings. *Eur Arch Otorhinolaryngol* 2009;266:261–265.)

made at the MDT meeting and indicates that waiting time recorded in this study (median 38 days) does not appear to jeopardize the medical safety of patients. The study concluded that while the quality of decisions made at MDT meetings is good, there is a need to improve the quality of premeeting workup (20). Likewise focusing on efficiency, Nouraei et al performed a systematic analysis of the MDT to identify factors delaying treatment planning and implemented a system-wide Internet-based database. After the database was employed, significant improvements were made in cross-specialty coordination resulting in statistically significantly fewer delays in treatment due to unavailability of adjunctive investigations. Overall efficiency of the MDT was improved by 60% (22).

In a prospective study, Wheless et al. concentrated on the efficacy of the MDT in altering diagnosis, stage, and treatment plan in patients with head and neck cancers. The study population consisted of 120 patients, and 27% overall had some change in tumor diagnosis, stage, or treatment plan after MDT presentation. Change in treatment plan occurred in one out of every five patients (18.3%). Treatment changes were significantly more common in cases of malignant tumors (24% vs. 6% benign tumors) and typically involved escalation in management by adding multimodality care (23).

As the management of head and neck tumors has become increasingly complex with multiple treatment modalities, the multidisciplinary tumor approach has become critical in optimizing treatment planning and patient outcomes. The available data show that tumor board meetings significantly affect diagnosis, treatment decisions, and delays in appropriate care. Many argue that multidisciplinary tumor boards are essential to managing head and neck cancer patients and represent a new standard of care (23).

MEDICAL ERRORS AND PATIENT SAFETY

Patient safety is a serious public health issue and is fundamental to achieving quality health care. In recent years, the importance of improving patient safety has been a priority both nationally and globally. It is also one of the core goals

defined by the IOM. Compared to health care, industries with a perceived higher risk such as aviation have much better safety records. There is a one in 1,000,000 chance of an aircraft traveler being harmed during a flight. In comparison, there is a one in 300 chance of a patient being harmed while receiving health care. The economic benefits of improving patient safety are compelling. Studies show that additional hospitalization, litigation costs, infections acquired in hospitals, lost income, disability, and medical expenses have cost some countries between US$ 6 billion and US$ 29 billion a year (24).

Medical Errors

Estimates show that as many as 1 in 10 patients is harmed on some level while receiving hospital care in developed countries. A range of errors or adverse events may lead to the injury. The American health care system, one of the most advanced and costly in the world, still has an unacceptably high number of medical errors. Estimates indicate that nearly 100,000 patients die each year from medical errors in the United States. In addition, patient safety measures have worsened by nearly 1% each year for the past decade (24).

In an effort to develop a classification system for errors in otolaryngology, Shah et al. conducted a retrospective anonymous survey to members of the AAO. The survey asked participants to disclose any errors that occurred in their practice in the last 6 months and to describe the error, its consequences, and the corrective measures taken. There was an 18.6% (488/2,500) survey response rate with 216 errors reported by otolaryngologists, including 78 cases of major morbidity and 9 deaths. From these data, errors were classified into several categories: history and physical, differential or final diagnosis, testing, surgical planning, wrong site surgery, anesthesia-related, wrong drug/dilution on the surgical field, technical, retained foreign body, equipment-related, postoperative care, medical management, nursing/ancillary, administrative, communication, and miscellaneous. The most common errors were technical errors (19.3%) and medication errors (13.7%). From these data, the authors proposed a "Top Ten Safety Recommendations" list for otolaryngologists. It cautions against dependence on image guidance for sinus surgery and intraoperative nerve monitoring, emphasizes the importance of adequate preparation before surgeries with testing of necessary equipment and examination of all tests and consults, and highlights the effectiveness using the "time-out" at the beginning of each procedure (25).

Patient Safety

Patient safety research is an emerging field important to improve these statistics. The World Health Organization (WHO) has developed a set of patient safety research core competencies and describes a cycle of five key areas of patient safety research. These include measuring harm through quantification of morbidities and mortalities, understanding the causes of adverse events, developing the solutions to reduce patient harm, evaluating the impact of solutions, and translating these improvements into policy and practice (26).

Surgery is one of the most complex health interventions to deliver. More than 100 million people require surgical treatment every year for different medical reasons. Problems associated with surgical safety in developed countries account for half of the avoidable adverse events that result in death or disability (24). A current example of a tool developed to improve surgical safety and reduce surgical adverse events is the WHO's Surgical Safety Checklist. Figure 109.3 shows an adapted version of this checklist. According to the WHO 2007–2008 pilot study for this checklist, the incidence of surgery-related deaths and complications can be reduced by one-third during major operations (9). These results have been reproducible in recent studies (27). The use of checklists significantly reduces surgical morbidity and mortality.

Helmio et al. detailed the feasibility of implementing of the WHO surgical checklist into the process of otorhinolaryngology–head and neck surgery and investigated whether it would have an impact on the awareness of safety-related issues. A structured questionnaire was given to the operating room team 1 month prior to and 1 month after surgical checklist implementation. Statistically significant findings after checklist implementation included improved verification of the patient's identity and awareness of the patient's medical history, medications, and allergies. Otolaryngologists and anesthesiologists more frequently discussed potential critical events. The authors concluded that the incorporation of the WHO surgical safety checklist into otolaryngology–head and neck surgery improved the sharing of patient-related medical information between team members (28).

DISPARITIES IN HEALTH CARE

One of the critical goals of the IOM's "Crossing the Quality Chasm" focused on establishing equitable care, both on the individual and population levels (29). Health care providers are to treat all individuals fairly and deliver high-quality care regardless of personal characteristics such as age, gender, race, ethnicity, education, disability, sexual orientation, income, or location of residence. More broadly, the health care system's goal is to improve health status and reduce disparities among subgroups. Multiple studies have examined these disparities among patients with head and neck cancer based on demographic factors such as race, socioeconomic status, and education.

Goodwin et al. performed a retrospective analysis evaluating racial disparities in the incidence and survival of head and neck cancer. Data showed that African American males have higher age-adjusted incidences and mortality rates for laryngeal and oral cavity/oropharyngeal cancers than black females, white males, and white females. Similarly, age-adjusted mortality rates were higher in black males for these subsites. Additionally, African American males have

Before induction of anesthesia *Nurse and anesthetist*	Before skin incision *Nurse, anesthetist, and surgeon*	Before patient leaves operating room *Nurse, anesthetist, and surgeon*
◎ Confirm identity, site, procedure and consent with patient	◎ Introduce all team members by name and role	◎ Verbal confirmation of procedure and complete instrument counts
◎ Surgical site marked ◎ Yes ◎ Not applicable—midline or bilateral sites	◎ Confirm patients' name, procedure and site of incision	◎ Read specimen lables aloud
	◎ Antibiotic prophylaxis within 60 min of incision ◎ Yes ◎ Not applicable	◎ Address any equipment problems
◎ Check anesthesia machine and medications		◎ Discuss key concerns for recovery and management
◎ Pulse oximeter in place and functioning	◎ Display any essential imaging	
◎ Identify any patient allergies	*Anticipated critical events*	
◎ Difficult airway or aspiration risk ◎ No ◎ Yes → Ensure appropriate precautions	Surgeon: ◎ Identify critical or non-routine steps ◎ Estimated operating time ◎ Anticipated blood loss	
◎ Risk of >500 mL blood loss ◎ No ◎ Yes → Prepare for fluid/blood replacement as necessary	Anesthetist: ◎ Recognize any patient-specific concerns	
	Nurses: ◎ Confirm sterility ◎ Check for any equipment issues	

Figure 109.3 Surgical safety checklist. (From Haynes AB, Weiser T, Berry WR, et al. A surgical safety checklist to reduce morbidity and mortality in a global population. *N Engl J Med* 2009;360:491–499.)

a lower overall survival for these cancers when controlling for stage of presentation (29,30).

Beitler et al. examined health literacy as a factor in access to quality health care, specifically for head and neck cancer patients who have undergone total laryngectomy. The National Institutes of Health defines health literacy as the "degree to which individuals have the capacity to obtain, process, and understand basic health information and services needed to make appropriate health care decisions" (31). The patients in this study had dismal results with more than half being unable to interpret an appointment card or determine the correct time to take a medication (32). Such deficiencies may have severe consequences on the degree and quality of care these patients receive. This can be further translated to highlight the potentially serious implications poor health literacy has on access to care and overall quality of care.

Recent head and neck oncology literature emphasizes variations in patient care, specifically regarding high-volume versus low-volume centers and socioeconomic status. Two papers have reported that treatment for head and neck cancer is more likely to be concordant with guidelines when it is performed at tertiary care centers (4). Additionally, treatment at low-volume facilities has been associated with higher risk for death in patients with early-stage laryngeal cancer (29). Investigators have also reported that care for advanced laryngeal cancer in centers other than academic medical centers is associated with higher risk for death.

COST OF CARE

With the rising price of health care in America, it has become increasingly important to practice cost-conscious medicine. Utilization reviews use cost analysis and other measures to justify appropriate allocation of resources and delivery of care. Inefficient care causes costs to increase unnecessarily and can negatively affect access to health care. Thus, appropriate quality care must be evaluated through clinical research to identify what the actual cost of care is and where improvements can be made. Yet, few studies address this topic, specifically regarding the cost of care for patients with head and neck cancer.

The economics of medicine is not like that of other industries; cost can never be fully separated from medical

decision making. In a review published in 1989, Eisenberg explained that the economic medicine does not imply that less money can or should be spent on health care but rather that efficient utilization of resources is essential. The review goes on to break down clinical economics into three dimensions of care: types of analysis, points of view, and types of cost. There are three types of analysis. *Cost identification*, most frequently used in clinical research, answers the question "what is the cost." It compares the lowest cost of different available diagnostic or treatment regimens, assuming that the outcomes of each are equal. *Cost-effectiveness* determines the net cost of a service and incorporates different outcomes through "cost per unit outcomes" measures. *Cost-benefit* analysis evaluates if the cost is truly worth the benefit by describing both aspects in equal units, typically currency. The patient, the payer, the provider, and society are the four perspectives to be considered. Finally, the types of cost are direct medical costs, direct nonmedical costs, indirect morbidity and mortality costs, and intangible costs. These dimensions of clinical economics are the tools used to further evaluate medical costs (33).

Westin et al. performed a comparative cost-identification analysis of total laryngectomy with postoperative radiotherapy versus preservation treatment for the larynx with chemotherapy/radiotherapy. The same survival was demonstrated with each treatment plan, but direct medical costs were nearly US$ 3,000 less for the surgical arm. This shows cost efficiency, but it has to be weighed against the loss of the larynx and its effect on quality of life of the patient (16).

Dedhia et al. also performed a cost-identification analysis of 119 patients undergoing total laryngectomy with bilateral neck dissections. The study revealed that mean total hospital cost for this relatively standardized procedure was $29,563 with a range from $10,915 to $120,345. Length of hospital stay was noted to correlate with cost. Most of the hospital costs were incurred on the day of admission (postoperative day 0), primarily attributed to operating room costs, which averaged 24% of total hospital costs (34).

Rabalais et al. evaluated the utility of PET–CT imaging for surveillance of neck disease and need for surgical intervention versus upfront neck dissection for patients who were treated with chemotherapy and radiation for cancers of the oropharynx with N2 neck disease. The study found that in patients who had a complete response to treatment at the primary site and neck, upfront neck dissection strategies had a 0.6% advantage in preventing neck recurrences as compared to the PET–CT strategies. The incremental cost-effectiveness ratio, that is, the additional cost if upfront neck dissection strategies were utilized as compared to PET–CT surveillance per patient cured, was calculated to be $3,854,397. This difference was so large because of the minimal difference in effectiveness of the strategies (35).

Further research evaluating the cost and outcomes of care will allow the health care system to better allocate needed resources and enable the provider to be a better-informed patient advocate.

CONCLUSION

In order to provide quality health care to the head and neck cancer patient, providers and members of the health care system must be educated on the benefits of utilizing clinical guidelines and pathways. In addition, development and utilization must be fostered. Centralized care through MDTs can help by facilitating better communication among treating physicians and improving access to efficient multidisciplinary evaluations for patients. Adverse events and patient safety must be carefully examined to reduce medical errors and to continually assess where improvements can be made. Measures should also be taken to address the disparities that exist in health care delivery and find ways to decrease them. Finally, appropriate cost analysis of treatment regimens is needed to ensure that limited health care resources are allocated appropriately.

Quality health care involves system-wide evaluations and improvements and is important from the perspective of the individual caregiver. The described principles of patient care stem from the basic medical ethics that guide each provider in conscientious medical decision making. Incorporating these components into everyday care will make for better providers and also aid in system-wide changes and improvements to provide the optimal care for patients.

HIGHLIGHTS

- Clinical guidelines and pathways incorporate EBM to provide individualized care for the head and neck cancer patient.
- MDTs incorporate clinical experience with EBM and provide the opportunity for the creation of individualized treatment protocols for diverse head and neck cancer patients.
- Multidisciplinary approaches incorporating clinical, functional, social, emotional, and rehabilitative aspects of patient care permit a comprehensive, effective, and efficient mechanism for management of the complex care of head and neck cancer patients.
- Cost-effective medicine is a crucial component to ensuring the appropriate utilization and allocation of limited health care resources.
- Providers of head and neck cancer care should be aware of the disparities in health care and address them through improved patient education.
- Few disease-specific guidelines exist for head and neck cancer care, and there is a significant need for development of clinical guidelines and incorporation of clinical pathways dedicated to various aspects of care of the head and neck cancer patient.

110 Principles of Radiation Oncology

Umamaheswar Duvvuri *Gregory J. Kubicek*

Radiation oncology plays an important role in the treatment of head and neck cancers, both in the adjuvant and the definitive setting. Radiation is an important modality and has a large influence in terms of both survival and toxicity for patients. The field of radiation oncology is rapidly evolving, and head and neck oncologists should be aware of some of the important and changing features of this field to ensure that the patients they refer are treated appropriately. The goals of this chapter are to review the fundamental basis of radiation oncology (radiobiology), to describe some of the everyday aspects of radiation therapy delivery and toxicity, and finally to describe some of the new innovations in the field of radiation oncology.

RADIOBIOLOGY

Radiobiology describes the effects of ionizing radiation on the cellular level. Ionizing radiation induces cell death via DNA damage. DNA damage occurs when radiation interacts directly with the DNA strand or, more commonly, when the radiation interacts with a water molecule with secondary DNA damage. When ionizing radiation hits a water molecule, it forms free radicals; these free radicals are very unstable and, if formed in the vicinity of the DNA strand, are able to inflict damage.

DNA damage does not always lead to cell death; the cell has the capability of repairing radiation-induced damage to DNA. The rate and capability for repair are different for different types of cells. In general, more rapidly growing cells are more susceptible to damage from radiation (the process of cell division makes the DNA more susceptible to damage and also DNA damage is declared during DNA division). This is why the mucosa of the oral cavity (which is always dividing and being replaced) is very sensitive to the effects of radiation. In general, normal tissues have greater capacity for DNA repair than cancer tissues; one of the rationales for fractionation of radiation is to allow repair of normal tissues during fractions.

The more radiation damage that is inflicted upon a population of cells, the more cell death; the initial radiation dose causes damage to the cell population but does not necessarily cause cell death. As the radiation damage accumulates, cell death starts to occur. A simplistic way to view this is to imagine that both strands of the DNA must be damaged before the cell is irreversibly killed; the initial dose of radiation is most likely to damage a number of single strands and occasionally both strands in a single cell. As radiation dose continues, it becomes more likely that double-strand damage occurs in more cells and thus causes cell death. During the initial (single strand) DNA damage, there is potential for the cell to repair the single-strand break and undo the radiation damage. The differential ability for DNA repair has led to the terms "radiosensitive" and "radioresistant." Although the exact terms are very subjective, the basic principle is that some types of cells and tumors have very little repair ability and die rapidly from even low doses of radiation. On the other side are "radioresistant" tumors; such tumors have ability to repair DNA, which makes them less likely to undergo cell death from radiation damage. Some typical radiosensitive tumors include lymphomas, while radioresistant tumors include sarcomas and melanomas. In Figure 110.1 we have three cell populations; cell population A would be radiosensitive (note the lack of a shoulder region and the immediate linear decline in surviving cells; such a curve is seen in blood cells that lack any repair mechanisms). Population C has a wide shoulder representing a radioresistant cell population; the initial portion of the curve is where cell repair is occurring preventing death from the radiation.

In addition to the capacity for DNA repair, another component that affects radiation sensitivity (and the slope of the cell death curve) is oxygenation. Under hypoxic conditions, it is thought that the free radicals, which are

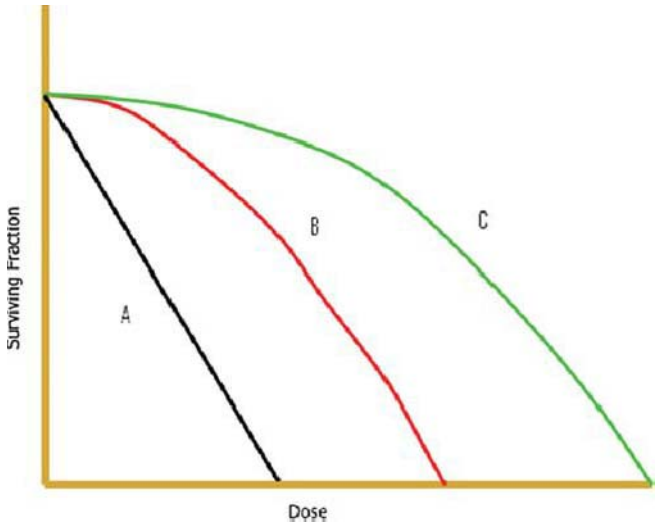

Figure 110.1 Three cell populations showing different levels of sensitivity to radiation. Cell population *A* would be radiosensitive (note the lack of a shoulder region and the immediate linear decline in surviving cells, such a curve is seen in blood cells that lack any repair mechanisms). Population *C* has a wide shoulder representing a radioresistant cell population; the initial portion of the curve is where cell repair is occurring preventing death from the radiation.

responsible for DNA damage, can be scavenged by the hypoxia-induced acidic environment and that oxygen itself may play a role in continuing the cascade of the free radical formation. Large tumors tend to grow faster than their blood supply, leading to hypoxic areas in the center of large tumors. This phenomenon is thought to contribute to the relatively poor control rates for large head and neck cancers treated with ionizing radiation.

DOSE AND DELIVERY

The most commonly used form of radiation is photons, but other particles can also be used, including electrons, protons, neutrons, and carbon ions. Electrons are widely available but not as commonly used as photons. Electrons have a short depth of penetration; this allows for good dose to the surface and minimal dose to deeper levels (e.g., 6 MV electrons will deposit 90% of their energy 2 cm into tissue). Because of the dose distribution, electrons are a very good treatment option for the treatment of skin cancers. Protons and carbon ions are other forms of radiation and are less frequently used. Protons, neutrons, and carbon ions (referred to as heavy particle radiation) are not produced by normal radiation oncology linear accelerators and require special (and very expensive) accelerators to produce this type of radiation (see below for a more detailed description of proton radiation oncology).

It should be noted that all types of radiation work via the same basic mechanisms although some of the logistics of delivery are different. For photon radiation (usually just described as radiation), the radiation is produced by a

Figure 110.2 Linear accelerator.

linear accelerator (Fig. 110.2). The patient lies on the treatment table, and the linear accelerator rotates around the patient to deliver the radiation. In order to ensure that the patient is not moving while the radiation is being delivered, an immobilization device is used; for HNC this typically consists of the thermoplastic head mask (Fig. 110.3).

Radiation is described in terms of dose; the common convention for dose is the gray (Gy). The definition of a Gy is the amount of energy dose absorbed per unit mass (1 Gy = 1 J/kg). Less often used is rads, 1 rad is equal to 0.01 Gy. The typical total dose for treatment of HNC is 60 to 66 Gy for adjuvant radiation and 70 to 74 Gy for definitive radiation. By comparison, doses for lymphoma would be 30 to 40 Gy, and the dose for a computed tomography (CT) scan is 0.1 to 0.2 Gy.

The total dose of radiation is divided into smaller doses called fractions. The dose for a fraction of radiation is usually between 1.8 and 2.0 Gy, although there can be a wide range (e.g., the dose for radiosurgery in the treatment of

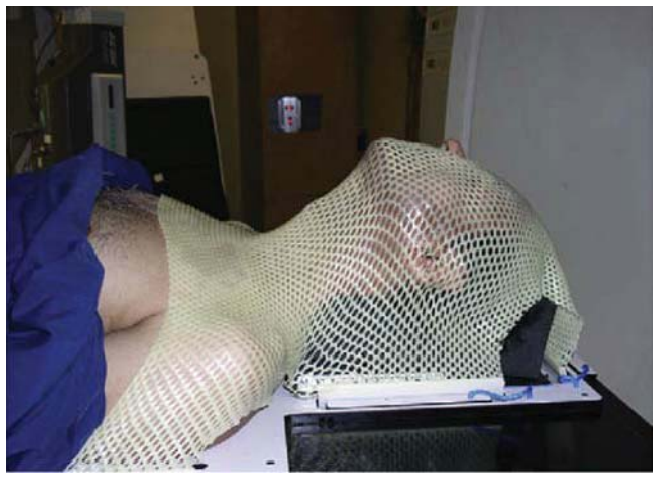

Figure 110.3 Thermoplastic head mask used for immobilization.

trigeminal neuralgia can be as high as 80 Gy in a single fraction). The purpose of delivering the total dose of radiation as a number of smaller fractions is to take advantage of normal tissue repair of DNA damage. For the most part, normal tissues have a much greater ability for DNA repair than do cancer cells. Thus, if damage is incurred to both normal tissues and cancer cells, the normal tissues will repair themselves while the cancer cells will die (this is not completely accurate as there is still a lot of normal tissue damage as discussed later).

The interplay between dose and fraction is sometimes referred to as "radiobiologically equivalent dose." Several mathematical models exist to convert from one dose and fractionation to another dose at a different fractionation (e.g., in terms of spinal cord tolerance, at 3 Gy per fraction, the maximum dose is 30 Gy, whereas at 2.0 Gy per fraction, the maximum dose is 45 Gy). The differential in repair between normal and cancer cells is magnified as radiation is delivered over a long period of time. This allows for improvement of the toxicity profile and minimizes toxicity to normal tissues.

FRACTIONATION AND TREATMENT TIME

The most common fractionation pattern is to deliver the radiation every day (Monday through Friday) and is referred to as "conventional" or standard fractionation. Hypofractionation is delivering less than one fraction per day (typically done in radiosurgery where the fraction is given every other day). Hyperfractionation is delivering more than one fraction per day. While there is repair of normal tissue DNA between radiation fractions, there is also (hopefully to a lesser extent) repair of cancer DNA and potential growth of the cancer itself. In order to decrease this risk, there have been several studies that have investigated the potential advantages of hyperfractionation.

The most well-known study is RTOG 90-03 (1). In this study, patients with stage III and IV HNC where randomized to conventional radiation (standard arm), hyperfractionation with twice daily treatments, hyperfractionation with twice daily treatments with a planned 2-week break during the radiation, and accelerated hyperfractionation or concomitant boost (which consists of daily radiation until the final 12 treatments at which time radiation is given twice daily). The results of this study showed an improvement in local control in the hyperfractionation and accelerated hyperfractionation arms (survival had a trend toward improvement, but did not reach statistical significance). Several other studies have shown similar results including DHANCA where patients were randomized to five versus six treatments per week, and local control was found to be improved with the six fraction regimen (5 year local control 70% vs. 60%) (2).

It should be noted that while tumor control appears to be improved with a reduction in treatment time, there is also an increase in acute toxicity (the normal tissues now have less ability to repair). However, the studies have not found a significant increase in late toxicity.

While hyperfractionation appears to be one method to improve outcome, chemotherapy is another. Chemotherapy has been shown to improve outcome versus radiation alone in both the definitive and the adjuvant setting. Brizel et al. (3) found that concomitant chemotherapy delivered with hyperfractionation provided better locoregional control than hyperfractionated radiation alone (70% vs. 44%). Brizel et al. (4) performed a mathematical analysis of the data obtained from RTOG 90-03 to determine what the impact of chemotherapy was on the radiobiologically equivalent dose. They determined that a 1% increase in radiobiologically equivalent dose lead to a 1.1% increase in locoregional control. Similarly, the addition of chemotherapy effectively increased the total radiobiologically equivalent dose by about 10 Gy. The authors concluded that this increase in effective radiation dose could not be safely achieved by simply increasing the amount of radiation delivered to the patient.

RTOG 0129 (5) set out to examine if chemotherapy (cisplatin 100 mg/m^2 every 3 weeks) plus hyperfractionated radiation (concomitant boost) was better than the same chemotherapy plus standard (once daily) radiation. The study did not find a difference between the two arms, and given the increase in acute toxicity and logistical difficulties with hyperfractionation, most institutions use once daily treatments for locally advanced HNC treated with chemoradiotherapy.

In summary, based on the known benefits of chemotherapy and the negative RTOG 0129 study, hyperfractionation is typically only used for patients who cannot get chemotherapy and have to be treated with radiation alone.

The overriding principle for the benefits of hyperfractionation is that a reduction in overall treatment time corresponds to an improvement in tumor control. The opposite is also true; when the overall treatment time is extended, tumor control decreases (6–9). RTOG (6) looked at the importance of treatment time in HNC radiation and found that local failure increased when the total treatment time (from surgery to completion of radiation) exceeded 11 weeks. This is why treatment breaks should be avoided unless absolutely necessary.

RADIATION ONCOLOGY PLANNING

The first step in radiation oncology planning is consultation with a radiation oncologist to examine the patient and discuss the risks and benefits of therapy. After this, a radiation planning CT scan is performed. This is similar to a diagnostic CT scan except that the CT scan is performed with the patient in the same position as they will be when receiving the daily radiation treatments. In order to reduce setup error between and during treatments, patients will have a plastic mask made that conforms to their facial

anatomy (Fig. 110.3). Because of the special positioning (including the mask), a diagnostic CT scan cannot be used as a substitute for a radiation planning scan (although the information from a diagnostic CT scan can certainly be used to help in planning). Sometimes a positron emission tomography (PET) scan can be done at the same time as radiation planning (see section on PET scans).

After the radiation planning scan has been performed, the radiation oncologist will begin planning the radiation beams. This process has evolved over time (see below) but in all cases involves distinguishing normal structures from areas that are targeted for radiation. Several terms are commonly used to describe this process (Table 110.1). Gross tumor volume (GTV) represents the areas of actual tumor; this can be defined either radiographically (CT, PET, MRI) or clinically. In patients who have had surgery, there should not be a GTV since there is no longer any gross disease. Clinical tumor volume (CTV) defines areas that are at risk for harboring microscopic disease (such as lymph node basins); there can be discrepancy between different physicians in deciding the CTV volumes (e.g., does the contralateral neck need to be covered in a patient with tonsil cancer). Planning tumor volume (PTV) is a small expansion on the CTV or GTV to account for errors in daily setup. A typical PTV expansion is 0.3 to 1.0 cm. At our institution, we use daily imaging verification to reduce random setup error and are able to use a smaller PTV margin (3 to 5 mm). Organ at risk (OAR) is defined as normal tissue that is not involved with cancer and needs to be protected from radiation (examples include the spinal cord, parotid glands, mandible, etc.). Depending on the degree of risk, different areas will receive different doses of radiation. For example, the gross disease (GTV) will typically receive 70 to 74 Gy; areas of low risk (uninvolved lymph node basins) are treated to 50 to 54 Gy, while intermediate risk regions receive 60 to 66 Gy (Table 110.2).

TABLE 110.1 ORADIATION TERMS

Term	Definition
Hyperfractionation	Delivery of more than one fraction of radiation a day
Hypofractionation	Delivery of less than one fraction of radiation a day
Gross tumor volume	Gross disease as defined by radiology and physical exam
Clinical tumor volume	Areas at high risk for microscopic tumor involvement
Planning tumor volume	Treatment field, which includes margin for setup error and other uncertainty
Organ at risk	Normal structure (such as spinal cord) that must be protected to some extent from radiation

TABLE 110.2 TARGET DOSES

Target	Dose Range	Description
High risk	70–74	Gross disease plus small margin
Intermediate risk	60–66	In adjuvant setting, tumor bed and resected but involved lymph node basins. In adjuvant or definitive setting, lymph node basins at high risk for failure
Low risk	50–54	In adjuvant and definitive setting, uninvolved lymph node basins at low risk for failure

After the radiation oncologist has distinguished the different target volumes, there is some time required for the radiation planning (mapping out the number and direction of the radiation beams) done by a dosimetrist and physicist. This can take anywhere between 10 minutes and 3 days depending on the complexity of the plan. When the radiation plan has been completed, the radiation oncologist will evaluate the plan to make sure that the target volumes (GTV, CTV, PTV, etc.) are adequately covered by radiation dose while simultaneously sparing the normal structures (OARs). There are general guidelines for how much radiation dose a normal structure can tolerate (Table 110.3). In order to evaluate a radiation plan and determine if it is safe for normal structures (OARs), a dose volume histogram (DVH) is constructed. A DVH plots percent volume of a structure versus the radiation dose. Oftentimes in order to cover the tumor, it is necessary to deliver radiation doses beyond tolerance to some normal tissue; this can lead to some of the long-term toxicities of radiation (discussed later). In the DVH shown in Figure 110.4 (patient with left base of tongue cancer), we see that the right parotid is being spared, because of the location of the tumor; the left parotid, being too close to the tumor, will receive dose that will likely make the

TABLE 110.3 NORMAL STRUCTURE DOSE TOLERANCE

Structure	Dose Limit	Toxicity
Spinal cord	45 Gy (point dose)	Paralysis
Mandible	70 Gy	Osteoradionecrosis
Parotids	25 Gy (50% of gland)	Xerostomia
Pharyngeal constrictor muscles	55 Gy (50%)	Swallowing difficulties
Optic chiasm	54 Gy	Blindness
Lens	10 Gy	Cataracts

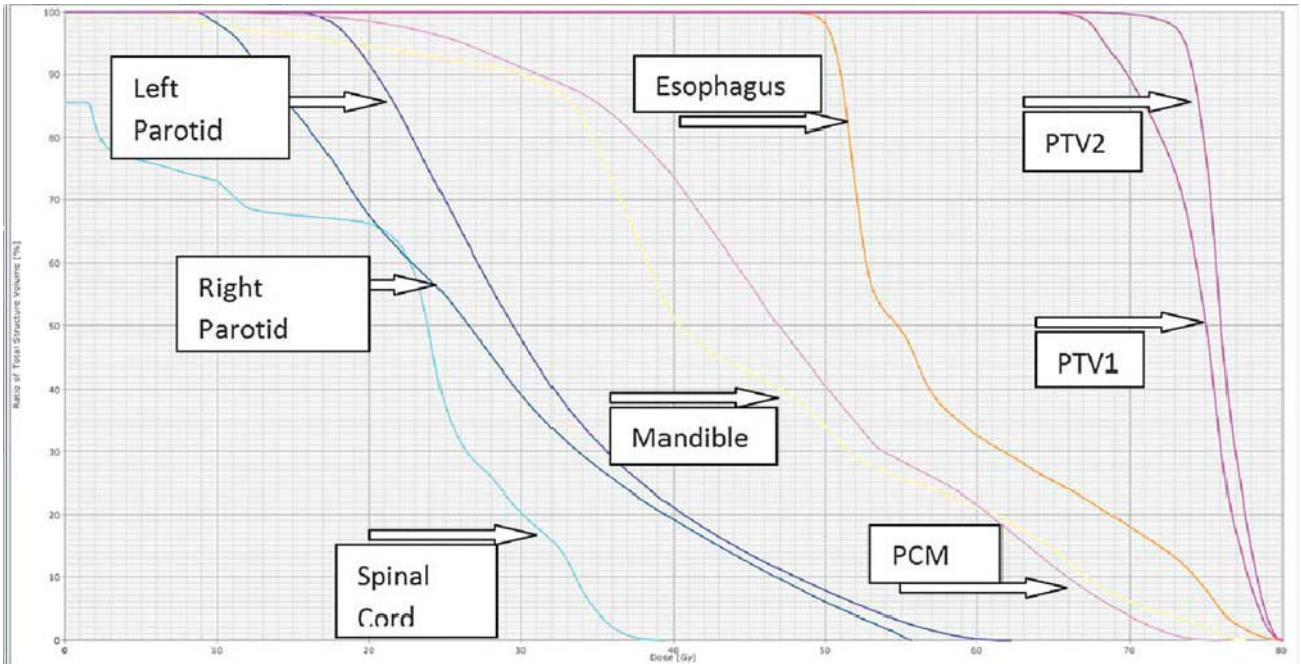

Figure 110.4 Dose volume histogram. This plots the percent volume of a structure (*y*-axis) versus the radiation dose (*x*-axis). In this DVH we see that the right parotid is receiving less radiation than the left parotid.

parotid nonfunctional (as seen in Table 110.3, the dose limit for parotid glands is 25 Gy at 50% of the organ; in Figure 110.4 we see that right parotid is getting about 25 Gy to 50% of the organ whereas the left parotid is getting 25 Gy to greater than 70% of the organ).

A typical time from consult to the start of radiation is a week to 2 weeks; this can be longer if a dental extraction is required or if patients are not compliant with appointments. As discussed above, overall treatment time is a very important metric in HNC outcomes; this is why it is valuable to have the consultation with the radiation oncologist within the first week of surgery for patients who may need adjuvant radiation. This allows everything to be set up and ready to start without undue delay.

The radiation therapy is typically delivered once daily (see above for discussion on fractionation). A typical treatment time is 5 to 10 minutes, and the entire session will be completed in about half an hour (time from in the door to out the door). The radiation oncologist will see the patient at a minimum of once per week; oftentimes there will also be weekly appointments with nursing and dietary staff as well. A typical course of radiation is 7 weeks for a definitive case and 6 weeks for adjuvant.

More details on the indications for adjuvant radiation are available in individual chapters, but in general, radiation is recommended in the adjuvant setting for positive lymph nodes, large tumor size (T3 or T4), perineural invasion (PNI), and positive surgical margins. Chemotherapy is added to radiation in the setting of positive margins and extracapsular extension (ECE) of a lymph node (see Table 110.4).

RADIATION DELIVERY

As computer technology continues to improve so does the delivery of radiation. Radiation delivery has evolved over time and continues to improve. The most basic system for radiation delivery is 2D (two dimensional) and involves planning the radiation from plain x-ray films. For 2D radiation delivery, a radiation planning CT scan would not be used. In 3D (three-dimensional) radiation delivery, an extra dimension is added to 2D planning; this incorporates imaging data from the CT scan used for radiation planning. 3D planning has the advantage of being able to accurately calculate doses to normal structures. The next step in radiation oncology evolution is intensity-modulated radiation therapy (IMRT). IMRT improves upon 3D radiation planning

TABLE 110.4 INDICATIONS FOR RADIATION AND CHEMORADIATION

Recommendations for adjuvant radiation

Extracapsular extension
+ margins

by using multiple radiation beams (referred to as beamlets) from different directions, all of which can potentially have different intensities of radiation. IMRT allows the radiation dose to "bend" around normal structures. In Figure 110.5 is a patient who had both a 3D and an IMRT plan. In the 3D plan, there is a beam from the right and a second beam from the left; everything in the radiation field gets a fairly high dose of radiation. In the IMRT plan, the dose is able to be shaped and bent; this allows less the radiation dose to the parotid glands to be drastically reduced. The consequence of this is an increase in the low-dose region with the IMRT plan as compared to the 3D plan (bottom row of Fig. 110.5). IMRT involves a large amount of planning. While a 3D plan can be generated within an hour, an IMRT plan can take up to a week to plan. The main catalyst for the evolution from 3D to IMRT is the multileaf collimator (MLC), an attachment to the head of the linear accelerator that allows the radiation beams to be modulated. MLCs are relatively cheap and easy to implement. As a result, IMRT is available essentially everywhere that radiation is available (at least in the United States).

There are obvious advantages to IMRT; with reduction in dose to normal structures, there is a reduction in the likelihood of late radiation-induced toxicity. As shown in Figure 110.5, the radiation dose delivered to the parotid glands is reduced; this will hopefully result in a reduction of xerostomia. However, IMRT also has some significant (and perhaps underappreciated) disadvantages. First of all, IMRT takes significantly longer to plan and is much more expensive than 3D. For patients with rapidly growing or bleeding tumors, it often makes sense to start with a 3D plan, which can begin rapidly and then convert to an IMRT plan to complete the radiation. Another disadvantage is the distribution of low-dose radiation. While Figure 110.5 shows a clear reduction in the areas of high radiation dose, we also see an increase in the low dose

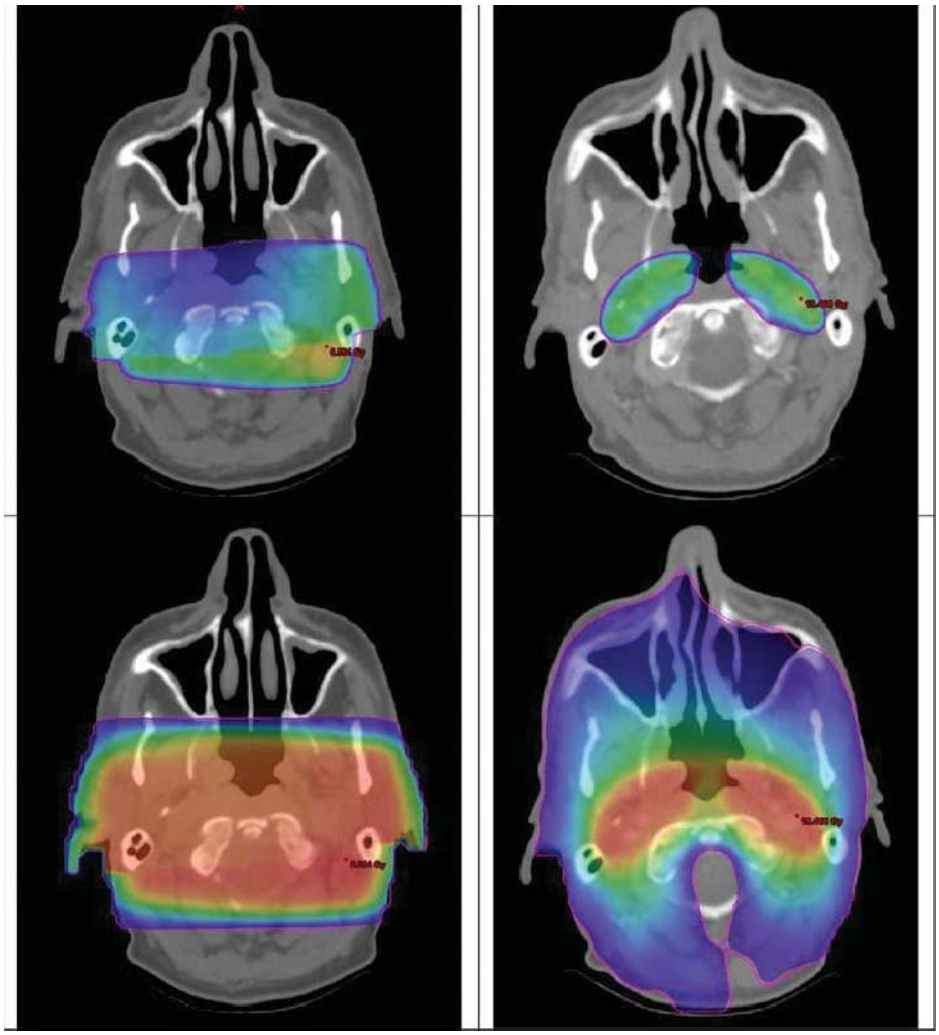

Figure 110.5 IMRT versus 3D plan The left hand column is a 3D plan (two opposed lateral beams). The right hand is the same patient with an IMRT plan. Notice that the top row is the high-dose region and it is much more conformal in the IMRT plan. The bottom row is the low-dose region and is much larger in the IMRT plan.

of radiation. In IMRT there is a significantly higher volume of tissues getting a low dose of radiation. The volume of low-dose radiation has some repercussions. There are toxicities that are seen in IMRT that were not seen in 3D planning; one of these side effects is nausea from radiation beams going through the brainstem. If the radiation oncologist does not mark an area as an OAR, the computer will not see it as being at risk, and this area will receive higher doses of radiation in the computer's attempt to spare areas that were marked as OARs. Another concern of the low-dose volume in IMRT is that this might confer a higher chance of a radiation-induced cancer. This risk is mainly theoretical, although it should be noted that IMRT has only been used in high volume recently and the average time to develop a radiation-induced cancer is 10 to 20 years. Figure 110.6 represents a typical IMRT plan for a base of tongue cancer.

Most of the date describing IMRT outcomes is retrospective, but there are some limited phase III data. The published level I evidence consists of two randomized prospective trials treating nasopharyngeal cancer (NPC). Similar in design, each trial randomized locally advanced NPC patients between conventional radiation and IMRT along with concurrent chemotherapy. The results showed that salivary gland (parotid) function was significantly and dramatically improved in the IMRT arms in both studies. Kam et al. (10) found a reduction in observer-rated xerostomia from 82.1% with conventional radiotherapy to 39.3% with IMRT and also measured improvements in measured parotid flow rates. Similarly, Pow et al. (11) found an improvement in stimulated saliva flow with IMRT and also found that patients treated with IMRT had an improvement in patient-reported quality of life scores. The primary end point for both studies was parotid function; neither trial was powered or intended to examine the role of IMRT in disease control or overall survival. Retrospective data in both nasopharyngeal (12–15) and nonnasopharyngeal HNC (16–21) compare very favorably to historical norms. It should be noted that the essentially all of the phase III HNC data acquired thus far

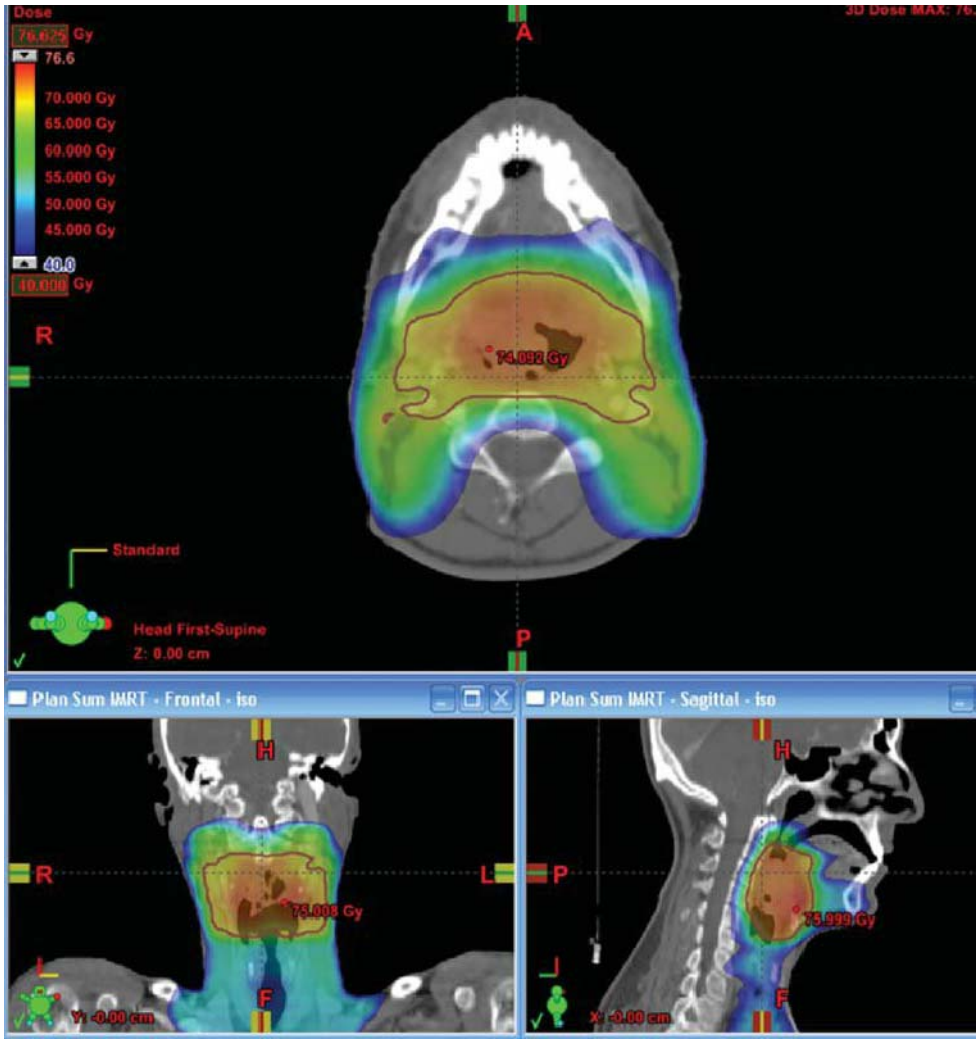

Figure 110.6 Base of tongue IMRT plan.

are from 2D or 3D radiation planning but that the general acceptance of IMRT technology has led to its inclusion in RTOG trials; RTOG 0234 and 0522 are the first major US cooperative group studies incorporating IMRT into radiotherapy planning.

RADIATION TOXICITY

Radiation has multiple side effects and toxicities, some of which occur during treatment (acute) and others that occur months to years after therapy (late). If chemotherapy is added to the radiation, there is a significant increase in the rate of acute toxicities, although late toxicities appear to be similar. There is a significant amount of variation between patients and how the radiation is tolerated, but some general remarks can be made. During radiation, the first 2 weeks typically proceed without much difficulty unless the first round of chemotherapy causes toxicity such as nausea and vomiting or dehydration. After the second week, the acute radiation steadily escalates; toxicities include pain (sore mouth and sore throat) from mucositis, taste changes, loss of facial hair (in treatment field) and skin irritation, thick mucus, and dry mouth. These toxicities will typically escalate until they plateau around week 5 to 6 and remain constant through the remainder of the therapy. The majority of patients state that pain is the most difficult of the side effects and often requires narcotic medications.

After the completion of radiation, the side effects slowly subside. The first-week postradiation remains a difficult time with modest improvement in pain and other side effects; around the 2-week mark, patients begin to feel some noticeable improvement in toxicity, and this continues for the next several weeks. Skin breakdown typically heals in about 2 weeks, thick mucus resolves around week 3 to 4, and the pain improves but is often still present until 8 to 12 weeks after radiation. Fatigue and ability to return to work are dependent on a number of factors, but in general most patients are able to return to work around 8 weeks after radiation.

In addition to the acute toxicities, there are a number of late radiation associated side effects. One of the most common side effects is xerostomia (dry mouth) from damage to the salivary glands; this sometimes responds to pilocarpine (Salagen), but oftentimes patient will need to carry a bottle of water around and may have difficulty swallowing dry meats and breads. Taste changes typically resolve by 3 months after radiation although patients may have some food items that never regain taste and develop intolerance to spicy foods (which taste too spicy). Some late side effects that develop months and even years after the radiation include hypothyroidism, neck fibrosis, carotid artery stenosis, osteoradionecrosis (the incidence of which can be increased by dental work after radiation), and dysphagia with concomitant aspiration. As seen in Table 110.3, there are general dose guidelines for how much radiation certain tissues can tolerate. Radiation tolerance doses are put together by a combination of retrospective studies and animal studies and while this data are tentative for obvious reasons cannot be easily expanded upon.

In general, toxicity rates are poorly documented and recorded; hence, a wide range of toxicity rates are reported in the literature. Machtay reported on the toxicity with chemotherapy and non-IMRT radiation in several RTOG studies; 43% of patients had severe late toxicity, mostly consisting of pharyngeal and laryngeal dysfunction (22). Eisbruch and coworkers recently published their prospective data using IMRT to treat oropharyngeal tumors (23). Swallowing function was assessed by two methods, videofluoroscopy and subjective symptom score assessment. Videofluoroscopy demonstrated that on average, mild pretreatment dysphagia progressed to moderate dysphagia after chemoradiotherapy. While many patients experienced recovery of swallowing function, some patients never had full recovery.

INNOVATIONS IN RADIATION PLANNING

In addition to IMRT, there have been several other innovations in radiation therapy, which have promise to improve outcomes in HNC. Some of the recent innovations in HNC radiation oncology have included incorporation of imaging such as PET scans, proton therapy, and radiosurgery.

One major innovation to the treatment of HNC has been PET scans. While the imaging aspect of PET scans is described elsewhere, there is also an important role for PET scans in radiation treatment planning. Geets et al. (24) reported that the use of pretreatment FDG–PET in combination with pretreatment CT or MRI improves target definition in oropharyngeal cancer and results in more normal tissue sparing. The same group also examined the role of PET contouring in larynx cancer, by comparing standard imaging techniques and PET findings with the pathologic specimens (25). They reported significantly smaller target volumes when targets were drawn on FDG-PET as opposed to CT scan. PET-based tumor volumes also showed better correlation with pathologic findings compared with CT, both for the primary tumor and the locoregional lymph nodes (26). Long-term clinical data are emerging; favorable 3-year overall state and disease-free survival rates have been shown in IMRT patients who all had PET-based contouring (27).

Proton therapy represents another possible evolution in radiation oncology. Protons are fundamentally different than photon radiation and are attractive because of its theoretical dose distribution in normal tissue. Photons lose energy slowly as they travel through tissue; energy is deposited in the tumor but is also in the normal tissue both in front and in back of the tumor. Protons on the other hand

have very low energy loss until they reach a certain depth at which point all of the proton's energy is released at once. Tissue distal to this point has almost no radiation dose. This sudden peak in dose is known as the "Bragg peak" and can allow the proton beam to be targeted on the tumor and has very little dose to normal structures on the other side (very little exit dose). Theoretic plans have been created testing conventional IMRT versus intensity-modulated proton therapy, showing a significant advantage in tumor coverage and normal tissue sparing with the intensity-modulated proton therapy plans (28,29). It should be emphasized that these were theoretic plans and not actual treatments. Currently, most proton treatments are given with conventional (3D; anteroposterior–posteroanterior, lateral) proton beams.

Protons are currently only available in a limited number of centers, and experience and published results are very limited, especially in the treatment of head and neck cancer. The majority of reported results of proton therapy in head and neck cancer involve rare and difficult to treat tumors, such as chordomas and other skull-base tumors (30). A small series from Loma Linda looked at 29 oropharyngeal HNC patients treated with a proton boost (66% of the radiation was delivered via photons); the study showed good local control and toxicity (31) but larger and more heterogeneous series are certainly needed.

Another radiation oncology innovation is radiosurgery. Radiosurgery is similar to IMRT in the delivery of the photon radiation; the only difference between conventional radiation and radiosurgery is in patient immobilization and image verification techniques. Radiosurgery requires very stringent immobilization and alignment techniques; this allows for high doses of radiation to be delivered in a highly conformal manner. There are multiple platforms that can be used for delivery of radiosurgery; some of the common devices include CyberKnife, Gamma Knife, Trilogy, and TrueBeam. Although some of the details differ, the basic performance for all of the machines capable of radiosurgery is similar. Because of the precise nature of radiosurgery, much higher doses per fraction can be used, which allows for fewer overall fractions. For example, in the treatment of early-stage lung cancer, 3 fractions of 20 Gy per fraction is a common radiosurgery schedule as compared to 35 fractions of 2 Gy per fraction for nonradiosurgery HNC. Most of the radiosurgery data in radiation oncology are in the treatment of central nervous system (CNS) disease (such as brain metastatic lesions) and in early-stage lung cancer. However, there are growing data in the use of radiosurgery in the treatment of head and neck cancer (32). Radiosurgery in the HNC setting is most often in recurrent HNC; the current approach at our institution is to use radiosurgery (40 to 44 Gy in five fractions) for patients with recurrent HNC that is not amenable to surgical salvage. This is a growing field and will certainly continue to evolve.

HIGHLIGHTS

- Conventional fractionated irradiation therapy is undertaken to allow normal tissue repair of DNA damage between fractions while cancer cells die.
- Hyperfractionation (more than one fraction per day) appears to improve outcome in patients treated with radiation alone. However, it is also associated with increased acute toxicity, and the benefit appears to be lost in patients treated with both radiation and chemotherapy.
- Common indications for radiation include T3–T4 tumors, positive lymph nodes, and positive or close margins, PNI.
- Tumor control decreases when total treatment time exceeds 11 weeks.
- Use of IMRT allows for the sparing of normal tissues such as parotids, mandible, and pharyngeal constrictor muscles.

111 Chemoradiation

Christine G. Gourin *Arlene A. Forastiere*

OVERVIEW

The addition of chemotherapy to radiation treatment, often referred to as chemoradiation, has been increasingly used since initial clinical trials in the 1990s showed that chemoradiation achieved comparable survival outcomes to surgery with postoperative radiation for patients with stage III advanced laryngeal cancer. Such patients formerly were only offered surgery with postoperative radiation; radiation alone was less effective than when combined with surgery to treat advanced head and neck cancer. The findings of these studies, and numerous phase II and III studies performed since then, have ushered in a new era for patients with head and neck cancer, many of whom can be treated with intent to cure using chemoradiation.

Chemotherapy refers to drugs that are cytotoxic—that is, they cause cell death. There are different types of chemotherapy drugs, all with different mechanisms of action that result in cell death. Chemotherapy may enhance the effects of radiation therapy, but chemotherapy by itself is not a curative modality. Though these drugs can result in impressive initial tumor shrinkage, the drugs may not reach cells in the center of the tumor. In addition, tumor cells vary in their response to chemotherapy—the less "normal" a cancer cell is, the less likely it is that the cells use normal cell growth patterns to divide and grow, and therefore, chemotherapy may not be effective. Head and neck cancer cells can also demonstrate resistance, both innate and acquired, to chemotherapy.

Chemotherapy has been shown to increase the effect of radiation on tumor cells when used with radiation therapy. Chemotherapy acts as a radiosensitizer, making cancer cells more sensitive to the effects of radiation and when used with radiation, utilizes the radiosensitizing effects of chemotherapy as well as the systemic cytotoxic properties of chemotherapy. It is indicated for patients with advanced stage head and neck cancers, who are at high risk for distant metastases. It is not indicated for patients with previously untreated stage I, II, or low-volume stage III disease (a small primary tumor with or without a single ipsilateral node measuring 3 cm or less in diameter). Initial studies of chemoradiation employed induction chemotherapy, where three courses of chemotherapy were administered several weeks apart: patients with a response to induction chemotherapy subsequently received definitive radiotherapy, while patients who didn't respond were treated with surgery and postoperative radiation. Induction chemotherapy regimens are still in use, but have been largely supplanted by concurrent or concomitant chemoradiation, where chemotherapy is given concurrently with radiation therapy, either as weekly treatments or for a total of three treatments during the 6- to 8-week course of radiation therapy, based on studies showing improved tumor response rates with this approach. The use of chemotherapy alone is reserved for palliation of patients with metastatic disease.

The radiosensitizing effect of chemotherapy on radiation means that the side effects of chemoradiation are greater than for radiation alone. All of the side effects associated with radiation occur; however, the mucositis of the tissues lining the mouth and throat are more severe with the addition of chemotherapy to radiation, and swallowing difficulties both during and after treatment may be more severe in intensity and duration.

CHEMOTHERAPY DRUGS USED TO TREAT HEAD AND NECK CANCER

The most commonly used cytotoxic drugs to treat recurrent or metastatic squamous cell cancers of the head and neck are cisplatin, carboplatin, docetaxel, paclitaxel, 5-fluorouracil (5-FU), and methotrexate. Activity also has been demonstrated for more recent biologic agents that target the epidermal growth factor receptor (EGFR) such as cetuximab.

Platinum-Based Agents

Platinum analogs represent a class of drugs that are platinum complexes, with biologic and chemical similarities to alkylating agents. The two platinum analogs used for head and neck cancer are cisplatin (*cis*-diamminedichloroplatinum II) and carboplatin (*cis*-diammine [1,1 cyclobutanedicarboxylate] platinum II). The major cytotoxic action of cisplatin results from the formation of covalent adducts with DNA that are capable of blocking DNA replication and transcription (1). Cytotoxicity of non-target tissues is common. Cisplatin is associated with renal toxicity, gastrointestinal toxicity largely resulting from mucositis with nausea and vomiting, myelosuppression, ototoxicity and neurotoxicity including peripheral neuropathy, visual impairment, and rarely, seizures. The effects of neurotoxicity and nephrotoxicity are cumulative with repeated administration of the drug; while nephrotoxicity may be prevented by aggressive hydration and diuresis, there are no methods for preventing or treating neurotoxicity or ototoxicity. Cisplatin-induced hearing loss results in loss of outer hair cells in the cochlea through generation of reactive-oxygen species, which deplete the cochlear antioxidant system (2). Hearing loss is usually bilateral and irreversible, and may occur in more than 75% of patients treated with cisplatin.

Carboplatin, in contrast, is associated with lower rates of nephrotoxicity and neurotoxicity, with less nausea and emesis reported; however, it is somewhat less active than cisplatin. Resistance to platinum-based agents may occur and can be either intrinsic or acquired.

5-Fluorouracil

5-FU is a fluorinated pyrimidine that was synthesized to specifically take advantage of the observation that carcinoma cells utilize uracil to a greater degree than normal cells. The cytotoxic effects of 5-FU result from its conversion via multiple alternate biochemical pathways to several different active cytotoxic forms that inhibit DNA synthesis by binding with thymidylate synthase with subsequent depletion of precursor proteins for DNA synthesis, and through incorporation into nuclear and cytoplasmic RNA and DNA (3,4). 5-FU is specific for cells in the S phase of the cell cycle. Resistance has been correlated with reduced levels of enzymes required for 5-FU activation and mutations in thymidylate synthase that decrease binding affinity. Side effects are primarily related to bone marrow suppression and gastrointestinal mucositis, but dermatologic manifestations including hyperpigmentation, dermatitis, and alopecia have been described. Ocular toxicity can occur resulting from an acute inflammatory response causing conjunctivitis, blepharitis, and epiphora.

5-FU has synergistic effects with other chemotherapeutic agents and with radiotherapy and is used in combination with other drugs to exploit this effect.

Taxanes

Taxanes represent a class of drugs that specifically target mitosis by binding to microtubules, stabilizing them and disrupting microtubule dynamics thus inhibiting spindle function. Docetaxel and paclitaxel are the most commonly used taxanes in head and neck cancer (5). Taxanes induce mitotic arrest, which is typically followed by the induction of apoptosis (6). Because microtubules are required for protein transport as well as cell division, the cytotoxicity of taxanes may also result from microtubule dysfunction causing dysregulation of motility and transport.

The toxicity of taxanes is primarily myelosuppression with neutropenia, which may be dose limiting, and hair loss. Docetaxel is associated with fluid retention and paclitaxel has been associated with peripheral neuropathy and arthralgia (6). Neurotoxicity is more common when taxanes are given in combination with platinum-based agents.

Methotrexate

Methotrexate is an antifolate antimetabolite that inhibits dihydrofolate reductase, a key enzyme in intracellular folate metabolism. This effect is thought to be the main mechanism by which methotrexate produces cytotoxicity (7). Inhibition of dihydrofolate reductase prevents normal thymidylate and purine nucleotide synthesis, which results in single- and double-stranded DNA breaks, and leads to the accumulation of dihydrofolate polyglutamates, which are potent inhibitors of folate-dependent enzymes. Additional cytotoxicity may result from transformation of methotrexate to polyglutamate forms, which are preferentially retained within cells. Methotrexate is most active against rapidly proliferating cells and active during the S phase of the cell cycle.

The primary toxicities of methotrexate are myelosuppression and gastrointestinal mucositis, although nephrotoxicity, hepatotoxicity, and neurotoxicity can also occur. Gastrointestinal symptoms and myelosuppression occur in a dose-dependent fashion, although myelosuppression can occur with even small doses in patients with compromised renal function. Acute and chronic hepatic dysfunction has been associated with methotrexate use and is dose and schedule dependent. Rarely, cirrhosis of the liver has been reported. High doses of methotrexate have been associated with encephalopathy and dementia. Polymorphisms in folate metabolizing enzymes and blood–brain barrier transporter genes may increase susceptibility to central nervous system toxicity (8).

Biologic Modifiers

Various biologic agents that target the EGFR pathway are under study in combination with chemotherapy, as single agents, and as multiple targeted agents. EGFR is highly

expressed in virtually all squamous cell cancers of the head and neck, and expression is inversely associated with prognosis. EGFR is a transmembrane receptor belonging to a family of ErbB receptors, which contain an extracellular ligand binding region and a cytoplasmic tyrosine kinase-containing domain. Ligand binding signals receptor autophosphorylation through intracellular tyrosine kinase activity, which triggers a series of intracellular pathways leading to cell proliferation, inhibition of apoptosis, activation of invasion and metastasis, and neovascularization (9). Monoclonal antibodies to the EGFR such as cetuximab and panitumumab and small molecule tyrosine kinase inhibitors such as gefitinib and erlotinib ultimately target tyrosine kinase activity with downregulation of pathways including the PI3K-Akt, MAPK, Src, and STAT pathways and block the proliferation of tumor cells. A major response is seen in approximately 10% of patients who are platinum refractory.

Cetuximab is the only biologic agent in its class approved for use in head and neck cancer, although clinical trials are in progress to test the efficacy of newer agents. Compared to conventional chemotherapy agents, cetuximab is associated with less systemic toxicity, but is associated with the development of an acneiform rash in 84% of patients during treatment, which resolves after discontinuation of drug (10).

ADMINISTRATION SCHEDULES

There are different ways to administer chemotherapy when used in conjunction with radiation therapy. Induction chemotherapy, sometimes referred to as neoadjuvant chemotherapy, refers to the use of chemotherapy before definitive treatment. Concurrent or concomitant chemotherapy is given simultaneously with radiotherapy.

Sequential therapy describes the use of induction chemotherapy followed by concurrent chemoradiation. Adjuvant chemotherapy refers to the use of chemotherapy after surgery. Treatment recommendations for chemotherapy administration vary by primary tumor site, extent of disease, and evidence-based data used to support the use of a particular chemotherapeutic approach generated by clinical trials.

CLINICAL TRIALS

Chemotherapeutic agents used in the treatment of head and neck cancer are initially offered in the setting of a clinical trial. Clinical trials test the efficacy and safety of new agents before they are introduced into clinical practice. Clinical trials are performed in phases, with each phase designed to answer a different research question.

Phase I Trials

Phase I trials are designed to test tolerance and safety in drugs that have already passed through phase 0 trials, which involve animal testing. These trials have a study endpoint of determining the maximal tolerated dose and toxicity usually through dose escalation; while the clinical intent of the eventual use of the drug is efficacy, phase I trials are largely safety trials and generally are limited to a small number of patients who may have a variety of tumor types. The maximal tolerated dose determined by phase I trials is then further studied in phase II trials.

Phase II Trials

Phase II trials are designed to determine the response of the tumor to treatment in order to provide an estimate of drug activity. The study endpoint is response of tumor to treatment, usually measured by a reduction in tumor size. Responses may be complete (no measurable disease) or partial (a 50% or greater reduction in disease), and must last a minimum of 28 days to be considered clinically significant. Disease that does not demonstrate a response is graded as stable (no change in size) or progressive (an increase in tumor burden). If 20% or more of study participants demonstrate a response of any kind to treatment, the treatment is considered to be successful. A secondary endpoint is usually toxicity as well. A larger number of patients are required for a phase II trial than for a phase I trial. Such trials are used to determine if a drug warrants further testing in a phase III trial.

Phase III Trials

Phase III trials are designed to compare the response of the new treatment to a treatment that is already in clinical use. This type of study requires large numbers of patients to participate in order to detect meaningful differences in survival, and usually has strict inclusion criteria limited to a particular tumor site or stage. Patients are usually randomized to treatment arm, which is the gold standard for a phase III trial, and the study endpoint is usually survival, although toxicity and symptom palliation may be study endpoints depending on the clinical research question. Phase III trials represent level I evidence, which is the best evidence to support treatment approaches to head and neck cancer (11) (Table 111.1).

USE OF CHEMOTHERAPY IN HEAD AND NECK CANCER

Chemotherapy is used in the management of advanced head and neck cancers as initial treatment when administered with radiotherapy for organ preservation or for locally advanced, unresectable disease; in the postoperative setting concurrent with radiotherapy for high-risk disease; and for palliation of recurrent, inoperable disease.

CHEMORADIATION FOR ORGAN PRESERVATION

The first prospective randomized controlled clinical trial that integrated chemotherapy into the curative treatment of patients with advanced head and neck cancer was the Head and Neck Contracts Program, a multi-institutional collaboration of surgeons, medical oncologists, and radiation oncologists (12). This trial randomized 462 patients into a control group of surgery and postoperative radiotherapy, an experimental arm of one cycle of induction chemotherapy with cisplatin and bleomycin followed by surgery and postoperative radiotherapy or a second experimental arm of induction chemotherapy with cisplatin and bleomycin followed by surgery and postoperative radiotherapy, followed by six cycles of adjuvant cisplatin. Study results were reported in 1987 and demonstrated that the group that received adjuvant cisplatin after definitive therapy had a lower rate of distant metastases; however, the addition of chemotherapy in both experimental arms did not impact survival (13). However, some laryngectomy specimens in patients with an apparent complete response to induction chemotherapy were found to be histologically free of tumor after resection. These findings drove subsequent studies of the feasibility of larynx preservation with induction chemotherapy followed by radiotherapy, with surgery reserved for patients without a response to induction chemotherapy or for salvage of patients with persistent or recurrent disease following radiotherapy.

Larynx Cancer

The current era of chemoradiation was ushered in by the Veterans Affairs (VA) Laryngeal Cancer Study Group, who performed a landmark randomized controlled clinical trial to determine if induction chemotherapy followed by definitive radiation, with laryngectomy reserved for salvage, was a viable option to the gold standard of total laryngectomy with postoperative radiotherapy for patients with advanced stage laryngeal cancer (14). Patients with stage III or IV laryngeal cancer who would have required total laryngectomy for cure were randomized to receive either three cycles of induction chemotherapy with cisplatin and 5-FU followed by radiotherapy, or surgery and postoperative radiotherapy. Clinical tumor response was assessed after two cycles of chemotherapy, and patients with a response to induction received a third cycle followed by definitive radiation therapy. Patients without a tumor response or patients with progressive disease, including nodal disease, underwent immediate surgical resection followed by postoperative radiotherapy; patients with recurrent disease following chemotherapy and radiation underwent salvage laryngectomy.

The VA study results were published in 1991 and showed that organ preservation could be attempted in patients with advanced laryngeal cancer with chemoradiation without reducing survival in patients who would otherwise have undergone total laryngectomy, with laryngeal preservation in 64% of patients. Patterns of failure did differ between treatment groups, with significantly more patients in the induction chemotherapy group failing locally and significantly fewer patients failing at distant sites, in comparison with the surgical control group. Rates of second primary cancers were significantly higher in the surgery group. This study demonstrated that for some patients with advanced laryngeal cancer, laryngeal preservation with chemoradiation was feasible. Significant predictors of the need for salvage surgery were T4 and stage IV disease. Salvage laryngectomy was required in 56% of T4 lesions compared with 29% of smaller primary tumors, and in 44% of patients

with stage IV disease compared with 29% for stage III disease. Patients with T4 lesions comprised 26% of participants in the VA study, with T4N0 disease present in 12% of patients. The subset of patients with T4N0 disease had significantly reduced survival in the nonoperative treatment arm compared to the surgical arm (15), suggesting that the encouraging results of organ preservation do not apply to this subgroup.

Advanced stage nodal disease is a known adverse prognostic factor and was related to the poorer survival of stage IV disease in the VA study, which includes N2 and N3 nodal disease by definition. When organ preservation therapy is used in patients with advanced neck disease, the response in the neck may be independent of the response at the primary site. A follow-up study of patients in the VA study showed poorer survival in patients with N2 or N3 disease and a partial response in the neck following induction chemotherapy, who subsequently required salvage neck dissection because of inability to control disease in the neck, compared to those with a complete response to induction therapy (16). The incorporation of early, planned posttreatment neck dissection after induction but prior to radiotherapy in such patients resulted in improved regional control and no difference in survival between patients with a partial response compared to complete responders (17).

A follow-up phase III study designed by the Radiation Therapy Oncology Group (RTOG) was designed to determine the contribution of chemotherapy and radiotherapy to larynx preservation to investigate three radiation-based treatments: induction cisplatin and 5-FU followed by radiotherapy in responders, similar to the induction arm of the VA study; chemotherapy with cisplatin administered concurrently with radiotherapy; and radiotherapy alone (18). Unlike the VA study, there was no primary surgical arm. The concurrent treatment arm was designed to test observations of the enhancement of radiation effects on tumor by concurrent treatment with cisplatin. Patients with stage III or IV laryngeal cancer, excluding T1 disease, were included. As a result of the poorer outcomes for patients with T4 disease in the VA study, patients with large volume T4 disease, defined as extension through cartilage or greater than 1 cm of base of tongue involvement, were excluded from the RTOG 91-11 trial. Patients with low volume T4 disease were incorporated into RTOG 91-11 and represented 10% or less of patients in each arm.

The RTOG 91-11 study demonstrated that overall survival rates were similar in all three treatment groups; however, locoregional control rates were significantly better in the concurrent chemoradiation arm (78%) compared with induction (61%) and radiation alone (56%) and 2-year laryngeal preservation rates were higher for concurrent therapy (88%) compared with induction (75%) or radiation alone (70%). Induction chemotherapy had the same rate of acute toxicity as concurrent chemotherapy; however, acute mucosal toxicity was twice as frequent in the concurrent chemotherapy arm as in the induction or radiotherapy alone arms and was associated with delayed recovery of swallowing function at 1-year assessment.

These data established concurrent chemoradiation with cisplatin as the standard of care for organ preservation in advanced laryngeal cancer, excluding T4 tumors with tongue base or cartilage invasion. A follow-up of RTOG 91-11 evaluating the subset of patients who required salvage laryngectomy confirmed that salvage laryngectomy was required significantly less often following concurrent chemoradiation (16%), compared with the induction (28%) and radiotherapy alone (31%) arms (19). However, among patients surviving at least 1 year, overall survival was significantly worse for patients who required salvage laryngectomy compared to those who did not, by approximately 10%. There was no statistically significant difference in survival among patients undergoing salvage total laryngectomy as a function of initial nonoperative treatment.

Severe late toxicity after concurrent chemoradiation causing dysphagia secondary to dysfunction of the larynx and/or pharynx is progressive over time and in an RTOG analysis of several RTOG studies, including 91-11, was present in as many as 43% of patients at 3 years, after excluding patients with pretreatment severe laryngopharyngeal dysfunction (20). On multivariate analysis, older age, advanced primary tumor stage and laryngeal or hypopharyngeal primary site disease were significant predictors of late toxicity, emphasizing the importance of careful patient selection for aggressive organ-sparing treatment and swallowing exercises.

Taken together, these landmark randomized controlled clinical trials established concurrent chemoradiation as the standard of care for laryngeal preservation in advanced laryngeal cancer, with the caveat that patient selection should consider whether survival *and* function with an organ-sparing approach can be anticipated to be equivalent to the standard of laryngectomy with postoperative radiotherapy. Patients with T4 disease have poorer survival with chemoradiation and should undergo primary laryngectomy. Patients with pretreatment organ dysfunction are inappropriate for organ preservation because of predicted laryngopharyngeal dysfunction and feeding tube dependence resulting from severe late toxicities associated with chemoradiation. The cohort of patients with advanced primary stage disease and evidence of pretreatment organ dysfunction are better served with primary surgery and reconstruction rather than attempting to preserve a dysfunctional organ. Finally, patients should be aware that salvage laryngectomy is associated with a decrease in survival.

Hypopharyngeal Cancer

Organ preservation strategies for hypopharyngeal cancer are associated with a lower laryngeal preservation rate than those reported for advanced laryngeal cancer. The

only randomized, prospective trial to date comparing chemoradiation to surgery with postoperative radiotherapy in hypopharyngeal cancer was conducted by the European Organization for Research and Treatment of Cancer (EORTC) Head and Neck Cancer Cooperative group (21). Modeled after the VA laryngeal cancer study, patients with T2–T4 lesions who required total laryngectomy as part of definitive surgical treatment were randomized to receive either induction chemotherapy with cisplatin and 5-FU followed by definitive radiotherapy, or surgery with postoperative radiotherapy. Patients with T4 lesions comprised 6% of participants. This trial found no significant difference between the induction chemotherapy arm and the surgery arm in local (12% and 17%, respectively) or regional (19% and 23%) recurrence rates and 5-year disease-free survival (25% and 27%).Overall survival was less than 30% and did not differ between treatment groups. Successful organ preservation was far less likely when compared with laryngeal cancer, with only 17% of patients treated with induction chemotherapy followed by radiation alive and laryngectomy-free at 5 years.

A subsequent phase III study, also conducted by the EORTC, directly compared induction cisplatin and 5-FU followed by radiotherapy in patients with a complete response at the primary site with a regimen of alternating cisplatin and 5-FU and radiotherapy (22). No significant difference in laryngeal preservation or survival rates was demonstrated, and at the present time, induction chemotherapy followed by radiotherapy is the evidence-based standard of care for laryngeal preservation in hypopharyngeal cancers, in the absence of site-specific trials evaluating concurrent chemoradiation.

A third trial was conducted by the European Groupe Oncologie Radiothérapie Tête et Cou (GORTEC) study group for organ preservation in patients with advanced cancer of the larynx or hypopharynx who, similar to the EORTC study, would be candidates for total laryngectomy for cure (23). A total of 220 patients were randomly assigned, and of those, just more than one-half had a hypopharynx primary tumor. The majority of patients had T3 primary tumors. The two treatment arms consisted of standard cisplatin and 5-FU for three cycles (control group) or combination docetaxel, cisplatin, and 5-FU for three cycles. Following induction of both therapies, responding patients received 70 Gy of standard radiation; patients without a response to induction chemotherapy underwent surgery. The three-drug therapy was shown to be statistically superior for the endpoints of response to the induction regimen (80% vs. 59%) and preservation of a functional larynx at 3 years (70% vs. 58%). Based on these data, induction therapy with the triple-drug combination of docetaxel, cisplatin, and 5-FU is superior to cisplatin and 5-FU for organ preservation in advanced hypopharyngeal cancer.

While subsite analysis was not described in the EORTC report, others have shown in retrospective studies that survival is better with surgery and postoperative radiotherapy compared with chemoradiation, and in such series the volume of disease and laryngeal involvement were factors that adversely impacted survival (24–26). As for advanced laryngeal cancer, patients with severe pretreatment organ dysfunction are inappropriate for chemoradiation because permanent laryngeal dysfunction and gastrostomy tube dependence are expected sequelae of nonoperative treatment. Hypopharyngeal cancer is a significant predictor of pharyngoesophageal stricture, with rates of gastrostomy tube dependence following chemoradiation twice as high as for laryngeal primary tumors (27). The hypopharynx is particularly predisposed to stricture formation because the dose to the pharyngeal constrictors cannot be reduced as the structures related to swallowing dysfunction are the primary target. Taken together, these data suggest that organ preservation in hypopharyngeal cancer should be reserved for those patients with stage III disease with low volume primary tumors. As for laryngeal cancer, patients with T4 disease have poorer survival with chemoradiation and should undergo primary laryngectomy (28).

Oropharyngeal Cancer

Concurrent chemoradiation has increasingly replaced surgery in the initial treatment of advanced stage oropharyngeal cancer, despite a lack of trials directly comparing surgery with postoperative radiation to concurrent chemoradiation. In contrast to the data for larynx and hypopharyngeal cancer, there are no clinical trial data that compare control rates and survival for patients with advanced oropharyngeal cancer treated with surgery with postoperative radiation versus chemoradiation, and therefore equivalence cannot be shown. Surgery with postoperative radiation therapy results in superior survival compared with radiation therapy alone, and has been the standard of care for patients with advanced stage oropharyngeal cancer. There has been one randomized controlled trial limited to patients with oropharyngeal cancer (29–31) and several nonrandomized or mixed primary site trials (31–36) that demonstrate improved locoregional control and survival rates with concurrent chemoradiation (cisplatin and 5-FU) of approximately 20% compared to radiation alone for advanced stage disease, which are comparable to the historical results of surgery and postoperative radiation (34,37–42) with organ preservation rates of 77% to 84%. No difference was observed between chemoradiation and radiation alone in the distant metastatic rate. Mucositis, related weight loss and need for a feeding tube, and hematologic toxicity occurred more frequently in the chemoradiotherapy group.

Despite the absence of level I evidence comparing concurrent chemoradiation to primary surgery, most oncologists consider these data sufficient evidence to offer

organ preservation using concurrent cisplatin and 5-FU to patients with oropharyngeal cancer. Exceptions are stage I or II disease, which is treated with either surgery or radiotherapy, and a subset of stage III oropharyngeal cancers with T1 or T2 lesions and N1 disease, who do not appear to receive significant benefit from the addition of chemotherapy and may be treated with primary radiation therapy alone (43). A major topic of debate is the influence of human papillomavirus (HPV) associated tumors on clinical trial results, which primarily involves males under age 65, and is increasing in incidence in the United States and Europe (44). The favorable response of oropharyngeal cancer to chemoradiation may be due to a subset of patients with HPV-associated disease, who have improved response rates to chemoradiation primarily due to improved disease-free survival (45). HPV-positive tumors have been shown to have improved survival and disease control rates compared to HPV-negative tumors, and this survival benefit is independent of treatment modality (46–50). Patients with HPV-positive tumors are more likely to present with smaller primary site disease and more advanced nodal disease (51,52). Advanced nodal stage is a poor prognostic factor for HPV-negative tumors, but does not carry the same adverse prognosis in HPV-positive disease that it does for HPV-negative tumors (52–54). The improved survival in HPV-positive disease has been attributed to increased radiosensitivity, but has been shown to be independent of treatment modality (46,47,49). Other factors such as a lower risk of distant disease and second primary cancers and an inverse correlation with adverse tumor biomarkers such as EGFR, p53 mutations, and survivin are equally plausible (46). Advanced primary site stage has been shown to be an independent risk factor for recurrence and survival after controlling for HPV status (54).

HPV-positive lesions appear to have increased sensitivity to radiotherapy and may not require intensive concurrent chemoradiation regimens for treatment with the attendant effects on swallowing function without further improvements in survival. This premise is the focus of current clinical trials and it will be several years before data are available. Current research is focused on delineating differences in patients with oropharyngeal cancer based on HPV status. The presence of a high proportion of HPV-positive patients confounds the interpretation of efficacy in novel regimens investigating both chemoradiation and surgical treatment. The favorable impact of HPV on oropharyngeal squamous cell cancer outcomes is a relatively recent discovery, and to date the majority of studies regarding oropharyngeal cancer outcomes does not include HPV status in outcome analysis. Patients with HPV-positive tumors appear to have a different disease, with improved locoregional control and survival despite a preponderance of advanced stage disease. This difference may be due to smaller primary site disease at presentation, or to differences in tumor biology conferred by HPV infection, including p53 and EGFR expression.

It is important to recognize that although initial disease control rates following chemoradiation are higher for oropharyngeal cancer than they are for larynx or hypopharynx tumors, successful salvage of oropharyngeal primary site recurrence is far less likely (55). Fewer than 20% of patients with recurrent disease are candidates for salvage surgery, which is associated with increased complication rates and the median survival of patients with recurrence in less than 1 year (31,36,55–57). The majority of patients with recurrence develop a second recurrence in less than 12 months (56,58). Patients with the greatest likelihood of salvage following chemoradiation failure are those with early stage primary tumors and no recurrent nodal disease (56,58). These data emphasize that successful locoregional control with initial therapy is a critical determinant of long-term survival. Patients with initial early stage disease who receive chemoradiation have been shown to have an increased risk of second recurrences after salvage surgery (56), and chemoradiation failure is associated with poorer survival even after controlling for other variables (55). These data suggest that chemotherapy may select for more aggressive tumor biology in a subset of patients. Because nonoperative therapy appears less likely to be successful in HPV-negative disease and the results of surgical salvage are poor, risk stratification of patients by biomarker status including HPV infection is an area of active investigation to optimize treatment selection and outcomes and may result in tailored therapeutic recommendations in the future.

Patients with T4 disease invading the mandible have been excluded from chemoradiation trials because of the high incidence of osteoradionecrosis resulting from chemoradiation, and such patients should undergo primary surgery with reconstruction and postoperative radiation therapy.

Nasopharyngeal Cancer

Nonoperative treatment is standard of care for the initial treatment of nasopharyngeal cancer in light of the close proximity of the nasopharynx to critical skull base structures, which makes surgical extirpation with adequate margins challenging, and the unique radiosensitivity of nasopharyngeal tumors. The clinical behavior of nasopharyngeal cancer varies by histologic subtype. World Health Organization (WHO) type I (squamous cell cancer) is more common in the United States than in endemic areas, with local–regional behavior that is similar to that of other head and neck cancers. WHO types II (nonkeratinizing cancer) and III (undifferentiated cancer) predominate in endemic areas, such as southern China and northern Africa, and have a higher propensity for distant metastases. WHO types II and III are more responsive to radiotherapy and chemotherapy than those with

differentiated squamous histology, and more than 90% of WHO type II and III cases are associated with the Epstein-Barr virus.

Radiation has historically been the mainstay of treatment for disease above the clavicles. The management of locally advanced nasopharyngeal cancer dramatically changed a decade ago after publication of the results of the Intergroup 0099 study, which was designed to test concurrent chemoradiation in nasopharyngeal cancer in an effort to improve locoregional control and to decrease the distant metastatic rate by the addition of adjuvant chemotherapy (59). In this trial, patients with stage III or IV nasopharyngeal cancer were randomly assigned to either radiation alone or radiation with three cycles of concomitant cisplatin administered every 21 days, followed by three cycles of adjuvant cisplatin and 5-FU. Most patients (91%) had stage IV disease, and WHO type I histology was more common compared with published series from endemic areas. Overall survival at 5 years was significantly improved for patients who received combined-modality therapy (67% vs. 37%, $P < 0.001$), as was progression-free survival (58% vs. 29%, $P < 0.001$). The survival advantage of combined therapy was significant even though only 63% of patients received all three planned cycles of cisplatin during radiation and only 55% received all three cycles of adjuvant cisplatin and 5-FU.

One criticism of the Intergroup 0099 study is that the relative contributions of concurrent and adjuvant therapy could not be determined, and clinical trial results may be less applicable to endemic areas where WHO type I histologic subtypes are infrequent. However, subsequent randomized trials (60–62) in endemic areas and two meta-analyses (63,64) have confirmed a significant survival advantage for concurrent platinum-based chemoradiation over radiation alone. In contrast, randomized trials of induction chemotherapy followed by radiation compared with radiation alone have shown no significant improvement in overall survival (65–68), although some reported improved disease-free survival. Two meta-analyses of clinical trials that compared any sequence of chemotherapy and radiotherapy with radiotherapy alone have been published. A meta-analysis of the published results of six randomized trials comprising 1,500 patients (63) reported that at 4 years, chemotherapy improved progression-free survival by 34% and overall survival by 20%. The second meta-analysis used updated individual patient data from eight randomized trials (1,753 patients) with locally advanced disease, covering 1966 to 2003 (64). The effect of adding chemotherapy to radiotherapy on overall survival resulted in an absolute survival benefit of 6% (56% to 62%) at 5 years (hazard ratio [HR] of death = 0.82; $P = 0.006$). The effect on event-free survival was an absolute benefit of 10% (42% to 52%) at 5 years (HR of tumor failure [local, regional, or distant] or death = 0.76; $P < 0.0001$). There was a significant interaction between the timing of chemotherapy and radiotherapy and overall survival, with the highest benefit resulting from concomitant administration of chemotherapy and radiotherapy ($P = 0.005$).

Based on these data, concurrent cisplatin-based chemotherapy and radiation provides a clear survival benefit and is the accepted standard of care within and outside of the United States. The benefit of adjuvant chemotherapy, which theoretically will suppress distant metastases common in nasopharyngeal cancer, is less widely accepted. In the United States, the standard of care for treatment of patients with nasopharyngeal cancer stages IIB, III, IVA (T4, N0 to N2, M0), and IVB (any T, N3, M0) is radiotherapy with concurrent high-dose cisplatin on days 1, 22, and 43, followed by three courses of adjuvant cisplatin and infusional 5-FU dosing as administered in the Intergroup 0099 trial (59). Radiotherapy alone is indicated for stages I and IIA (N0 disease with no parapharyngeal space involvement).

Current areas of investigation in the management of nasopharyngeal cancer include the potential benefit of changing the sequencing of the three cycles of chemotherapy from adjuvant (after chemoradiation) to sequential (prior to chemoradiation) and the exploration of alternative cytotoxic regimens. The high incidence of distant metastases coupled with the limited ability to successfully deliver all three cycles of adjuvant chemotherapy in only 55% of patients in the Intergroup 0099 trial has motivated the investigation of sequential chemotherapy followed by chemoradiation. However, there is concern that this sequence of treatment might compromise the delivery of chemoradiation, the critical curative component of the treatment. The early results from several single-institution trials of sequential therapy have shown feasibility and encouraging response and survival data, and multicenter trials are under consideration. Circulating Epstein-Barr viral DNA can be quantitated by real-time polymerase chain reaction (PCR) in 96% of patients and predicts tumor load and risk of recurrence; this biomarker may have a role in stratifying patients by risk for additional systemic therapy (69). Pretreatment levels appear predictive of distant failure in patients with stage I or II disease, while posttreatment levels correlate with disease-free survival (70,71), and a validation trial is now in progress.

Oral Cavity Cancer

Cancer of the oral cavity should be distinguished from other sites as biologically distinct, and is managed surgically. Data from patients with advanced oral cavity treated with concurrent chemoradiation in phase I or II trials show equivalent survival compared to historic control patients treated with primary surgery, but a high rate of osteoradionecrosis (72–74). There are no level I data to suggest that nonoperative treatment effectively controls advanced oral cavity tumors, which is reflected in the 2011 National Comprehensive Cancer Network (NCCN) guidelines that

recommend surgery as the preferred modality of treatment for advanced oral cavity cancer (28).

CHEMORADIATION FOR LOCALLY ADVANCED UNRESECTABLE DISEASE

Inoperable disease is defined as tumor that invades the base of the skull, prevertebral fascia, pterygoid musculature, or encases the carotid artery. Historically patients with inoperable disease were managed with radiotherapy alone, with a median survival time of 12 months and only 20% of patients alive at 2 years. The radiosensitizing properties of chemotherapy were explored in this population in several randomized controlled clinical trials that showed the potential for improved survival. The focus of these studies has been on drugs that show activity against both the disease and radiation-enhancement properties (e.g., cisplatin and 5-FU). The three general strategies that can be employed are (1) concomitant single-agent or combination chemotherapy with continuous-course radiation; (2) combination chemotherapy with planned split-course radiation; and (3) rapidly alternating chemotherapy and radiation. More recently, altered-fractionation radiation approaches have become an additional radiotherapy option. Currently, the best evidence supports concurrent chemoradiotherapy with a platinum-based agent as the standard of care for locally advanced head and neck cancer, but recommendations may change as new data become available.

Concurrent Chemoradiation

The first study to investigate concomitant chemoradiotherapy for the treatment of unresectable advanced head and neck cancer was reported in 1992 (75). The investigators randomly assigned 157 patients with unresectable squamous cell cancer of the head and neck were randomly assigned to radiation alone (70 Gy, conventional fractionation) or to a cisplatin and 5-FU combination alternating with radiation (60 Gy). Compared to patients treated with radiation alone, the group treated with chemotherapy showed significantly better complete response rates (43% vs. 22%) and survival (41% vs. 23%; $P = 0.01$).

A subsequent trial randomized 295 patients with unresectable squamous cell cancer of the head and neck to one of three treatment groups: radiation alone, radiation with concurrent cisplatin on days 1, 22, and 43; or split-course radiation with three cycles of concurrent bolus cisplatin and infusional 5-FU. Surgical resection was offered for patients in all three groups if feasible after the completion of treatment; patients in the third arm had an option for surgical resection after the second cycle of chemotherapy, if feasible (76). This study demonstrated a significant survival advantage at 3 years for patients treated with concurrent cisplatin and radiation (37%) compared with radiation alone (23%; $P = 0.014$). The split-course concurrent regimen offered no survival advantage (27%) over radiation alone. Grade 3 toxicity or higher was significantly more common with concurrent therapy (89%) compared with radiation alone (52%; $P < 0.0001$). This study established radiation with concurrent high-dose cisplatin as the standard of care for locally advanced unresectable head and neck cancer.

A meta-analysis by Pignon et al. (77), the Meta-Analysis of Chemotherapy in Head and Neck Cancer (MACH-NC), highlighted the favorable results seen with a concurrent approach. Despite significant heterogeneity in study trial designs, overall concurrent chemoradiotherapy regimens were associated with an 8% absolute benefit in survival at 5 years compared with radiation alone (HR = 0.81; $P < 0.0001$). An updated analysis of 87 trials and more than 16,000 patients showed the same absolute benefit for survival with concomitant treatment (HR = 0.81; $P < 0.0001$) (78).

A meta-analysis of randomized concurrent chemoradiotherapy studies for patients with locally advanced squamous cell cancer of the head and neck was performed to develop clinical recommendations (79). Subgroup analysis of data from 1,514 patients in nine trials demonstrated that platinum-based concurrent programs offered the greatest survival advantage compared with radiation alone (odds ratio [OR] = 0.57; $P < 0.00001$). The meta-analysis suggested that platinum-based regimens for concurrent chemoradiation that were associated with a positive trial and a more favorable side-effect profile should be used. Overall, cisplatin-based chemoradiotherapy provided the most significant benefit in terms of survival and local–regional control (80).

In summary, concurrent chemoradiotherapy leads to improved disease control compared with radiation alone for patients with unresectable squamous cell cancer of the head and neck and represents standard treatment for patients who are able to tolerate the additional treatment-related toxicity of chemotherapy. The data showing improvement are best established for platinum-based concurrent regimens; an advantage for the use of chemotherapy persists even when newer altered-fractionation radiotherapy approaches are employed.

Induction Chemotherapy Using Cisplatin and 5-Fu with a Taxane

Three randomized controlled trials have directly compared induction chemotherapy using a combination of docetaxel, cisplatin, and 5-FU to standard cisplatin plus 5-FU in unresectable head and neck cancer (81,82). The TAX 323 trial enrolled more than 300 patients with locally advanced unresectable disease. The control arm consisted of four cycles of the two-drug combination followed by radiotherapy, and the experimental arm consisted of four cycles of the three-drug combination (docetaxel, cisplatin, 5-FU) followed by radiotherapy (81). The response rate to

induction with the three-drug regimen was significantly higher compared with that of the two-drug regimen (68% vs. 54%, $P = 0.006$) as was overall survival (HR = 0.73; $P = 0.016$). Less toxicity was observed with the three-drug combination than with the two-drug combination.

Similarly, the TAX 324 trial randomly assigned 501 patients with unresectable or resectable disease (all sites) to three cycles of standard cisplatin and 5-FU or to combination docetaxel, cisplatin, and 5-FU (docetaxel, cisplatin, 5-FU) (82). Definitive local therapy in both arms consisted of standard radiotherapy plus weekly carboplatin. Overall survival was significantly improved for patients who received the three-drug therapy (HR = 0.70; $P = 0.0058$).

A third phase III trial compared induction combination paclitaxel, cisplatin, and 5-FU to induction cisplatin and 5-FU in a heterogeneous population of patients with both resectable and unresectable cancer (83). Chemoradiation was planned following induction chemotherapy but the actual treatment was not uniform. The taxane-containing treatment group had a higher overall response rate (80% vs. 68%); however, the difference in overall survival was not significant.

These trials demonstrate that the combination of docetaxel, cisplatin, and 5-FU followed by radiotherapy alone or radiotherapy and concurrent carboplatin is superior to cisplatin and 5-FU followed by the same definitive local therapy. The three-drug regimen administered in the TAX 323 trial seems to have an acceptable toxicity profile with lower rates of severe and life-threatening myelosuppression than observed with the two-drug regimen (81). These trials indicate that treatment with a taxane plus cisplatin and 5-FU is more effective than cisplatin and 5-FU alone when using response rate as the outcome measure. They do not indicate that induction combination docetaxel, cisplatin, and 5-FU is the standard of care, but provide support for a prospective, randomized controlled trial that compares induction chemotherapy followed by chemoradiation (termed sequential treatment) against the standard of care of chemoradiation for nonsurgical management of resectable disease or for management of unresectable disease. Several such trial designs are in progress in the United States. Combination docetaxel, cisplatin, and 5-FU should replace cisplatin and 5-FU as a new standard regimen for induction chemotherapy and is being used in ongoing trials. A second approach for patients with unresectable disease focuses on the addition of biologic agents to chemoradiation and trials by both ECOG and the RTOG testing the addition of cetuximab to concurrent chemoradiation are in progress. The results of these trials may redefine the standard of care for unresectable disease.

POSTOPERATIVE CHEMORADIATION FOR HIGH-RISK DISEASE

Two randomized controlled trials have investigated the role of chemoradiation in the postoperative adjuvant setting when compared with radiotherapy alone. A study conducted by EORTC (22931) (84) and a trial conducted by the RTOG (9501) (85) were designed to address the issue of whether the addition of cisplatin to standard postoperative radiotherapy based on adverse pathologic criteria would improve disease control and survival. The experimental arms of both studies consisted of standard fractionation radiation with concurrent cisplatin on days 1, 22, and 43. At 5 years, the EORTC study demonstrated significant improvement in disease-free survival (47% vs. 36% for radiation alone, $P = 0.04$), and overall survival (53% vs. 40% for radiation alone, $P = 0.02$) for the arm treated with concurrent cisplatin and radiation. The RTOG study demonstrated a significant advantage with combined-modality adjuvant therapy for disease-free survival, but not for overall survival. In both studies, concurrent chemoradiotherapy was associated with greater toxicity.

While the experimental treatment arms were similar for both studies, the definition of high-risk pathologic features differed between studies. The RTOG study defined high-risk pathologic features as the presence of multiple positive nodes, extracapsular extension of nodal disease, or a positive surgical resection margin. In contrast, the EORTC trial defined high-risk pathologic features as a positive surgical resection margin, extracapsular extension of nodal disease, vascular embolisms, or perineural disease; for oral cavity or oropharynx primary sites, high-risk pathologic features included positive nodes in level IV or V. These differences may in part explain the variable outcome of the two trials. In an attempt to reconcile the differing results of these two trials, a pooled analysis was performed which showed that the subset of patients in both trials who received a significant benefit from the addition of cisplatin to postoperative radiotherapy had either microscopically involved margins or extracapsular extension of disease in neck nodes (86). The presence of either or both of these risk factors is therefore now considered a definite indication for adjuvant chemoradiation. Patients who were enrolled only because of tumor present in multiple positive lymph nodes did not benefit from the addition of chemotherapy to postoperative radiation.

Since these analyses were performed, the RTOG trial data have been reanalyzed with longer follow-up times and now demonstrate a significant advantage for chemoradiation in local–regional control, with locoregional failure in 21% of patients receiving adjuvant chemoradiation compared with 33% of patients treated with radiation alone (87,88). The difference in disease-free survival was marginally significant (18% vs. 12%; $P = 0.05$). These results do not change current treatment recommendations, which are adjuvant chemoradiation in patients with extracapsular spread or a positive surgical margin on final pathology.

BIOLOGIC THERAPY

EGFR is highly expressed in head and neck squamous cell cancer, and the expression of EGFR has an inverse relationship with prognosis. Inhibitors of the EGFR have been the

focus of targeted therapy trials in head and neck cancer. Cetuximab is a chimeric immunoglobulin G antibody that binds to EGFR with high affinity. In preclinical studies, cetuximab demonstrated at least additive effects when combined with radiotherapy or with cisplatin, paclitaxel, and other cytotoxics. Cetuximab was approved by the FDA for use in combination with radiotherapy in patients with advanced head and neck cancer based on a multicenter trial phase III trial published by Bonner et al. (89). This trial randomly assigned patients with locally advanced squamous cell cancers of the oropharynx, larynx, and hypopharynx to treatment with radiotherapy alone (using either standard or altered fractionation schedules) or to radiotherapy with concurrent weekly cetuximab. The addition of cetuximab significantly improved local–regional failure-free survival and overall survival rates: median local–regional failure-free survival was 24.4 months with cetuximab and 14.9 months with RT alone ($P = 0.005$), and 5-year overall survival rates were 45% with cetuximab and 36% with radiotherapy alone ($P = 0.018$) (10). Cetuximab had no effect on distant metastases. Cetuximab is associated with the development of an acneiform rash in 84% of patients during treatment, which is prominent in 73% of patients. Of the patients who received cetuximab, those who developed a prominent cetuximab-induced acneiform rash had longer overall survival (69 months) compared to those with mild rash (26 months), which was significant ($P = 0.002$). There was no association between the cumulative dose of cetuximab and rash.

A limitation to this study is extrapolation of the results to the larger head and neck cancer population: cetuximab was only studied in combination with radiotherapy, using radiation alone as the control group. In addition, the study population was heterogeneous with respect to resectability, primary site, and radiation schedule. Whether the combination of radiotherapy and cetuximab is as effective as the standard of chemoradiation is unknown. At the present time, the only indication for cetuximab with radiotherapy is in the treatment of patients whose age, performance status, or comorbidity precludes treatment with platinum-based chemoradiation. Cetuximab with radiotherapy provides a 9% absolute survival advantage at 5 years over radiotherapy alone. Numerous trials are currently testing the addition of cetuximab or small-molecule tyrosine kinase inhibitors to chemoradiation in various disease settings. One such trial, RTOG 0522, directly compared concurrent cisplatin and radiation with or without cetuximab: preliminary data presented at the American Society of Clinical Oncology annual meeting in 2011 showed no survival benefit with the addition of cetuximab (90).

INCURABLE RECURRENT OR DISTANT METASTATIC DISEASE

Inoperable disease that has been previously irradiated or disease that involves distant organs is considered incurable. Commonly used chemotherapeutic agents to treat recurrent or metastatic squamous cell cancers of the head and neck are cisplatin, carboplatin, docetaxel, paclitaxel, 5-FU, and methotrexate. Less commonly used drugs that also show some activity against head and neck tumors are bleomycin, irinotecan, gemcitabine, capecitabine, oxaliplatin, cyclophosphamide, ifosfamide, pemetrexed, and biologic agents such as cetuximab. Randomized trials comparing combination chemotherapy and single-agent therapy show an approximate doubling of the response rate with platinum-based combinations of chemotherapy, but the duration of response is brief (2 to 4 months) and does not significantly impact overall survival (91–93).

Combination chemotherapy is associated with greater toxicity. In a meta-analysis of all studies in which cisplatin and 5-FU, the gold-standard combination drug regimen, was compared with single-agent therapy, a significant improvement in response (OR = 0.43) was documented, which translated into only a 2-week difference in the median survival (94). Toxicity was greater for patients who received combination therapy. While numerous single agents have activity against head and neck cancers and can be used, weekly methotrexate is the historical gold standard because of its ease of administration, lower toxicity profile, and relative lower costs (95). Combination chemotherapy should be limited to patients who have a good performance status (ECOG performance status of 0 to 1) and as a result are better able to tolerate the added toxicity: in such patients the higher response rate may translate into better palliation, although no objective quality of life data exist to support this concept. A poor response to palliative chemotherapy can be predicted for patients with poor performance status, the presence of comorbidities, bulky local–regional disease or high tumor volume, and prior treatment for recurrence.

Despite the favorable results of the use of taxanes in induction chemotherapy protocols, no improvement in survival with the use of taxanes has been documented for patients with recurrent disease. A study comparing two different weekly schedules of paclitaxel in patients with recurrent disease offered no advantage compared with weekly single-agent methotrexate (96). The addition of paclitaxel to cisplatin did not significantly impact outcomes when compared to the use of standard cisplatin plus 5-FU with respect to median survival times (9 vs. 8 months) and the 1-year survival rates (30% vs. 41%), although the paclitaxel regimen was better tolerated (97).

Cetuximab is the only biologic agent to be approved for use in head and neck cancer, but as previously mentioned, its only approved indication is in patients who are resistant to or cannot receive platinum-based agents. In phase II trials of cetuximab alone or combined with cisplatin in patients who had either stable or progressive disease, the best response rates are in the range of 10% to 13% (98–100). In a randomized trial of 123 patients

comparing the combination of cisplatin and placebo with cisplatin and cetuximab, no significant difference was found in median progression-free survival (2.7 months compared with 4.2 months, respectively; $P = 0.27$), although the rate of a major complete or partial response was significantly higher for patients who received cisplatin and cetuximab (10% compared with 26%, respectively; $P = 0.03$) (101).

Another phase III trial randomized 442 patients to receive either cisplatin–5FU–cetuximab or cisplatin–5FU as first-line treatment in patients with recurrent or metastatic squamous-cell carcinoma of the head and neck (102). The addition of cetuximab to cisplatin/5-FU prolonged the median overall survival from 7.4 to 10.1 months (HR for death, 0.80; $P = 0.04$), prolonged the median progression-free survival time from 3.3 to 5.6 months (HR for progression, 0.54; $P < 0.001$) and increased the response rate from 20% to 36% ($P < 0.001$). This was the first trial to show any improvement in overall survival by the addition of cetuximab when compared with the standard regimen of cisplatin/5-FU, although gains were modest.

Interest has been generated in the use of the small molecule tyrosine kinase inhibitors gefitinib and erlotinib, which have modest activity in the setting of recurrent disease, including responses in patients who have received prior chemotherapy. In a phase II trial of 52 patients, the administration of 500 mg/d of gefitinib resulted in an 11% major response rate (103). In a phase II trial in 115 patients, the administration of 150 mg/d of erlotinib resulted in a 4% major response rate (104). Stable disease was demonstrated in 50% of patients. Combination trials using other agents directed at EGFR pathway downstream targets, such as the vascular endothelial growth factor (VEGF) inhibitor, are in progress (105). In a phase II trial, the combination of erlotinib and bevacizumab resulted in a 17% response rate, with median survival of 7.5 months in patients previously treated for recurrent disease (106).

CONCLUSIONS

In summary, concurrent chemoradiotherapy leads to improved disease control compared with radiation alone for patients with unresectable squamous cell cancer of the head and neck and represents standard treatment for patients who are able to tolerate the anticipated added treatment-related toxicity. There also is a role for this approach in the organ-preservation and larynx-preservation setting and for advanced local–regional nasopharyngeal cancer. The data showing improvement are best established for platinum-based concurrent regimens; an advantage persists even when newer altered-fractionation approaches are employed. Induction chemotherapy results in superior rates of laryngeal preservation in advanced hypopharyngeal cancer. Adjuvant chemoradiation is indicated for patients with high-risk pathologic features of extracapsular spread or positive margins. The use of biologic therapy with radiation provides a survival benefit in patients with advanced head and neck cancer who would otherwise only be candidates for radiation alone because of contraindications to the use of chemotherapy. Current evidence-based indications for standard of care use of chemoradiation are listed in Table 111.2. Clinical trials testing the addition of cetuximab to concurrent chemoradiation, and induction chemotherapy with the addition of a taxane are in progress. The results of these trials may redefine the standard of care for both resectable and unresectable disease.

TABLE 111.2 CURRENT EVIDENCE-BASED INDICATIONS FOR CHEMOTHERAPY IN THE MANAGEMENT OF ADVANCED HEAD AND NECK CANCER

Primary Site	Regimen	References
Organ preservation, larynx (resectable stage III and IV disease, excluding T1 disease)	XRT 70 Gy + high-dose cisplatin	(18,19)
Organ preservation, hypopharynx (resectable stage III and IV disease, excluding T1 disease)	Cisplatin (100 mg/m^2) + 5-FU (1,000 mg/m^2/d × 4) × 3 cycles followed by XRT 70 Gy	(21,23)
Oropharynx, resectable T3–T4 or N2–N3	XRT 70 Gy + cisplatin or carboplatin (70 mg/m^2/d × 4) + 5-FU (600 mg/m^2/d × 4) × 3 cycles	(29–31)
Nasopharynx, stages IIB, III, IVA, IVB	XRT 70 Gy + high-dose cisplatin, adjuvant cisplatin (80 mg/m^2) + 5-FU (1,000 mg/m^2/d × 4) × 3 cycles	(59)
Unresectable, all sites	XRT 70 Gy + high-dose cisplatin	(76)
Postoperative adjuvant high-risk factors: extracapsular spread or margin positive	XRT 70 Gy + high-dose cisplatin	(84–88)
Contraindications to systemic chemotherapy, stage III or IV disease	Cetuximab (400 mg/m^2) followed by XRT 70 Gy + cetuximab (250 mg/m^2/wk)	(10,89)

High-dose cisplatin = 100 mg/m^2 days 1, 22, and 43. XRT = external beam radiation therapy.

HIGHLIGHTS

- In patients with unresectable squamous cell cancer of the head and neck, concomitant cisplatin and radiotherapy significantly improves survival, compared with radiotherapy alone, and is the standard of care.
- Concomitant cisplatin and radiotherapy is the standard of care for postoperative adjuvant treatment for patients with positive resection margins or extracapsular extension of nodal disease.
- To preserve the larynx of patients with locally advanced, resectable laryngeal cancer, concomitant cisplatin and radiotherapy is the standard of care. T4 disease is associated with poorer outcomes and survival following chemoradiation, and should be treated with primary laryngectomy.
- To preserve the oropharyngeal functions of speech and swallowing in patients with locally advanced, respectable oropharyngeal cancer, concomitant chemotherapy and radiotherapy is the standard of care for T3 to T4 or N2 to N3 disease.
- To preserve the larynx of patients with locally advanced, resectable cancer of the hypopharynx, induction chemotherapy and radiotherapy is the standard of care based on randomized controlled trials.
- The standard of care for treatment of nasopharyngeal cancer is radiotherapy alone for early stage disease (stages I and IIa), and concurrent cisplatin and radiotherapy followed by three cycles of adjuvant cisplatin and 5-FU for advanced stage disease (stages IIb, III, IVA, and IVB).
- Cetuximab when added to radiotherapy for definitive treatment of locally advanced cancer showed significantly improved survival compared with radiotherapy alone. However, no indications for using cetuximab plus radiotherapy in place of standard platinum-based chemotherapy plus radiotherapy have been established.
- Induction chemotherapy using a taxane with cisplatin plus 5-FU regimen followed by concomitant chemoradiation (sequential therapy) shows promise in improving disease-control and survival, but this is not at present standard of care. Trials comparing chemoradiation with or without induction chemotherapy in high-risk populations are in progress.
- Combination chemotherapy in the palliative setting leads to increased response rates as well as increased toxicity over single-agent chemotherapy, but does not significantly improve survival compared with single-agent methotrexate, a platinum-based agent, or 5-FU.
- Various biologic agents that target the EGFR pathway are under study in combination with chemotherapy, as single agents, and as multiple targeted agents. Antibodies to the EGFR and small molecule tyrosine kinase inhibitors cause major response in approximately 10% of patients who do not respond to platinum agents. Cetuximab is the only biologic agent approved for use in head and neck cancer.

112 Therapeutic Options for Patients Who Fail Primary Chemoradiation

Steven B. Cannady *Mark K. Wax*

Single institution reports, randomized controlled trials, and meta-analyses have established that chemoradiotherapy protocols improve locoregional control and reduce distant metastases in patients with head and neck squamous cell carcinoma (HNSCC) (1–9). These protocols have been collectively termed "organ preservation strategies" as they inherently maintain the anatomic structure being treated. Increased usage of organ preservation strategies has led to scenarios in which surgical salvage for recurrent or persistent disease requires removal of an organ from a significantly treated soft tissue and vascular bed. Studies have confirmed that operating in the previously treated field leads to a greater risk of complications resulting in added morbidity after surgery (10,11). In patients with advanced recurrent HNSCC, long-term survival is rare, and the quality of life (QOL) cost to such added morbidity and decreased function may outweigh the benefit of surgery unless adequate reconstruction is feasible (12,13). The advent of microvascular free tissue transfer has reduced the risk of complication and increased the possibility of regaining function in the posttreatment patient, rendering salvage more appealing even for short-term control of disease, amelioration of pain, or improvement of function (14–24).

Free tissue transfer has revolutionized the management of posttreatment sequelae encountered following nonsurgical upfront treatment of HNSCC. The functional consequences of high dose radiation therapy with concomitant chemotherapy can now be surgically addressed in the cured patient to improve QOL (14), swallowing, and deglutition (25). Microvascular techniques also allow for preservation of normal tissue outside the body during chemotherapy and radiotherapy (CRT) with reimplantation afterward as in the case of submandibular gland preservation techniques.

Within this chapter, treatment options following failed chemoradiation are discussed. The applications of microvascular free tissue transfer in the treatment of recurrent HNSCC following previous nonsurgical treatment are reviewed. The relative merits of free tissue transfer in the treatment of each subsite of HNSCC are assessed. The use of free tissue transfer in the reconstruction of treatment-related complications is also discussed.

Surgical salvage after failed chemoradiation is by far the most common treatment option available for these patients. Other options that that have been described include chemotherapy, reirradiation (external beam and brachytherapy), and hospice care. Each of these is briefly described.

(CHEMO) RADIOTHERAPY EFFECTS ON TISSUES OF THE HEAD AND NECK

Before we can discuss the possible treatment options for patients that have failed chemoradiation, we must understand the underlying tissue consequences of the initial treatment.

The role of chemotherapy in the treatment of head and neck oncology is well discussed in a previous chapter in this textbook. There are many agents available for treatment in the primary setting. Investigational agents have been used in Phase I and Phase II trials, and there is some question about whether, in Phase III trials, chemotherapy as a single modality treatment may be efficacious. Chemotherapy in the majority of head and neck tumors is combined with radiation therapy in a protocol known as chemoradiation. Here, the chemotherapy may be used as a sensitizing agent or as a direct combination therapy with the radiation to kill the tumor cells. Consequently, the majority of patients who present for salvage treatment, who have had chemotherapy, will have had this as a combined modality treatment with radiation therapy.

Chemotherapy has been demonstrated to not only enhance the tumor kill effectiveness of the radiation therapy but also to increase the postoperative complications in

patients who require salvage surgery. The effects of radiation therapy on the tissues have been described both from a short- and long-term toxicity perspective. Chemotherapy will adversely affect patients in the short term as well as in the long term. Patients who recur and who require salvage treatment in the close term will oftentimes be debilitated, have lost significant amounts of body weight, and still be suffering from some of the acute toxicity, such as mucositis and soft tissue necrosis. These patients will have underlying metabolic disorders and will be in a high catabolic state. Their ability to heal their wounds will be less than patients who have not undergone this treatment. Consideration of these issues should be undertaken with nutritional supplementation, and g-tube placement will need to be considered in these patients.

The effects on soft tissue of chemotherapy and chemoradiation will be greater than that of just radiation alone. The soft tissue fibrosis and long-term scarring will be more extensive. Combined with the patient's inability to heal well, the patients who undergo salvage surgery following chemoradiation are more prone to develop local morbidities and complications from poor tissue and wound healing. Not only must the primary closure site of the ablated defect be considered, but the prophylactic reconstruction of the soft tissues that have been affected by the previous treatments must also be considered if one is to rehabilitate these patients and allow them to heal the arterial response to radiation that occurs most severely within the capillary endothelium and is the mechanism of late tissue manifestations of radiation therapy (XRT). The results of histologic changes to the capillaries lead to tissue anoxia and dilation of remaining capillaries (26,27). Larger arteries have different responses to XRT based on their sizes; small (less than 100 μm) to medium (100 to 500 μm) vessels suffer adventitial fibrosis, medial hyalinization, and intimal foam cell accumulation, whereas large arteries (greater than 500 μm) tend to be more resistant to these changes (28–30). Large arteries can suffer complications associated with neointimal proliferation, atheromatosis, thrombosis, and rupture, whereas the effect of chronic radiation on medium to large vessels is caused by injury to the vasa vasorum owing to a greater incidence of atherosclerosis within these vessels—a major concern in the use of microvascular free flaps (Fig. 112.1). This phenomenon is well documented in studies of irradiated carotid arteries, to which most head and neck reconstructive free flaps are anastamosed (31). Finally, the vascular physiology itself is altered by radiation therapy such that less blood flow occurs due to increased smooth muscle vasoconstriction and increased pressure in the capillary system secondary to tissue fibrosis of surrounding tissues (32).

Additional tissue-specific treatment effects of particular interest to oncologic surgeons include late toxicity to the skin, mucosa, salivary tissue, mandible, and laryngotracheal cartilages. It is well established that when exposed to radiation therapy, mucocutaneous tissue changes that include increases in vascular permeability, fibrin deposition, collagen formation, and ultimately, tissue fibrosis occur (33). Salivary tissue is exquisitely sensitive to XRT causing marked degeneration and loss of saliva. In a series of studies on XRT-related damage to the mandible, Marx (34) demonstrated that the triad of hypoxia, hypocellularity, and hypovascularity in posttreatment bone leads to tissue breakdown and chronic nonhealing wounds associated with osteoradionecrosis (ORN) of the jaw. It is thought that this process occurs in up to 56% of patients that undergo XRT to the head and neck, but it is unclear how many will manifest clinical symptoms; however, as many as half of those that become clinically apparent will require surgical interventions (35) (Fig. 112.2). A similar process is plausible in the cartilaginous structures of the

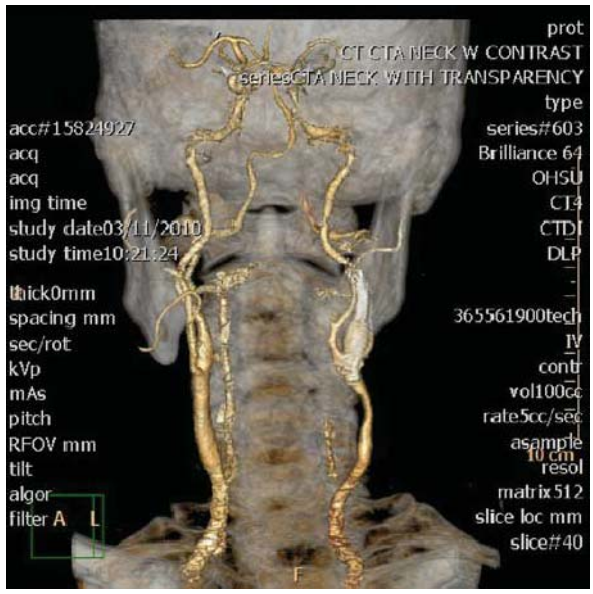

Figure 112.1 This CT angio of the carotids demonstrates severe disease of the left carotid system. There is a stent present, but the common carotid below the stent has severe atherosclerotic changes.

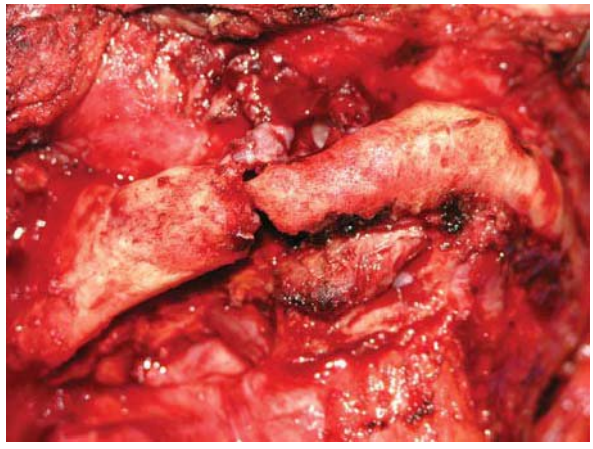

Figure 112.2 This intraoperative photograph demonstrates ORN with a fracture. The bone around the fracture site is dead.

upper aerodigestive tract leading to chondroradionecrosis (CRN) with less frequency than mandible necrosis—5% to 12% of radiated laryngeal cancers (36). These latter two tissue effects can mimic cancer recurrence and thus often require a thorough workup for recurrence. In addition, the effects on bone and cartilage may be severe enough to warrant ablative surgery of the structure in question with reconstruction, even in the absence of recurrent disease, to improve pain and function.

RECURRENT HNSCC: EFFICACY OF TREATMENT

Surgery remains the standard of care and occasionally is the only available treatment for recurrent HNSCC that is deemed resectable by multidisciplinary care teams (37). In a large meta-analysis, Goodwin established the survival, complications, operative mortality, and treatment effect of salvage surgery for patients with recurrent HNSCC (13). In addition, his concomitant observational study collected QOL data, performance status, and financial considerations to assess the overall effectiveness of salvage on these parameters.

It was established within Goodwin's meta-analysis that the 5-year overall average survival after salvage surgery is 39%, but a large separation was noted between early (Stage I or II) larynx recurrence (83%) versus late (Stage III or IV) larynx (37%), oral cavity (43%), and pharynx (26%) recurrences. Disease-free survival was similarly stratified denoting a clear difference in outcome for patients with early laryngeal recurrence. Surgical complications and mortality were also assessed in this analysis with a 5.2% risk of death from surgical salvage or its complications. Although the definition of major and minor complication is variable within the literature, a consistent risk in the range of 30% to 40% for salvage surgery of the primary is cited in the literature (10,11), with better outcomes in patients requiring only planned neck dissections or dissections for persistent disease (38).

In the prospective arm of Goodwin's study, survival for 109 patients was 21.5 months. Recurrent stage was again a significant survival predictor, with decreasing survival as stage advanced, but original cancer stage was not a predictive factor. Interestingly, patients that had received prior chemotherapy had worse survival than those that did not, but no survival effect was noted for prior radiation or surgical treatments. QOL was assessed by the Functional Living Index-Cancer Questionnaire before and after surgery and demonstrated a decline with increasing stage of recurrent disease; the percentage of patients showing improvement was 64%, 65%, 41%, and 39% for Stage I, II, III, and IV, respectively. No significant difference in QOL existed for site of recurrent disease. Performance status was also assessed via the Performance Status Scale for Head and Neck Cancer Patients. Normalcy of diet varied considerably by site of recurrence and declined with advancing stage of recurrence and showed that only 47% of patients had a successful outcome after surgery. Forty-one percent (41%) had a successful outcome with respect to understandability of speech following surgery. Public eating behavior was improved in 50% of patients following surgery and again varied with recurrent stage. Operative mortality was slightly less (1.8%) in this series than in the retrospective review as were complications (20.2%). Average length of stay in the hospital following salvage was 11.5 days with an average cost of $5,700 per day in the year 2000.

This study was paramount to the understanding of outcomes for patients undergoing surgical salvage of recurrent HNSCC; however, many of these patients had undergone radiotherapy as the sole modality of treatment, and there was no analysis of free-flap surgery's contributions to complications, QOL, or performance status. Recent studies have suggested that QOL may be maintained at a stable level (despite some performance impairments) with the use of free-flap reconstruction after head and neck ablative surgery (14). Bozec et al. employed the European Organization for Research and Treatment of Cancer's Core Quality of Life Questionnaire (EORTC-QLQ-C30) before surgery and at 6 and 12 months in 13 patients with recurrent tumors to determine that no drop in global QOL occurred.

In addition, Kim et al. (22) studied the outcomes of patients undergoing salvage surgery with free-flap reconstruction for recurrent HNSCC. One hundred and six patients treated at the University of California at Los Angeles were reviewed. Sixty-nine patients were radiation alone failures, 14 were chemoradiation failures, and the remaining patients failed after either surgery alone or combined therapy. Major perioperative complications occurred in 34% of patients and were comprised mostly of skin necrosis (7.5%) or fistula (3.8%). Many of these patients re-recurred (74%) at an average time interval of nine months, an occurrence that was predicted by recurrent T class and persistent smoking. These results are disappointing with respect to tumor control, but remain consistent with Goodwin's review and reflect similar rates of survival and complications to reirradiation protocols (37,39–42). No functional or QOL data are available from this study; however, based on the previously mentioned QOL study by Bozec, one can extrapolate that patients may die before reaching maximal QOL; average time to death was 9 months in the 74% of patients that re-recurred, but QOL is not maximized until between 6 and 12 months following surgery. This creates a significant treatment dilemma that requires sound clinical judgment and open communication with patients to make appropriate decisions on an individual basis.

Although some evidence exists suggesting that primary closure is superior to flap reconstruction for swallowing outcomes following ablative head and neck surgery, previous treatment limits the availability of healthy tissue for primary closure (43). As evidenced by Khariwala et al. (25), four out of five patients undergoing ablation followed by free-flap reconstruction will resume oral intake, which compares favorably to historical data using pedicled or

local tissue reconstructions. In this study, nearly half of patients had been previously irradiated, and nearly 20% had previous surgery, further adding to the impressiveness of their swallowing results. They also determined that preoperative irradiation, total glossectomy, hypopharyngeal defect, base of tongue surgery, and oropharyngeal surgery were risk factors for poor swallowing (g-tube dependence) following reconstruction. The authors recognized that in addition to subsite importance, the size of defect and reconstruction was important to include in the swallowing prognosis when counseling a patient.

Taken as a whole, these studies suggest that salvage surgery offers a viable, albeit low likelihood, chance for long-term survival with acceptable QOL and swallowing rates. Therefore, in properly selected patients that are motivated to attempt salvage, ablation with free tissue reconstruction should be considered after in-depth counseling.

FREE TISSUE TRANSFER TO A PREVIOUSLY TREATED FIELD

Free tissue transfer is now accepted as the standard of care in the reconstruction of many head and neck defects, with high probability success rates (95%) (44). However, transferring free tissue to a previously treated head and neck site poses several challenges. Whether the initial treatment was surgery, radiation, chemoradiation, or a combination thereof, clear tissue effects may limit local reconstructive options as well as the ability to transfer free tissue (45).

Multiple studies document that decreased vascularity of skin results in relatively high rates of local skin flap necrosis for salvage surgery following XRT or CRT (Fig. 112.3) (10,11,22). The reconstructive surgeon must be prepared to deal with local wound complications resulting from skin changes and should counsel patients preoperatively of the potential for a protracted wound healing course. Some authors advocate the use of concomitant regional flaps for superficial coverage of important structures due to the expectation of some degree of skin loss in the heavily treated neck, particularly when single free-flap procedures will not be adequate to provide the volume of tissue necessary to reconstitute the internal defect and bolster marginal skin (19). Surgical planning is paramount to limiting skin flap loss, as prior incisions must be coordinated with planned salvage incisions in a way that limits devascularization of tenuous skin. Proper planning can limit minor skin flap loss as well as potentially lethal exposures of deeper neck structures such as the carotid arteries.

Figure 112.3 Representative example of skin flap necrosis—a common wound complication encountered in salvage surgery.

Nonetheless, free tissue transfer has proven feasible in the previously treated patient with similar rates of flap failure (15–17,19,22–24,46). In a study by Choi et al. (16) which compared patient cohorts that had no XRT to those undergoing preoperative or postoperative XRT, no difference in rate or severity of local postoperative complications was noted, but high complication rates were cited in all groups (46% to 65%). Additionally, Cohn et al. (17) examined the use of free tissue reconstruction after twice previous chemoradiation and found that wound complication was common (66%), but flap loss was not (6%). However, of the 24 patients undergoing free-flap reconstruction, four required additional free flaps for wound healing issues, and eight required additional regional flaps for the same.

In contrast, other authors have noted increased free-flap loss in addition to expected delays in wound healing and increased infections in second flap procedures (21). The largest such cohort examined results with 50 second flaps and 12 third flaps and reported 88% and 75% success, respectively, compared with 94% in primary flap surgery (45). Whether the lower success rates are related to vessel selection, flap choice, patient physiology, or other reasons remains speculative.

The emerging sentiment from these studies seems to be that even though free-flap success rates are high, the surgeon should expect some degree of minor wound complication with the potential for more severe healing problems that require second flaps. The small cohort of patients reported by Dubsky et al. (19) lends promise to the concept of double flap reconstruction; they utilized jejunum-free tissue with pectoralis major rotational flaps in the reconstruction of recurrent hypopharyngeal tumors and suffered no flap losses or wound complications requiring further surgical therapy.

The selection of recipient vessels remains a challenge in the previously treated patient; some authors report a 50% rate of contralateral vessel use when previous neck surgery had been performed, necessitating long vascular pedicles in reconstruction (47). In addition, the surgeon must be prepared to utilize out of field recipient vessels if the health of in-field vessels is suboptimal. Particularly in the previously irradiated and surgically treated neck, the internal mammary artery and transverse cervical arteries and veins should be held in reserve, and saphenous vein grafts may be necessary (17) (Fig. 112.4).

Figure 112.4 A RFFF is demonstrated here. The vascular pedicle has been lengthened by the addition of saphenous vein grafts to the radial artery and the two venae comitantes.

Few papers exist specifically addressing the use of free flaps in the salvage setting. Below is a summary of pertinent literature on the use of free flaps in previously treated patients. Some reference is made to larger series that include treated and treatment naïve patients in the interest of completeness.

Nasopharynx/Skull Base/Paranasal Sinuses

Intergroup Study 0099, a phase III randomized controlled study comparing chemoradiotherapy to XRT alone for nasopharyngeal carcinoma (NPC), established chemoradiation as the primary treatment of NPC (48). Recurrent nasopharyngeal HNSCC occurs in approximately 30% of patients; treatment options include reirradiation with either external beam or brachytherapy or nasopharyngectomy (49). Survival following reirradiation ranges between 16% and 45% with 5-year local control of 50% to 60%. Reirradiation of locally recurrent NPC has been well described in the literature. The inaccessibility and the reluctance of many centers to undertake nasopharyngectomy have led to a large experience in the management of local failure. The patients with local recurrence do well with nasopharyngeal retreatment. Mortality rates are less than 5%. Patients who have limited volume or current disease may be treated with break therapy and also have excellent local control rates.

While local control rates with reirradiation can be achieved, the patient population often is preselected. Patients will have significant morbidity secondary to the tumor as well as from the treatment. The definitive answer to the role of reirradiation awaits being answered by a multiinstitutional controlled study. Nasopharyngectomy results in survival between 4% and 67% with local control from 43% to 67% (50). QOL studies indicates that nasopharyngectomy using the anterolateral or maxillary swing approach results in acceptable outcomes (51,52).

When larger resections of the nasopharynx, skull base, or paranasal sinuses are necessary, a free flap may be required to reconstitute nasal–cranial separation or to cover vital structures. As nasopharyngectomy must remove the nasopharynx, pterygoid musculature, Eustachian tubes, and pre-/post-styloid tissues, it is often performed via an anterolateral approach which also provides access for reconstruction (53). In 2005, Bridger et al. (53) studied 11 patients who underwent nasopharyngectomy for recurrence, seven of which were reconstructed with radial forearm free flaps (RFFF). The facial vessels were used as recipient artery and vein, and there were no instances of flap loss. The authors felt that the inset of free flaps was feasible when anterolateral approaches were used, but recognized the potential for bone loss with this approach with later need for bone replacement. Following extensive nasopharyngectomy, it is important to reline both the skull base and parapharyngeal space to avoid carotid and brain exposure whenever possible.

Skull base tumor resections require extensive reconstruction particularly when performed in the setting of previous surgery or radiation as regional tissue may not be suitable for use (54). A large series of patients who underwent craniofacial resection with free-flap reconstruction was reported by Chiu et al. in 2008 (54). In this series from Memorial Sloan-Kettering Hospital, the rectus abdominis myocutaneous flap was used in 68 patients, a radial forearm in one, and latissimus flap in one; all 70 free flaps survived. It is difficult to separate complications that are directly related to free-flap surgery; however, early and late complication rates were similar to reports that did not use free-flap reconstruction (54). Speech, oral intake, globe position and vision, and aesthetics were all assessed postoperatively with acceptable results. Cerebrospinal fluid (CSF) leak was avoided in 93% percent of patients. Weber et al. reported on the Oregon Health and Sciences University Hospital experience and reported similar results with the use primarily of radial forearm (25), rectus abdominis (12), latissimus (4), and one each of anterolateral thigh (ALT), scapula, serratus anterior, and ulnar flaps for post-surgical or post-traumatic defects. In their study, seven patients (18.4%) required second flaps for flap death (3), partial necrosis (2), pneumocephalus (1), or tumor recurrence (1) (55).

Although these groups did not specifically address results in recurrent disease, it is known that complication rates are higher in this setting; the University of Michigan has published results with the use of free flaps in recurrent skull base resections (15). Chepeha et al. performed free-flap reconstructions on 20 patients following recurrent tumor surgery. All patients underwent radial forearm flap surgery, six with bony components for orbital rim reconstruction. Local complications were common (35%), but major complications were rare (15%), with only one instance of CSF leak. Complications attributed to reconstruction were CSF leak (5%) and venous compromise (5%)—both were resolved with single reoperation. Given the usually high rate of major complication with skull base surgery (27% to 75%), and even higher incidence in patients with previous treatment, the use of free tissue seems to improve results (15).

Review of these studies suggests that free flaps may reduce complication rate and severity in surgery for recurrent nasopharyngeal and skull base. When the degree of resection dictates reconstruction, free tissue should be considered safe and potentially useful in wound healing.

Oral Cavity

The oral cavity encompasses the following subsites of the head and neck: lip, buccal mucosa, lower alveolar ridge, retromolar trigone, upper alveolar ridge and hard palate, and floor of mouth and anterior tongue. Because the oral cavity is essential in the handling of food boluses, taste, and speech, microsurgical reconstruction of the oral cavity has emerged as a well-established and effective technique for rehabilitation following primary ablative procedures in these areas (56). The 5-year survival for oral cavity cancer is 46% to 59%, but is significantly related to site and stage, Stage I—53% to 90%, Stage II—54% to 100%, Stage III—37% to 71%, and Stage IV—15% to 50% (57). Primary surgery is common for tumors of the oral cavity, and postoperative XRT is employed frequently; therefore, recurrences occur in an irradiated, previously operated field.

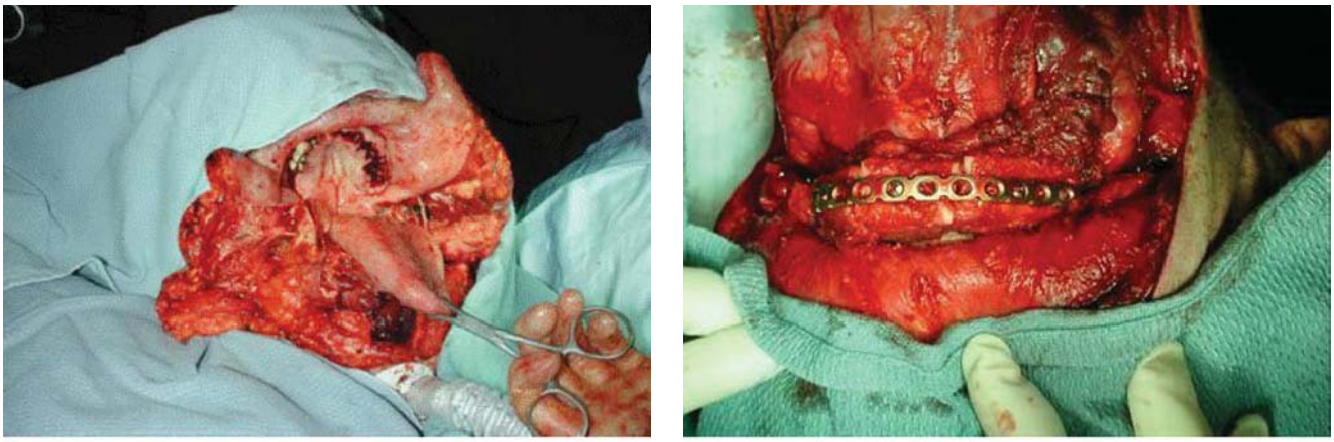
Local recurrences generally require more aggressive ablative procedures, and locoregional tissues are less available due to prior surgery and/or radiation. Thus, microvascular free-flap reconstruction is frequently employed to reconstruct re-resected structures. Often, initial surgery will have resulted in a prior reconstruction with a free flap. However, second flap surgery has been shown feasible with acceptable results for both soft tissue and bone reconstruction (56,58). In the largest study of second free flaps for recurrent cancer, Demirkan et al. (56) studied 35 patients who underwent a total of 75 free tissue transfers for their first and second reconstructions. Second resections were reconstructed with more bone flaps since the second resection more frequently required segmental mandibulectomy. Flap survival rate was 94.6% in salvage surgery with a re-exploration rate of 13.5% (56). The same group also demonstrated that a third flap after a third resection is feasible (59). In contrast, Ross et al. (45) recently showed that free-flap success rates decline for second flaps (88%) and third flaps (75%) compared with primary flaps (95%) in their series of patients.

Evidence suggests that free-flap reconstruction in the oral cavity allows the patient better opportunity for functional rehabilitation than local flap closure (25). Swallowing data from the Khariwala et al. study showed that free-flap reconstruction of the buccal mucosa, or mandible, resulted in no significant impact on swallowing. These patients tended to have normal or soft solid diets. In addition, few patients with ventral tongue or hemiglossectomy defects were unable to swallow after microvascular reconstruction (19% to 22%). Total glossectomy defects had much worse swallowing results and will be addressed as part of the oropharynx subsite. A large number of these patients underwent prior treatment, so this study gives the best estimate available of swallowing outcomes after salvage surgery with free-flap reconstruction in the oral cavity. In addition, decannulation rates are in the 85% to 100% range and are superior to pedicled flaps in this regard (60).

Optimal free-flap choice for oral reconstruction is debatable. Some authors suggest ALT flaps are superior to RFFF because they do not sacrifice a major blood vessel and are usually primarily closed (61). However, flap selection should consider the donor site defect as well as the optimal reconstruction on an individual defect basis. The majority of oral cavity defects may be reconstructed with ALT or RFFF. More extensive defects may required musculocutaneous free tissue transfer as in the case of through and through resections involving buccal mucosa and cheek skin. A special consideration is that of bony defect in oral cavity reconstruction. Bony reconstitution is best for long-term function and can be accomplished with fibula free flaps, osteocutaneous RFFF, iliac crest free flaps, or scapula free flaps (Fig. 112.5). Each has relative merits and should all be considered part of the armamentarium of reconstructive flaps available to the surgeon—these are further explored in a section on ORN reconstruction later in this chapter. Regardless of flap choice, successful rehabilitation of speech and swallowing requires mobile tongue and ability to use it in the transit of a food bolus through the oral cavity.

Oropharynx

Chemoradiation protocols are well established as upfront organ-sparing treatments for Stage III and IV tumors of the oropharynx and N2–N3 neck disease (62). No trials exist that have compared surgery and reconstruction to organ-sparing treatment as an upfront treatment; however, when compared with historical data, chemoradiation affords increased overall survival, disease-free survival, and locoregional control over radiation alone or surgery. With a reported 66% rate of locoregional control, roughly a third of patients will go on to require surgery in a heavily treated bed. Thus, salvage surgery, when viable, should be coupled with reconstruction



A B

Figure 112.5 This patient presented with recurrent oral cavity tumor that required surgical resection. **A**: Oral cavity resection including the floor of mouth and angle-to-angle mandibulectomy. **B**: A fibula free flap was used to reconstruct the soft tissue defect and the bone.

to employ vascularized tissue in the form of rotational or free flaps. More recently, several retrospective reviews have begun to investigate the role for upfront surgery in the form of transoral robotic surgery, transoral laser surgery, or traditional open surgery for oropharyngeal cancers (63–66). However, many patients still undergo postoperative radiation or chemoradiation protocols, and salvage surgery will still occur in the radiated field for these patients.

Literature exists to suggest primary closure of oropharyngeal defects in the untreated patient affords improved swallowing of liquids, less pharyngeal residue, and shorter pharyngeal delay times on videofluoroscopic studies compared with patients undergoing myocutaneous rotational flaps or free flaps (43). In the previously treated patient, especially when chemoradiation has been employed, there is little disagreement among experts that local tissue is not often a viable option for large defects. In smaller resections for T1 recurrent disease, primary closure or local flaps are still an option. Examples of local options include primary closure, buccal flaps, facial artery myocutaneous flaps, tongue flaps, palatal island flaps, and submental island flaps. Compromised vascularity, fibrosis, and limited viable tissue make local reconstructions difficult in previously treated beds. Rotational flaps should be considered in the reconstructive ladder when assessing the oropharyngeal defect. However, recent data suggest that function is improved with free-flap reconstruction over rotational flaps (25). The authors prefer reconstruction of most oropharyngeal salvage defects with free-flap reconstruction. Information on free-flap success for oropharyngeal salvage is sparse; however, most of the patients in Kim et al. series were oropharyngeal reconstructions, and a high rate of success was encountered (no free-flap failures) (22).

Shiley et al. examined 30 patients treated by chemoradiation for advanced-stage oropharyngeal cancer. They reported that 82% of patients required g-tubes at some point in their treatment. After 1 year of follow-up, patients without recurrence required g-tubes 31% of the time to maintain their weight. In contrast, a study from the same institution that reviewed patients treated by surgery involving free-flap reconstruction reported that 50% of patients were g-tube dependent. While the number was small, the patients that are salvageable can be expected to achieve relative good swallow function when considered in the context of their prior treatment status.

Depending on which subsites (tongue base, tonsil, pharyngeal walls, soft palate) of the oropharynx and adjacent structures (mandible) are involved in a resection, the optimal free flap used in reconstruction may vary considerably (44). As previously mentioned, operations in the previously chemoradiated field are associated with increased rate of complications, some of which can be catastrophic. Therefore, the goal of reconstruction is to reconstitute the deficient tissue in a functional way, circumvent complications such as fistula, and avoid compromise of the adjacent normal tissue and its functions. The tongue base requires bulky reconstruction to allow for its function in propelling food boluses posterior by abutting the oropharynx. When adjacent oropharynx is involved with a resection, a more complex three-dimensional reconstruction is important to preserve function and swallowing. As expected, when multiple subsites of the oropharynx are involved in a resection, swallowing tends to be poorer with a 59 times greater likelihood of poor swallowing outcomes (25). RFFF allows for resurfacing of large area of defect without adding excess bulk that might impede breathing or swallowing while affording a long vascular pedicle that can reach second or third choice donor vessels often employed for salvage surgery. The radial forearm flap may also be transferred as a sensate flap to aid in swallowing. Alternatives include the lateral arm flap, or ALT, both of which tend to be of thicker caliber, with shorter pedicle length; however, they may be useful in reconstruction of the tongue base where bulk is desirable (44).

Important QOL outcomes following oropharyngeal reconstruction with free flaps have been evaluated and indicate excellent results. The vast majority of patients achieve tracheotomy decannulation (44). Khariwala et al. found that over 70% of reconstructed patients achieve the ability to swallow after oropharynx resection and free flap. However, the total glossectomy defect is unique in that no patients were able to resume oral intake (25). Total glossectomy defects combine oral cavity and oropharyngeal resections and have poorer swallowing results than for either site alone. A bulkier flap can be effective at providing tissue to oppose the pharynx and soft palate in attempts to swallow; however, it is infrequently sufficient alone to rehabilitate swallowing. In addition, an increased risk of aspiration is associated with this defect and reconstruction, therefore resulting in fewer decannulations (44).

Larynx

Level I evidence now exists to establish concomitant chemoradiotherapy as an accepted method for definitive organ preservation treatment in advanced laryngeal cancer based on multiple important studies starting with The Department of Veterans Affairs Larynx Trial as well as Radiation Therapy Oncology Group Trial 91-11 (RTOG 91-11) (1,8). In a follow-up study to RTOG 91-11, Weber et al. examined a cohort of 129 patients from the trial that required total laryngectomy (TL) after an attempt at upfront organ preservation strategy (67). The incidence of TL was 5% for aspiration of chondronecrosis with the remaining TL for recurrence or persistence. The incidence of complications was 52% to 59%, with fistula formation in 15% to 30%. The concomitant chemoradiotherapy group experienced minor complication rates of 41% and major complication rate of 5%. Locoregional control was 74% to 90% depending on upfront treatment. Thus, data support an upfront nonsurgical management strategy for organ preservation with excellent salvage rates for persistent or recurrent disease. Hence, the heavily treated salvage bed scenario is frequently encountered in salvage laryngeal surgery.

Free tissue transfer is a useful adjunct in salvage TL surgery that has been shown to reduce the risk of leak and complication. Fung et al. reported results from the University of Michigan in which patients undergoing salvage laryngectomy after failed radiotherapy or concurrent chemoradiotherapy received free-flap reconstruction to reinforce the pharyngeal flap closure (patients that required skin paddle for closure were excluded). These patients were compared with a historical control of 27 patients from RTOG 91-11 with the same eligibility criteria but did not undergo free tissue reinforcement. The fistula rate was comparable between groups, but the rate of major wound complication was reduced from 14.8% without a flap to 0% in the flap group (20). Further, Winthrow et al. demonstrated that even when sufficient mucosa is present to close the defect primarily, free-flap reconstruction results in a lower rate of fistula (18%), stricture (18%), and feeding tube dependence (23%) than primary closure (50%, 25%, and 45%, respectively) (24). In their series, the free flap was used as a patch to supplement the anterior post laryngectomy defect and take it off tension; 16 were RFFF, and one was a rectus.

The RFFF is well suited for reconstruction of the post laryngectomy defect (Fig. 112.6). It is thin and has adequate pedicle length to reach multiple donor vessel choices. Thicker fasciocutaneous flaps are less desirable due to the relative fibrosis of posttreatment skin and inability to close it well primarily with added bulk. Both the Michigan series and Winthrow et al. relied primarily on forearm flaps with good success. The authors advocate for the use of this flap given its success. Based upon the two studies described, swallowing results are good overall following laryngectomy with free-flap closure and represent an improvement over primary closure alone. When the laryngectomy is extended to include partial or total pharyngeal defects, the reconstructive options change as described in the hypopharynx section below. Others studies have confirmed that pectoralis muscle flaps either to provide coverage of the pharyngeal repair or as a patch graft also if effective means of preventing leaks (68–70).

Partial laryngeal surgery appears oncologically safe in some sets of circumstances in recurrent laryngeal cancer (71–74). No data exist to support the use of free flaps in this setting; however, as more conservation surgery is employed, these data will likely follow. Currently, free fasciocutaneous tissue is used at our institution on a case-by-case basis with data forthcoming on its relative benefits.

Hypopharynx

Recurrent tumors involving the hypopharynx presumably extend the tissue deficit after resection and the need for free tissue to reconstitute the swallowing tract. Multiple small series demonstrate the feasibility of total laryngopharyngectomy with free-flap reconstruction with acceptable functional and wound outcomes (19,75,76). Disease-specific survival at 5 years is low in recurrent hypopharyngeal carcinoma (20%) (13,77). When resection is possible, free tissue has provided a tool to decrease severe complications, shorten hospital stay, and speed time to resumption of oral intake as compared with pedicled (78).

QOL studies confirm that the use of free jejunal tissue transfer in the reconstruction of total laryngopharyngectomy (TLP) defects results in acceptable QOL with mildly perceived clinical dysphagia; however, radiologic assessment often showed disturbed bolus transport through the jejunal segment. The radiologic and clinical findings did not seem to correlate suggesting that the flap functions well even when radiographic tests suggest abnormal swallowing (75).

Most series that directly investigate post-CRT or XRT-free tissue reconstruction of TLP are too small to remark

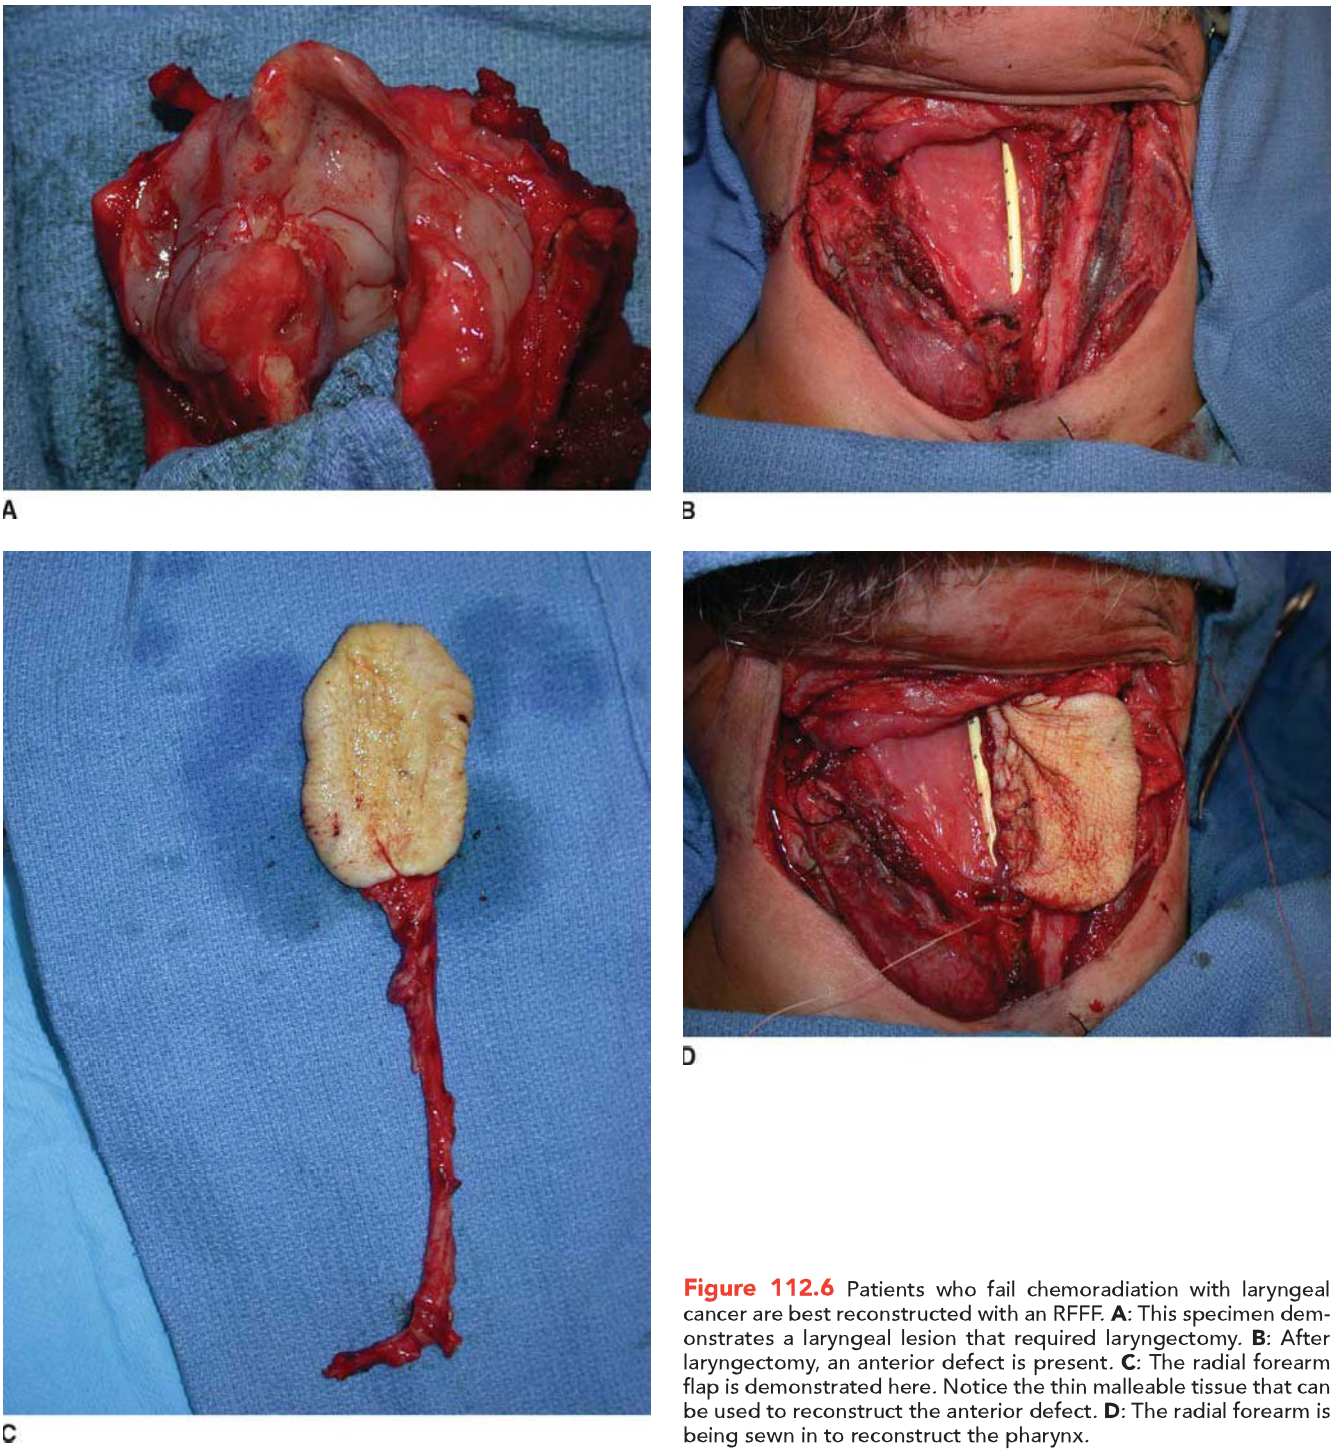


Figure 112.6 Patients who fail chemoradiation with laryngeal cancer are best reconstructed with an RFFF. **A**: This specimen demonstrates a laryngeal lesion that required laryngectomy. **B**: After laryngectomy, an anterior defect is present. **C**: The radial forearm flap is demonstrated here. Notice the thin malleable tissue that can be used to reconstruct the anterior defect. **D**: The radial forearm is being sewn in to reconstruct the pharynx.

on complication rates; however, the series' sited state that the perioperative courses were unremarkable—no significant complications occurred after jejunal free tissue was transferred. The possibility of soft tissue breakdown led Dubsky et al. to provide additional coverage with a pectoralis major rotational flap when they performed TLP with jejunal free flap with no complications. However, it is unclear whether this is necessary without direct comparison to cases in which no regional flap was used. In another study, the use of a second jejunal free flap after failed first surgery was proven feasible—an important consideration in surgery for recurrent disease in which a first flap may have already been utilized (79).

The jejunal free flap is well suited for large segment reconstructions of the TLP defect with extension to the cervical esophagus (Fig. 112.7). The flap can be harvested in a two-team approach, and bowel complications are rare following the harvest. The flap is easily transferred to the head and neck on large-caliber vessels that usually result in one draining vein and one feeding artery. Additional flap choices have been described and include tubed radial forearm or ALT free flap. The disadvantage of tubed skin flaps

Figure 112.7 Patients with recurrent hypopharyngeal cancer or extensive laryngeal lesions may require total laryngopharyngectomy. **A**: This photograph demonstrates a defect after total laryngopharyngectomy. **B**: The jejunum is harvested based on a single vascular pedicle. **C**: Enough jejunum is used to reconstruct the pharyngeal defect and to provide for an external monitor.

is in their lack of mucous-secreting glands and peristalsis that comes along with jejunum. Therefore, at our institution, the jejunum is preferred when possible. However, Genden reported good success with the tubed ALT without any stenoses in 12 patients, compared with 3 stenoses out of 11 radial forearm flaps (80). The low complication rates associated with fasciocutaneous flaps and elimination of abdominal complications have led some authors to suggest that these flaps are preferred. As more functional data emerge, the question of what flap to use will be clarified, but it remains clear that single stage reconstruction is best for patients to regain function and QOL fast.

A significant local complication is that of an anastomotic leak. Leaks are difficult to treat as they often result in a local infection in a poorly vascularized bed. Neck wraps are not useful as the vascular pedicle may be compressed. Therefore, local wound care with fistula packing, antibiotics, and observation is preferred. Some patients will require second operations to address the leak with salivary diversion or bypass followed by delayed reconstruction. This scenario seems to be rare in the reported literature, but anecdotal reports of frequent local wound problems are found.

UNRESECTABLE

There exists a subset of patients who are not candidates for surgical resection, having failed primary chemoradiation. This may be on the basis of a technically unresectable disease, being medically unfit due to a significant comorbid condition, or patient refusal to undergo significant,

long-term debility because of the sacrifice of multiple structures. In this select group of patients, reradiation may be the only potentially curative treatment. Two Phase II studies using chemotherapy and reirradiation have been performed by the RTOG. Survival rates of between 8.5 and 12 months, with a 2-year survival rates of 15% to 25%, were obtained. Of significance was the acute toxicity that developed in all patients. Death was seen in 5% of patients undergoing these secondary treatments. Grade III and IV toxicity occurred in more than half of the patients. No QOL information was available from these studies or in the literature. Certainly in selected cases, reirradiation may be indicated. Chemotherapy as a single modality of treatment in the salvage patient has not been shown to be efficacious in prolonging life. Short-term local response is possible but not maintained.

Figure 112.8 This panorex demonstrates the classic findings of a destructive lesion of the mandible secondary to ORN. Tumor has been ruled out.

USES OF MICROVASCULAR SURGERY IN THE MANAGEMENT OF CRT COMPLICATIONS

Osteoradionecrosis

Chemoradiotherapy modalities may result in long-term tissue fibrosis and ORN. When conservative measures are unsuccessful at resolving pain, tissue loss, or pathologic fractures, a more aggressive approach is warranted. Previous studies have established antibiotic treatment and hyperbaric oxygen treatment as a first-line treatment in management of early ORN (34,81–83). However, the degree of necrosis observed following concurrent chemo radiotherapy (CCRT) may exceed the ability of conservative therapy to cure, in which case surgical treatments may be required. Mandibular reconstruction for nonhealing ORN has grown in favor owing to its ability to remove necrotic tissue and restore dental function (84). The fibula, scapula, and iliac crest free flap have been shown to be useful in the reconstruction of the mandible and can serve to reconstitute the entire mandible including the temporomandibular joint (85).

The pathogenesis of ORN of the mandible has been alluded to previously; it occurs as the result of a complex interplay between impaired bone healing ability, load bearing stress on the mandible, and the frequent need for post-XRT dental extractions that result in chronic infection and fracture (35). In recent years, there has been a downward trend in occurrence likely due to increased awareness of the implications of ORN and management by multidisciplinary teams accustomed to dealing with post-CCRT-type patients.

Causes of ORN include dental extractions, spontaneous, surgery related, and from prosthetics in descending order of frequency (86). Diagnosis of ORN is both clinically and radiographically based. However, a universal staging system is lacking in the literature (87). Diagnosis requires the absence of recurrent disease as a prerequisite (which may occur in 10% to 21% of ORN cases), the observation of exposed bone and/or deficient mucosal covering, and lytic x-ray changes on panorex or maxillofacial computed tomography (CT) (88). Often, biopsy is performed of the questionable area as it can be difficult to differentiate recurrence from necrosis (84) (Fig. 112.8).

Treatment for ORN begins with prevention. Superior oral care is paramount to maintain the health of existing teeth and prevent progressive deterioration of those that are beginning to decay. Care of xerostomia, oral rinses, gum care, and prosthetic care should be adhered to carefully. Marx' protocols appear to be capable of managing early ORN with acceptable cure rates (83). However, one recent review and meta-analysis by Wahl indicated that prophylactic hyperbaric oxygen is not of clear benefit in ORN prevention (86). Once ORN segments occur, local treatment can be viewed as a stepwise effort starting with minor surgical intervention such as sequestrectomy and ending with major reconstruction and segmental resection +/– soft tissue resection and reconstruction. Microvascular reconstructive options have expanded the ability to restore bone and remove bone in the process of necrosis in order to speed the recovery and rehabilitation of suffering patients.

The ability to use free tissue in reconstruction is not impeded by use of prior hyperbaric oxygen, and therefore, conservative therapies should not be bypassed (89). However, if a reconstruction is performed, it is best to resect all questionable bone segments to avoid the need for later surgery when marginal bone necroses. QOL studies indicate that mandibular reconstruction afforded by free flaps results in significant improvements in cosmesis and swallowing function (14).

Reconstructive options following ORN resections include osteocutaneous free tissue or fasciocutaneous free tissue without bony reconstitution of the mandible. The

osteocutaneous free flap serves as an excellent tool in the surgical management of mandibular ORN as it is best served to restore long segments of resected bone. Among the options, radial forearm, fibular, scapular, and iliac crest flaps are best described. Osteocutaneous forearm flaps are extensively utilized by the group at University of Kansas in the management of segmental mandibulectomy defects and have therefore been studied in the setting of ORN reconstruction (90). In a pair of publications, Militsakh et al. showed that osteocutaneous radial forearm flaps for mandibular reconstruction result in low rates of complications, good restoration of mandibular continuity, and resumed PO diet intake. In addition, they found that the forearm osteocutaneous flap afforded comparable morbidity at the primary and donor site and functional outcomes to that of patients reconstructed with fibular or scapular free flaps (91). Critics of radial forearm reconstruction cite the risk of pathologic radius fracture and inability to place dental implants as the major deterrents to routine use of this flap for ORN.

The workhorse of oromandibular reconstruction is the fibular free flap (Fig. 112.9). It provides a long segment (up to 20 cm) of solid bone stock capable of angle-to-angle reconstructions and large soft tissue paddles for orocutaneous fistula separation (89). The Chang Gung Memorial Hospital experience with 780 fibula flaps for segmental resections of the mandible effectively established the merits of a lengthy bicortical bone with long, large-caliber pedicles, minimal donor site morbidity, and the ability to sculpt the donor tissue to suit the defect (92). Success of this flap in the setting of ORN is well established, although, so is a high rate of wound complication (21% to 43%) and resultant protracted healing (89, 93). With a rate of flap loss that is higher than that of other free tissue defect reconstruction, it is wise to counsel patients of the potential need for second free flaps and comparable morbidity with the first flap (58). Studies exist that suggest removing the temporomandibular joint and reconstructing with free fibular bone with or without an Alloderm covering may be functionally better than attempting to achieve bone–bone union with a small segment of condyle (85, 94).

Scapular or iliac crest free flaps are also established means of mandibular reconstruction. The scapula flap can provide sufficient bone for unilateral body defects, but must be harvested in the prone position after resection has occurred. It also affords the advantage of multiple skin paddles, should both intraoral and external skin be required to replace badly damaged, or chronically fistulized tissue. Similarly, the iliac crest provides adequate bone for hemimandible defects and additional muscle and cutaneous tissue for soft tissue reconstruction (95).

Figure 112.9 This patient had ORN that required surgical resection. **A**: The dead bone has been resected back to living healthy bone. **B**: A radial forearm osteocutaneous free flap has been used to reconstruct the bony defect. **C**: A postoperative panorex shows good bony union.

The psychological impact of surviving one's cancer only to be handicapped by treatment sequelae cannot be ignored, and free tissue affords surgeon's the ability to restore what is lost to an extent. However, it seems clear that ORN surgery comes with a significant risk of complication (21% to 43%) and flap loss (0% to 14%), and thus, should not be offered without restraint or until deemed absolutely necessary (84,89).

Chondroradionecrosis

The application of free tissue transfer in the management of CRN is less well established. The Chandler classification, established in 1979, is still widely accepted as the standard grading system for CRN ranging from I to IV depending on symptoms and signs present. Previously, Grades III and IV frequently resulted in TL, but recent advances in conservative therapy, including antibiotic treatment and hyperbaric oxygen (HBO), have limited this practice (35). When necessary, TL with free-flap reconstruction can rehabilitate patients suffering from debilitating pain and swallowing handicaps. Some emerging evidence suggests that partial laryngeal surgery is oncologically sound for laryngeal cancer recurrence with acceptable wound complications, and therefore, these techniques may be employed for CRN in similar fashion. Adjunctive fasciocutaneous free flaps should decrease fistula rates in partial laryngeal surgery in the post-XRT setting similarly to their role in TL (71–74). This finding suggests that revascularization of cartilage may occur through the free tissue and may represent a viable method to reverse CRN short of requiring laryngectomy, but no literature has yet been published to support this use.

CONCLUSIONS

Microvascular free tissue transfer has revolutionized the field of head and neck surgery and added greatly to the ability to treat recurrent disease that would otherwise have left patients with debilitating tissue loss. Free tissue may be applied in an organized fashion to allow for reconstruction of most head and neck subsites, and the review above indicates that this approach remains viable even in the previously treated patient. With the greater use of non-surgical upfront treatment for HNSCC, recurrences increasingly occur in settings where native tissue is not sufficient for reconstruction after ablation. Therefore, regional, and now free flap, reconstructions have become the standard of care for bringing healthy tissue into the treated bed. High success rates and improving functional results underscore the impact of free tissue on ablative surgery for recurrence. Although recurrent HNSCC carries a poor prognosis, when surgery is an option for cure or treatment sequelae, free tissue remains a strong ally in the overall care of these patients.

HIGHLIGHTS

- Chemoradiation affects all the tissue of the head and neck adversely and will lead to a greater incidence of operative wound complications.
- Oftentimes the only option for salvage of a failed chemoradiation protocol is surgery.
- Reconstruction of the salvage patient is best accomplished with free tissue transfer.
- Surgical ablation will yield a complex composite defect that can be reconstructed with composite tissue to achieve adequate functional and cosmetic outcomes.
- Reconstruction of patients with complications from primary treatment for head and neck cancer is efficacious but complex.

Cutaneous Malignancy

113

Cherie-Ann O. Nathan *Timothy S. Lian*

Skin cancer is the most common human malignancy, with an estimated 3,500,000 nonmelanoma skin cancers cases in the United States annually (1). Most tumors arise on the sun-exposed regions of the head and neck. Basal cell carcinoma is the predominant histologic type and accounts for about 90% of all cutaneous neoplasms in the head and neck region. Second in incidence is squamous cell carcinoma. Less common is melanoma, which accounts for approximately 8,700 deaths each year in the United States. There are 3,000 additional deaths related to other forms of cutaneous cancer (2). Cutaneous malignancies are classically divided into epidermal, dermal, adnexal, and melanocytic. Malignant melanoma has a distinct biologic behavior and is addressed separately in Chapter 114. Other rare skin malignancies of the dermis and adnexa are not discussed specifically, but principles of evaluation and treatment of cutaneous cancers are applicable. This chapter is dedicated to a discussion of nonmelanoma cutaneous malignancy, specifically basal cell carcinoma, squamous cell carcinoma, Merkel cell carcinoma (MCC), their precursors, and associated epidermal neoplasms.

RISK FACTORS

Risk factors for basal and squamous cell carcinomas are strikingly similar. These lesions, although seen in younger age groups, are most often encountered in patients 60 years of age or older.

The mechanism by which ultraviolet (UV) light causes sun-damaged skin has been extensively studied. Laboratory experiments indicate that the wavelengths with the most potential for carcinogenesis are those in the range of 280 to 320 nm, the UVB band. This UVB is responsible for the common sunburn. The transition from normal to actinic (i.e., sun damaged) to cancerous skin is usually a progressive process that occurs over several decades. With the current environmental changes occurring with the earth's protective ozone layer, the concern for skin cancer becomes much more significant. A dramatic ozone depletion above the Antarctic continent has been detected (3). For each 1% reduction in atmospheric ozone concentration, there is a concomitant 2% increase in UVB penetration (4). Approximately 90% of nonmelanoma skin cancers are estimated to be associated with exposure to UV radiation from the sun (5).

The carcinogenesis of epidermal tumors parallels the multistep development of other neoplasms. As with other neoplasms, certain characteristics render the host more susceptible to the development of cancer. Traits that are associated with an increased incidence of skin cancer include fair complexion, light hair, blue or green eyes, inability to tan, propensity to sunburn, history of multiple or severe sunburns, and Celtic ancestry (6). Other factors implicated include age, occupation, habits (tanning booths), and residential geography, which are considered indirect causes of increased sun exposure.

The bulbs used in tanning booths are almost exclusively UVA wavelength and are promoted as providing a safe suntan. However, recent evidence indicates that UVA (320 to 400 nm) synergistically augments UVB responses and is independently capable of producing deleterious skin alterations and neoplasias (7).

Other etiologic factors are associated with the development of cutaneous carcinoma (6). Chronic exposure to chemical agents, such as arsenic in patients treated with Fowlers solution, has been associated with the development of multiple squamous and basal cell tumors. Patients with chronic radiodermatitis, resulting from superficial radiation therapy, demonstrate a propensity to develop multiple and aggressive lesions. Trauma in the form of burns, ulcers, and scars is also associated with the development of skin cancer (i.e., Marjolin ulcer). Immunosuppression, common in transplant patients and patients with leukemia or lymphoma, can be complicated by an increased incidence or aggressiveness of skin malignancies (8).

Studies of human papillomavirus offer additional support for the importance of immune dysfunction in the development of skin squamous cell carcinoma. One study showed human papillomavirus presence in 60% of cutaneous squamous cell carcinoma lesions found in renal autograft recipients. Moreover, human papillomavirus presence was significantly higher than that found in matched transplant recipients without cutaneous malignancy (9). Furthermore, there is evidence to suggest that human papillomavirus may be related to the development of some nonmelanoma cutaneous malignancies not necessarily associated with immune suppression.

Genetic syndromes, such as xeroderma pigmentosum (autosomal recessive) and nevoid basal cell carcinoma syndrome (autosomal dominant), are associated with a predilection for developing multiple basal cell carcinomas, often at an early age.

BASAL CELL CARCINOMA

There are several clinical types of basal cell carcinoma. Smith (10) outlined five clinical forms: nodular or noduloulcerative, morphea-like or sclerosing, superficial multicentric, pigmented, and fibroepithelioma. Although other less common types exist, subclassification is not clinically useful. The most common type is the nodular or nodulouloulcerative lesion. This lesion typically presents as a discrete, raised, circular lesion that appears pink and waxy with a capillary network that is easily visible. There is often an area of central ulceration and the border of the lesion is rolled. This is the type of basal cell carcinoma that is easiest to recognize and treat. A variant of this lesion is cystic basal cell carcinoma, which is also waxy and well demarcated but is more cystic in appearance.

The superficial basal cell carcinoma lesion shows evidence of scarring and atrophy, with a thread-like waxy border. This lesion may consist of one or several red scaling patches. These crusted lesions have irregular borders and gradually increase in size by peripheral extension. They are relatively uncommon in the head and neck and more frequently occur on the trunk or extremities.

The most aggressive clinical form of basal cell carcinoma is the morphea type, also called sclerosing or fibrosing basal cell carcinoma. This variety is typified by its macular, whitish, or yellowish plaque. Some physicians have noticed an increased incidence among women. The margins may be quite indistinct, and the lesion may go unnoticed for years in some patients. Complete excision is difficult because of ill-defined margins. The lesion may look like a scar, may develop telangiectasia, or may ulcerate.

A less common basal cell carcinoma variant is pigmented basal cell carcinoma, which is characterized by its brown pigmentation and may resemble a pigmented nevus or a melanoma. The appearance and behavior of this lesion seems to parallel that of nodular basal cell carcinoma. Pigmented basal cell carcinoma differs from the nodulouloulcerative type only by the brown pigmentation of the lesion. This type of lesion may also be mistaken for seborrheic keratosis, melanoma, or dermatofibroma.

Fibroepitheliomas, another variant, present as firm pedunculated lesions that resemble fibromas. It was first described in 1953 by Pinkus (11). These lesions commonly occur on the back.

The nevoid basal cell carcinoma syndrome is an autosomal dominant disease. During childhood, small cutaneous nodules appear, often numbering in the hundreds. These lesions initially have a rather indolent course during the nevoid phase, but as the patient ages, a neoplastic phase may occur in which the lesions show a marked change in aggressiveness. The lesions become invasive, destructive, and mutilating. Abnormalities associated with nevoid basal cell carcinoma syndrome include jaw cysts, bifid ribs, scoliosis, mental retardation, and frontal bossing.

The characteristic cell in basal cell carcinoma has a large, oval, or elongated nucleus with relatively little cytoplasm. These cells may resemble the basal cells of the epidermis, but the neoplastic forms lack intercellular bridges. The nuclei are rather uniform in size and configuration. A connective tissue stroma proliferates with the tumor and is oriented in parallel bundles around the tumor masses, causing peripheral palisading of the cells and stromal retraction. This is commonly referred to as peritumoral lacunae. The stroma is often mucinous. Because mucin shrinks with dehydration and fixation of the specimen, the stroma may show retraction from the tumor islands. This detachment of tumor islands from the stroma is known as clefting and is a helpful diagnostic sign.

Lever (12) divided basal cell carcinoma into four basic histologic patterns: solid, keratotic, cystic, and adenoid. In the solid pattern, the cells show no differentiation. This type generally displays tumor masses of various sizes and shapes embedded in the dermis (Fig. 113.1). The peripheral cell layer may show a palisading of the nuclei. Basal cell carcinomas that differentiate toward hair structures are referred to as keratotic. This lesion is typified by undifferentiated cells in combination with parakeratotic cells and horn cysts (Fig. 113.2). Cystic tumors show differentiation toward sebaceous glands. Histologically, there may be one or several cystic spaces within the tumor lobules. In the adenoid variety of basal cell carcinoma, the tumors display a tubular or glandular formation. The strands of epithelial cells commonly form a lace-like pattern (Fig. 113.3).

Keratotic basal cell carcinoma, also known as basosquamous cell carcinoma or metatypical carcinoma, has been the subject of much controversy. The confusion arises because histologically there are coexistent features of both basal cell and squamous cell carcinomas in the same lesion, frustrating accurate assessment of prognosis and behavior. Most dermatopathologists currently believe that basosquamous tumor is a variant basal cell carcinoma, referred to by many as keratotic basal cell carcinoma (12). Although there is limited potential for metastasis, keratotic basal cell carcinoma is thought to be more biologically aggressive than many of the other types of basal cell carcinomas.

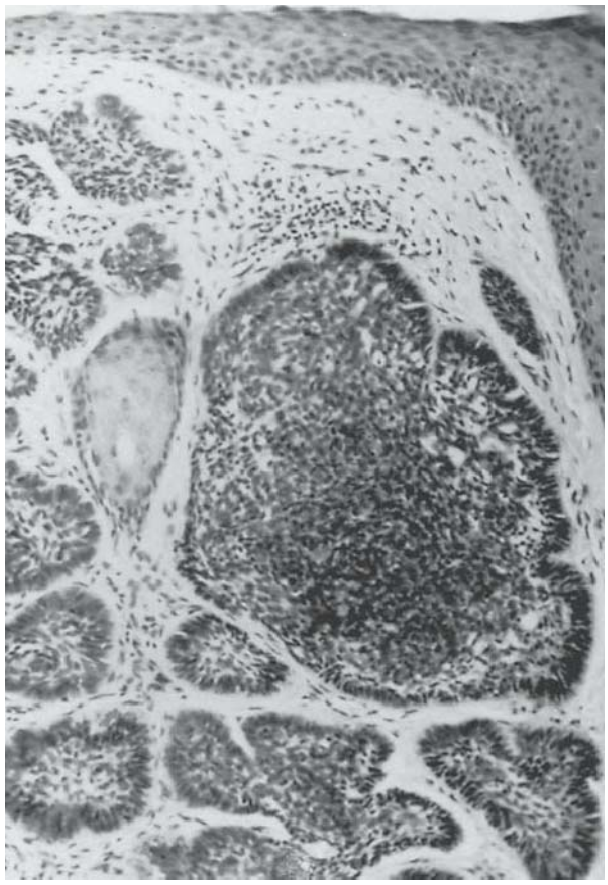

Figure 113.1 Basal cell tumor masses (solid type).

SQUAMOUS CELL CARCINOMA

Far less common than basal cell carcinoma, squamous cell carcinoma accounts for approximately 10% of skin malignancies. As with its counterpart, basal cell carcinoma, squamous cell carcinoma is related to chronic (i.e., 10 to 20 years) sun exposure. As the equator is approached, the relative incidence of squamous cell carcinoma increases compared with basal cell carcinoma. Cutaneous squamous cell carcinoma, like basal cell carcinoma, is more common in men.

Squamous cell carcinoma of the skin usually presents as an erythematous, ulcerated, crusting lesion. The tumor often demonstrates a granular base that may be friable and tends to bleed with minimal trauma. There is usually an elevated area of induration at the lesion edge and there may be an inflammatory response in the adjacent tissues.

These lesions present in different patterns. Squamous cell carcinoma can present as a thickened hyperkeratotic patch or an area of crusting. Under this crust is an ulcerated base with a rolled margin. Other lesions may be recognized as areas of persistent ulceration, possibly in the site of previous trauma, burns, or an old scar (i.e., Marjolin ulcer). Neoplastic change in a chronic ulcer may result in basal cell or squamous cell carcinoma and is associated with a poorer prognosis and higher rates of metastasis. Superficial multifocal lesions can arise in actinic skin. These lesions are usually accompanied by a scaling patch that bleeds with minimal trauma. Diagnosis and determination of the extent of the lesion can be difficult, and multiple biopsies may be necessary. Squamous cell carcinoma occasionally presents as a nodular exophytic lesion. Initially cystic, it later tends to become ulcerative and progressively enlarges. These lesions may also demonstrate a sudden growth spurt.

Several histologic characteristics are important in analyzing squamous cell carcinoma. The usual histologic picture of squamous cell carcinoma of the skin is that of irregular masses of epidermal cells that proliferate downward and invade the dermis. The tumor masses may be well differentiated or may show atypical or anaplastic cells. The differentiated tumors tend to be associated with evidence of keratinization, such as keratin pearls.

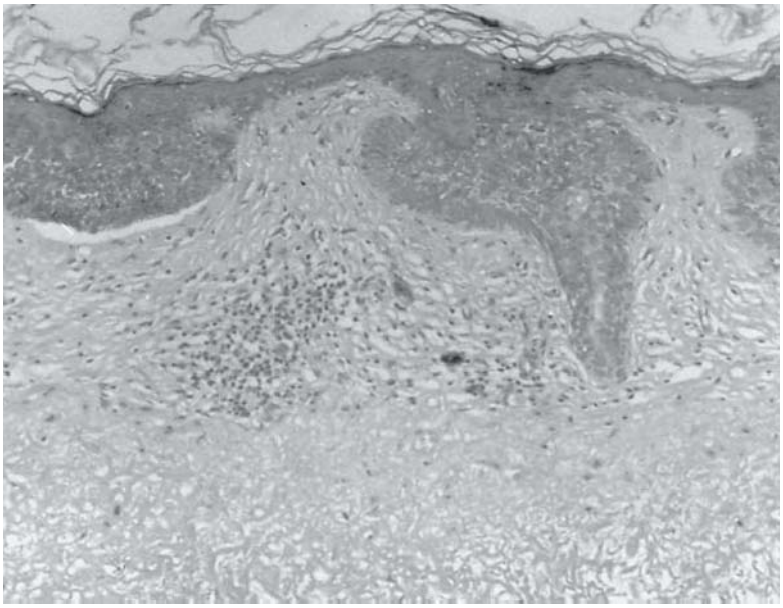

Figure 113.2 Undifferentiated cells with parakeratotic and horn cysts (keratotic type).

Figure 113.3 Lace-like patterns of epithelial cells (adenoid type).

Some squamous cell carcinomas are actinically induced, and some arise *de novo*. Lesions arising in sun-exposed areas appear to follow a more benign course with a low incidence of metastasis. The *de novo* lesions are more aggressive in their behavior and exhibit greater potential for metastasis. It has been estimated that up to 54% of patients with *de novo* lesions develop regional or distant metastases (13). It is often possible to differentiate clinically between the two types of squamous cell carcinoma. Histologically, a determination can usually be made by looking for actinic changes in the skin adjacent to the squamous cell carcinoma.

Squamous cell carcinoma has metastatic potential, and regional metastatic spread is correlated with depth of invasion. Squamous cell carcinoma lesions that penetrate to Clark level IV or V are associated with a 20% regional metastatic rate.

Histologic variations of squamous cell carcinoma are numerous and include adenoid, bowenoid, verrucous, and spindle–pleomorphic types (14). The generic type is characterized by actinic changes. In the adenoid type, there is a pseudoglandular arrangement. These tubular or alveolar formations result from dyskeratosis and subsequent acantholysis. The lumina are lined with one or several layers of epithelium and are filled with desquamated acantholytic cells. The bowenoid type of squamous cell carcinoma is characterized by evidence of invasion coexistent with the findings of Bowen disease.

Verrucous carcinoma is seldom seen as a skin neoplasm on the head and neck, but it is well known as a tumor of the oral cavity and larynx. It presents as a white cauliflower-like lesion. The tumor is well differentiated, demonstrating hyperkeratosis, parakeratosis, and acanthosis. Clinical and pathologic correlations are needed to confirm the diagnosis.

In the spindle–pleomorphic type of squamous cell carcinoma, there is little evidence of differentiation. These tumors are anaplastic, show little or no keratinization, and are usually considered to be a Broders grade 4 tumor. The spindle cells are intermingled with collagen, may be arranged in whorls, and can be associated with pleomorphic giant cells.

PREMALIGNANT LESIONS

Several skin lesions are considered premalignant. This group includes a low-grade malignancy that can be treated as if it was a premalignant lesion. The most common of these are actinic keratosis, Bowen disease, and keratoacanthoma.

Actinic Keratoses

Actinic keratoses (i.e., solar keratoses or senile keratoses) is the most common premalignant lesion of the head and neck and is seen almost exclusively in sun-exposed areas of the skin. The lesions are generally less than 1 cm in diameter and are commonly located on the face, scalp, hands, and forearms (Fig. 113.4). They are considered precancerous. The chance of progression to epidermal cutaneous carcinoma has been estimated to be as great as 20% (12). They usually present as an erythematous patch, often covered by an adherent scale. Clinically, they show little or no sign of inflammation. Occasionally, there is a marked hyperkeratosis, giving the appearance of a cutaneous horn. A sandpaper-like scale is the most distinctive feature on clinical examination. Because these lesions have malignant transformation potential, most physicians believe they should be treated. Depending on the clinical setting, superficial shave excision, cryosurgery, topical treatment

Figure 113.4 Actinic keratosis on forehead.

with 5-fluorouracil, or trichloroacetic acid peel may provide effective treatment. The differential diagnosis includes seborrheic keratosis, benign lentigo, squamous cell carcinoma, and basal cell carcinoma.

Bowen Disease

Bowen disease is considered a preinvasive form of squamous cell carcinoma. It can be considered synonymous with carcinoma *in situ* of the skin. Histologically, there is full-thickness dysplasia of the epidermis without evidence of invasion. Clinically, the lesion presents as a well-circumscribed, erythematous, scaly patch or plaque with an irregular border. As with squamous cell carcinoma, these lesions generally occur in sun-exposed areas. They are particularly common in patients with a history of chronic arsenic ingestion in whom lesions often occur on nonexposed skin. The lesion may resemble a superficial basal cell carcinoma, but it lacks the fine pearly border.

Keratoacanthoma

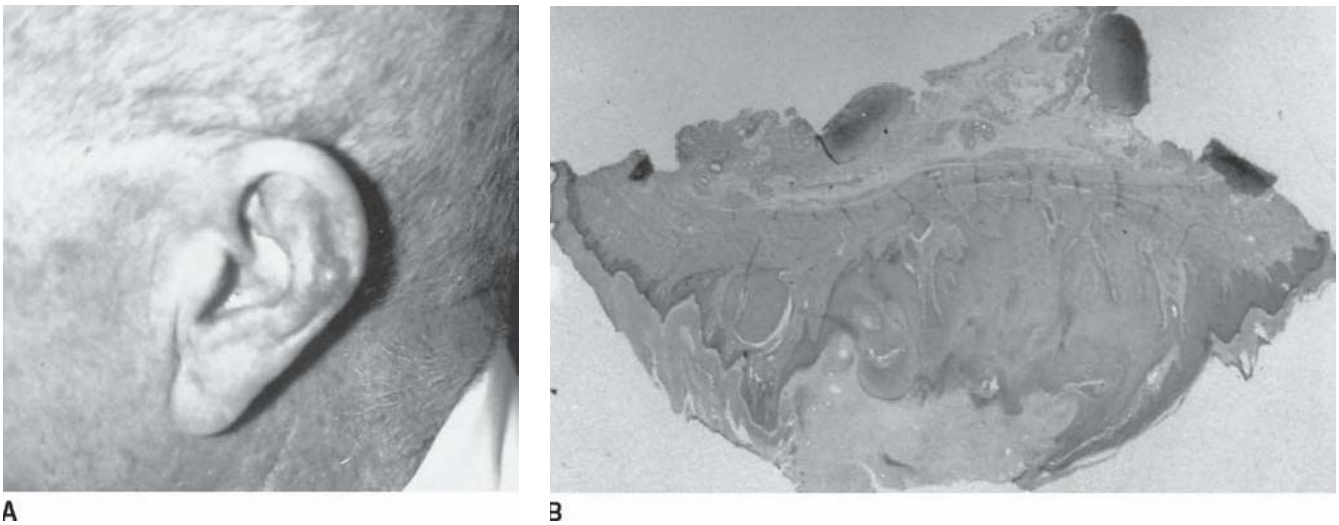
Keratoacanthoma is a benign usually self-limited epithelial tumor that is easily confused clinically and histopathologically with squamous cell carcinoma. It is more common in males and typically presents in older patients. There is a history of rapid growth, usually over 2 to 6 months. The lesion begins as a smooth rounded nodule, but with further enlargement, the center becomes ulcerated and filled with keratinous material, taking on a volcano-like appearance. The hallmark of keratoacanthoma is rapid growth over weeks or months.

The most common site affected is the nose. Although histologically the lesion resembles a squamous cell carcinoma (Fig. 113.5), it may involute spontaneously, leaving only a depressed scar. Because of the lack of predictability, surgical excision is recommended.

TUMOR BEHAVIOR

Staging for cutaneous basal cell carcinoma and squamous cell carcinoma has been defined by the American Joint Committee on Cancer using the TNM classification as shown in Table 113.1 (15). Tumor histology, local extent or infiltration, tumor size, anatomic site, associated risk factors (e.g., age, prior irradiation, genetic syndromes), and previous treatment must be considered in determining the risk of recurrence for a given lesion. High-risk features include depth and extent of invasion, anatomic location, and histologic differentiation (Table 113.2).

The clinical and histologic types are significant prognostic variables. The morphea type of basal cell carcinoma is well known for its subversive attitude. This lesion generally spreads centrifugally by way of finger-like projections



A B

Figure 113.5 **A:** Keratoacanthoma of the auricle. **B:** Histologic volcano-appearance.

TABLE 113.1 AJCC CLASSIFICATION FOR CUTANEOUS SQUAMOUS CELL CARCINOMA AND OTHER CUTANEOUS CARCINOMAS (EXCLUDING THE EYELID)

Primary tumor (T)
- TX: Primary tumor cannot be assessed.
- T0: No evidence of primary tumor
- Tis: Carcinoma *in situ*
- T1: Tumor 2 cm or less in greatest dimension with less than two risk features
- T2: Tumor >2 cm or tumor of any size with two or more high-risk features
- T3: Tumor with invasion of the maxilla, mandible, orbit, or temporal bone
- T4: Tumor with invasion of the skeleton (axial or appendicular) or perineural invasion of the skull base

Regional lymph nodes (N)
- NX: Regional lymph nodes cannot be assessed.
- N0: No regional lymph node metastasis
- N1: Metastasis in a single ipsilateral lymph node, 3 cm or less
- N2a: Metastasis in a single ipsilateral lymph node, more than 3 cm but not more than 6 cm
- N2b: Metastasis in multiple ipsilateral lymph nodes with none more than 6 cm
- N2c: Metastasis in bilateral or contralateral lymph nodes with none more than 6 cm
- N3: Metastasis in a lymph node more than 6 cm

Distant metastasis (M)
- M0: No distant metastasis
- M1: Distant metastasis

of tumor. It is deceptive in its behavior and can be difficult to evaluate and control. Keratotic (i.e., basosquamous), recurrent basal cell, and spindle cell variants of squamous cell carcinomas are also associated with worse prognoses. Poorly differentiated or undifferentiated tumors are considered high-risk features for staging purposes.

Squamous cell lesions can be virulent. They have the potential to metastasize to regional nodes and are sometimes associated with distant metastases. Locally, these tumors are more likely to grow in a vertical fashion and less likely to respect the barriers of cartilage and bone than basal cell carcinoma. It is prudent to evaluate the regional lymphatic drainage when dealing with squamous cell carcinoma. Tumor thickness greater or equal to 2 mm, Clark level IV or greater, and perineural invasion are high-risk features with regard to staging.

The anatomic location influences the prognosis because various regions of the head and neck have a propensity for tumor recurrence. Lesions on the nose and ear have higher rates of recurrence, which is probably associated with embryonic fusion planes (16). These embryologic sites of fusion afford greater access for tumors, which use the planes as avenues for spread. The most prominent sites are the preauricular and postauricular regions, the floor of the nose and columella, and the nose–cheek crease. The periorbital region is also at risk for tumors tracking along the bone or periosteum, particularly in the medial canthal region. Mohs (17) speculated that basal cell tumor cells migrate along the periosteum or perichondrium of the nose and the medial canthi because of the close apposition of the skin to the bone and cartilage in these locations.

Swanson (18) determined that the high-risk sites fall within an "H" zone on the face (Fig. 113.6). In highlighting the specific regions at risk, he cited the junction of the ala with the nasolabial fold, the nasal septum, the nasal ala, the inner canthi and lower eyelids of the periorbital region, the periauricular region extending to the temple, and certain scalp lesions. Primary tumor site of the ear or non–hair-bearing lip are considered high-risk features for staging purposes (Table 113.2).

TABLE 113.2 HIGH-RISK FEATURES OF CUTANEOUS SQUAMOUS CELL CARCINOMA AND OTHER CUTANEOUS MALIGNANCIES

Depth/invasion	More than 2 mm of thickness
	Clark level IV or greater
	Perineural invasion
Location	Ear
	Non–hair–bearing lip
Differentiation	Poorly differentiated or undifferentiated

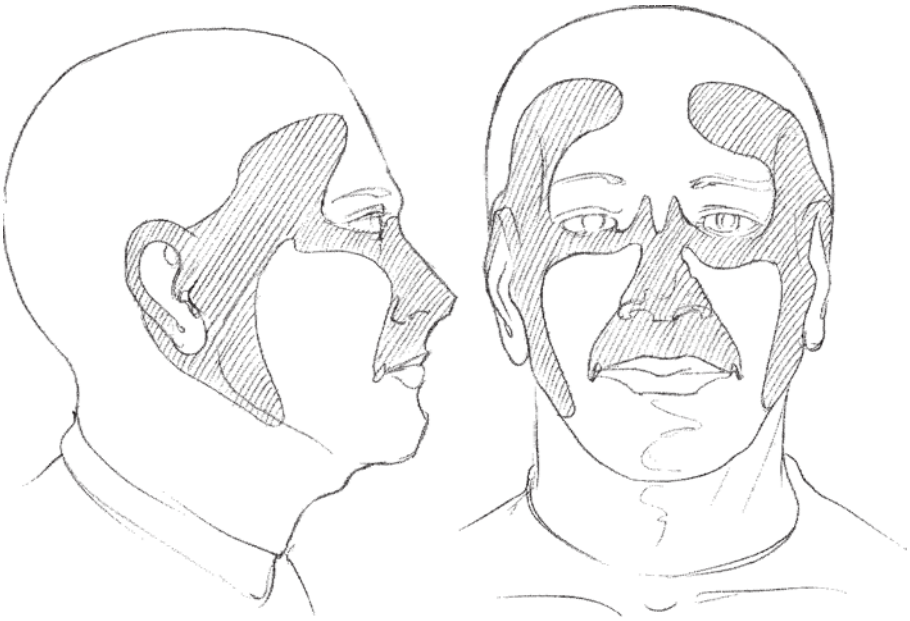


Figure 113.6 H zone: high-risk areas of aggressive cutaneous malignancies. (Adapted from Swanson NA. Mohs surgery: technique, indications, applications, and the future. *Arch Dermatol* 1983;119:761.)

RECURRENT CUTANEOUS LESIONS

A recurrent carcinoma of the skin presents a much more challenging problem than the primary lesion. Recurrent cancer indicates inadequate initial therapy or a persistence of disease in the tissue adjacent to the original lesion. Levine and Bailin (18) evaluated 496 cases of recurrent basal cell carcinoma in an attempt to identify significant risk factors. They found the midface region was involved in 57.6% of the cases and the auricular and preauricular areas accounted for 13.4% of the recurrences. The nose is the most common location of recurrence (25.5% to 41%). The relative risk for recurrence was calculated in one study for different locations (19). In order of decreasing magnitude of risk, the locations are the nose (2.38), the ears (1.43), the periorbital areas (1.17), the remainder of the face (1.04), and the neck and scalp (0.55). The distribution of these recurrent tumors is shown in Figure 113.7. It is suggested that treatment of positive margins in the immediate postoperative period may decrease the recurrence rate and thus avoid a more extensive treatment if the cancer were to recur (20).

Jackson and Adams (21) described 33 cases of extensive basal cell carcinoma. These lesions were large (greater than

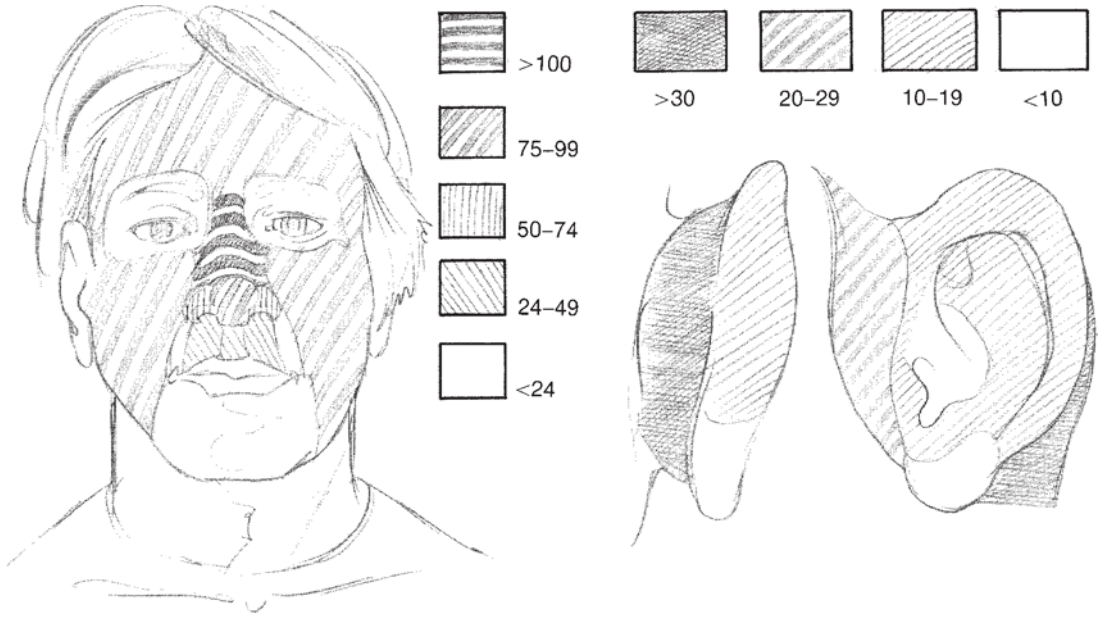

Figure 113.7 Distribution of recurrent cutaneous malignancies.

3 cm), destructive, locally uncontrollable, or metastatic. In defining the predominant characteristic of each lesion, they found that 18 were large, 6 destructive, 5 locally uncontrollable, and 4 metastatic. They concluded that these neglected tumors usually had an onset before age 40 and recurred more than twice despite adequate treatment and that each recurrence appeared sooner and became larger than the preceding tumor. In many patients, underlying conditions predisposed them to cutaneous basal cell carcinoma, including arsenic ingestion, nevoid basal cell syndrome, preexisting burns, and radiodermatitis.

Levine (22) studied the pathogenesis and treatment of large recurrent cutaneous neoplasms. The advanced lesions, called massive or previously uncontrolled, met one or more of the following criteria: diameter greater than 3 cm, involvement deeper than skin and subcutaneous fat, four or more previous treatments without control, or proven metastatic disease.

MANAGEMENT OF CUTANEOUS SQUAMOUS CELL AND BASAL CELL CARCINOMA

An advantage of nonsurgical management of primary skin malignancies is cure rates reported in excess of 95% for selected skin malignancies. These nonsurgical modalities use field therapy for their mechanism of treatment. Skin cancers grow both radially and vertically in a predictable and proportional manner. Field therapy uses these growth characteristics to treat a defined area containing both tumor and a surrounding layer of normal tissue.

Curettage With Electrodesiccation

One of the most common treatments for basal cell carcinoma is curettage excision combined with electrodesiccation, also known as electrosurgery or electrodesiccation with curettage. It is used primarily by dermatologists, who manage most of these lesions, and is quite successful when used appropriately, yielding cure rates of 81% to 97% (23).

The rationale for using this modality is that basal cell and squamous cell tumors have a soft feel that can be detected as a lesion is curetted. In experienced hands, this allows the removal of all palpable tumors with different sizes of curettes. After normal-feeling tissue is encountered over the entire base of the excision, electrodesiccation or fulguration of the wound is performed. This process is completed from two to six times, and the wound is treated topically and allowed to heal by second intention.

The advantages of electrosurgery include maximal sparing of normal tissue, ease of performance, and expediency. The disadvantages include care of an open wound, depressed or hypertrophic scarring, and delayed bleeding. Electrosurgery should be used only in selected lesions, usually basal cell lesions less than 2 cm in diameter. Contraindications for this treatment modality include lesions with deep invasion, morphea-like and sclerotic basal cell carcinomas, and recurrent tumors. If squamous cell tumors are treated by this modality, they should be carefully selected.

Cryosurgery

Cryosurgery is another treatment option that may be appropriate for some basal cell lesions. As with electrosurgery, the skill and experience of the treating physician are critical. The most common cryogen used is liquid nitrogen. A temperature of at least 30°C is considered to be lethal to cutaneous malignant tissue, although some surgeons consider −50°C to be more appropriate. The tumor and an area of surrounding tissue are frozen to ensure the adequacy of the ablation. A thermocouple inserted at the margin of the treatment area ensures that the proper temperature for cell killing is reached. The tissue is allowed to thaw, and after an appropriate period, the freeze–thaw cycle is repeated.

Proponents of this technique cite as advantages its high cure rate, tissue-sparing capabilities, and expedience (24). It is thought to be useful in tumors overlying cartilage that can be frozen without undergoing necrosis. It may be particularly useful in patients with multiple lesions. The disadvantages include a prolonged healing phase and wound care. Hypopigmentation and unsatisfactory scarring can occur. Its use should be limited to lesions with well-defined borders and should not be used for morphea-like tumors or recurrent skin cancers.

Radiation Therapy

Radiation therapy has the capability of effectively treating skin cancers successfully and has been used extensively in the past (25). As more expedient and less radical methods of treatment have become popular, its use in recent years has waned. The advantages of irradiation include the ability to treat a wide field of tumor and avoidance of surgery. The disadvantages include the protracted treatment course, expense, adjacent tissue effects, limited effectiveness if tumors involve cartilage or bone, and the possibility of radiodermatitis and delayed carcinogenesis. Radiation therapy is currently used in the treatment of poor operative candidates, as an adjuvant to surgery, or for palliation in advanced lesions. It can be curative, but careful selection of lesions and patients is crucial.

Photodynamic Therapy for Cutaneous Malignancy of the Head and Neck

Photodynamic therapy (PDT) is a therapeutic modality using a photosensitizing drug that selectively localizes in tumors and that, on being activated by exposure to light, causes preferential tumor necrosis. Despite its initial promise, PDT remains an investigational modality at the present time. The two components needed for this therapy

are a photosensitizer drug and a laser to activate the drug. The most widely used drug in head and neck has been porphyrin. Some of the other drugs that have been used as photosensitizers are tetracyclines, fluorescein, rhodamine, and more recently sulfonated metallophthatlocyanines. The light source consists of a laser either delivered down a fiber for surface illumination (which is the technique of choice for superficial cancer) or implanted into the substance of the tumor (used for bulky tumors). The argon ion dye pumped laser is most commonly used in North America.

Review of the literature reveals that initially this treatment was used predominantly for palliation of advanced skin cancer. Most series reveal a dramatic initial response in many patients, but long-term follow-up was rarely possible because of the advanced nature of these cancers (26). The response was variable and unpredictable, and severe pain and skin necrosis were common. A major problem in evaluating the literature is the tremendous variability in technique, drug, and light dosage in the reported series.

The advantages of PDT are that multiple lesions can be treated at the same time, it has good cosmetic results, and no anesthesia is required. The disadvantages include lack of predictable response in more advanced lesions and occasional photosensitivity. Once the technique has been further refined, it has great potential in the management of skin cancers.

Interferon-Alpha

Interferon-alpha (IFN-α) has been demonstrated to be useful for the treatment of select primary skin cancer. Studies demonstrated that basal cell carcinoma of the nodular and superficial types shows excellent responses (27,28). Treatment is typically initiated with low-dose intralesional IFN-α three times a week. Local reactions include pain and persistent erythema. The most common side effect is a flu-like illness, the symptoms of which respond to acetaminophen. Hematologic side effects include leukocytopenia and thrombocytopenia.

The mechanism is believed to be due to the antiproliferative and immunomodulating properties of interferon. Through a nonspecific stimulating effect on macrophages and natural killer cells, localized administration of IFN-α focally increases the host response to the neoplastic tissue.

Excisional Surgery

Surgical excision for cutaneous neoplasms is the modality with which most head and neck surgeons have the most experience. The success rate for this method of treatment is 86% to 97% (29). The major advantages of excisional surgery include the ability to obtain tissue for diagnosis and to assess the completeness of excision. By use of frozen sections, the surgeon can evaluate the margins of excision histologically. Another benefit is the excellent cosmesis, particularly if defects are amenable to primary closure. The disadvantages are that excisional surgery can be more time consuming, inconvenient, and expensive for the patient than other treatments. Most surgeons believe that the histologic confirmation of the adequacy of excision outweighs these relatively minor disadvantages. The carbon dioxide (CO_2) laser can also be used for excision of cutaneous carcinomas.

Mohs Surgery

Mohs pioneered a new technique for removal of cutaneous neoplasms while he was a medical student in the 1930s. His first results were published in 1941, and the new modality was dubbed chemosurgery technique (30). With this method, zinc chloride paste (a chemical fixative) was applied to the cancer, fixing it *in situ* and permitting careful serial excisions with examination of the entire specimen histologically. This permitted him to map extensions of residual tumor, so that reexcision of these pockets of cancer was possible. The cure rates associated with the technique range from 96% to 99% (30,31). Tromovitch and Stegman (32) revised the original technique and used a fresh-tissue technique that adhered to the same tenets of serial excisions and mapping of residual tumor deposits. The nomenclature for the techniques has now evolved to the point that Mohs chemosurgery implies a fixed tissue technique and Mohs micrographic surgery indicates use of the fresh-tissue technique. Most dermatologic surgeons now use the fresh-tissue technique, commonly called Mohs surgery. Details of the technique are published in numerous sources (30,31). A schematic of this process is shown in Figure 113.8.

The advantages of Mohs surgery lie in its ability to examine the resection margins in their entirety, unlike routine or frozen-section margins that evaluate a random sampling of margins. Microscopic foci of tumor can be identified, mapped, and reexcised with this technique. It also allows removal of the neoplasm with maximal preservation of surrounding normal tissue. Another benefit of the Mohs fresh-tissue technique is the ability to immediately reconstruct the defects that have been created. The major advantage is that this technique has the highest cure rate in the management of advanced, high-risk, or recurrent lesions. Mohs surgery is most useful in the high-risk lesions. The disadvantages of the Mohs technique are the special expertise, time, and expense involved. Someone with this special training may not be available in all communities. These drawbacks are compensated for by achieving a disease-free status.

Carbon Dioxide Laser

Laser excision is appropriate in the management of some skin malignancies. It is indicated instead of standard excision for patients whose cardiac status or other medical

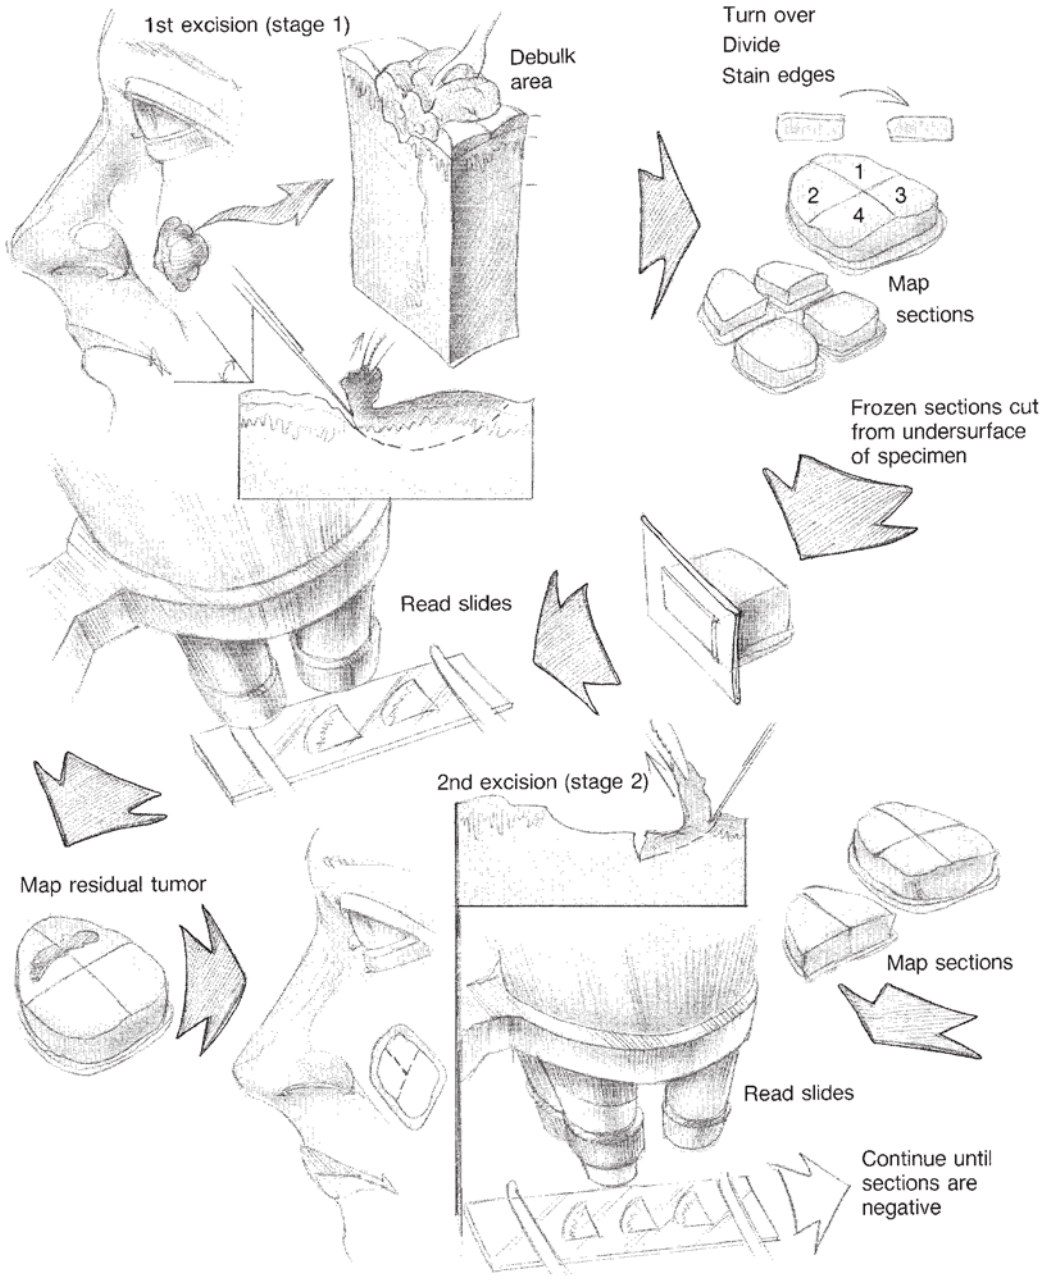

Figure 113.8 Schema used by micrographic cutaneous tumor excision. (Modified from Mohs FE. Microcontrolled surgery for skin cancer. In: Epstein E, Epstein E, eds. *Skin surgery.* Philadelphia, PA: W.B. Saunders, 1987, with permission.)

conditions render it unwise to use epinephrine in the local anesthesia. Lidocaine without the addition of a vasoconstrictor has a duration of approximately 15 minutes, more than adequate time for the few minutes required to resect most facial lesions in a bloodless fashion with the CO_2 laser. If margins are positive, more anesthesia is infiltrated where required and more tissue removed as needed. After margins are determined to be free of tumor, the area of the local flap is infiltrated and the reconstruction carried out. We have also found laser excision to be of benefit in patients with bleeding disorders.

Another indication for use of the CO_2 laser is the resection or vaporization of small multiple lesions that then require no reconstruction. Lesions as large as 7 to 8 mm can be resected bloodlessly and are left with a physiologic dressing that heals completely within 10 days, resulting in excellent cosmesis. This method is particularly effective in managing multiple premalignant or potentially malignant lesions in patients with skin cancer.

Palliation of the neglected lesion in the very elderly or debilitated patient whose skin cancer is of less concern than more major health considerations is carried out with alacrity using the CO_2 laser. These patients often reside in limited-care facilities, and palliation can be directed toward improved nursing care, better patient comfort, and convenience. These goals prompt some type of treatment,

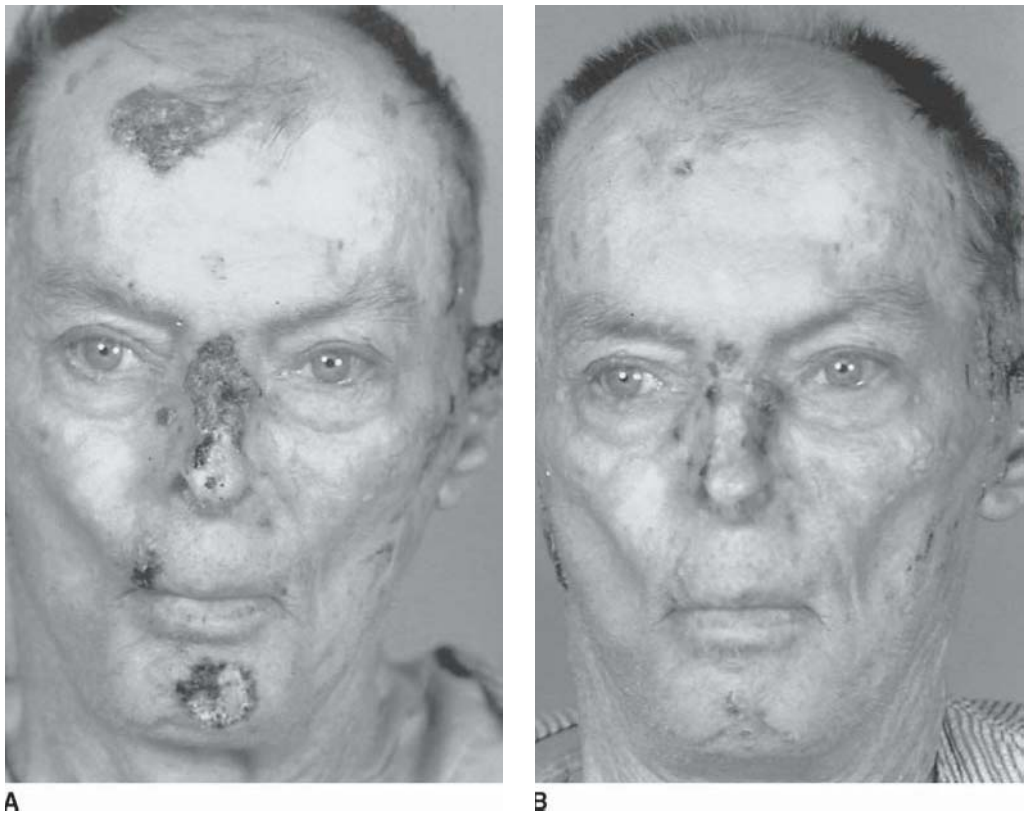

Figure 113.9 **A:** Multiple basal cell cancers palliated with laser. **B:** Six weeks after laser ablation.

although cure may not be realistic or possible (Fig. 113.9). Success rates for the various treatment modalities of basal cell carcinoma are outlined in Table 113.3. Our approach to management techniques is summarized in Table 113.4.

Surgical Reconstruction

There are three fundamental methods of managing the defects created by excisional surgery for skin cancer: no reconstruction, immediate repair, or delayed reconstruction. The first alternative is used if the wound is allowed to heal by second intention or is covered by a graft and the subsequent defect not reconstructed. This may be appropriate for patients who are palliated or who for other reasons are not candidates for reconstruction. Other patients may be candidates or better served with a prosthesis. The surgeon's choice is influenced by many factors, such as the general health of the patient and his or her life expectancy. The location and extent of the lesion and the social situation of the patient may play a role in the decisions concerning reconstruction. Large defects are of little concern to some people, but a minimal defect can be devastating to others.

Functional restoration takes precedence over cosmesis if this choice must be made (e.g., reconstruction of the upper lip to ensure a competent oral sphincter before embarking on a nasal reconstruction). Early reconstruction of nasal ala and eyelid defects is of paramount concern because reconstruction after contracture has occurred is rarely satisfactory.

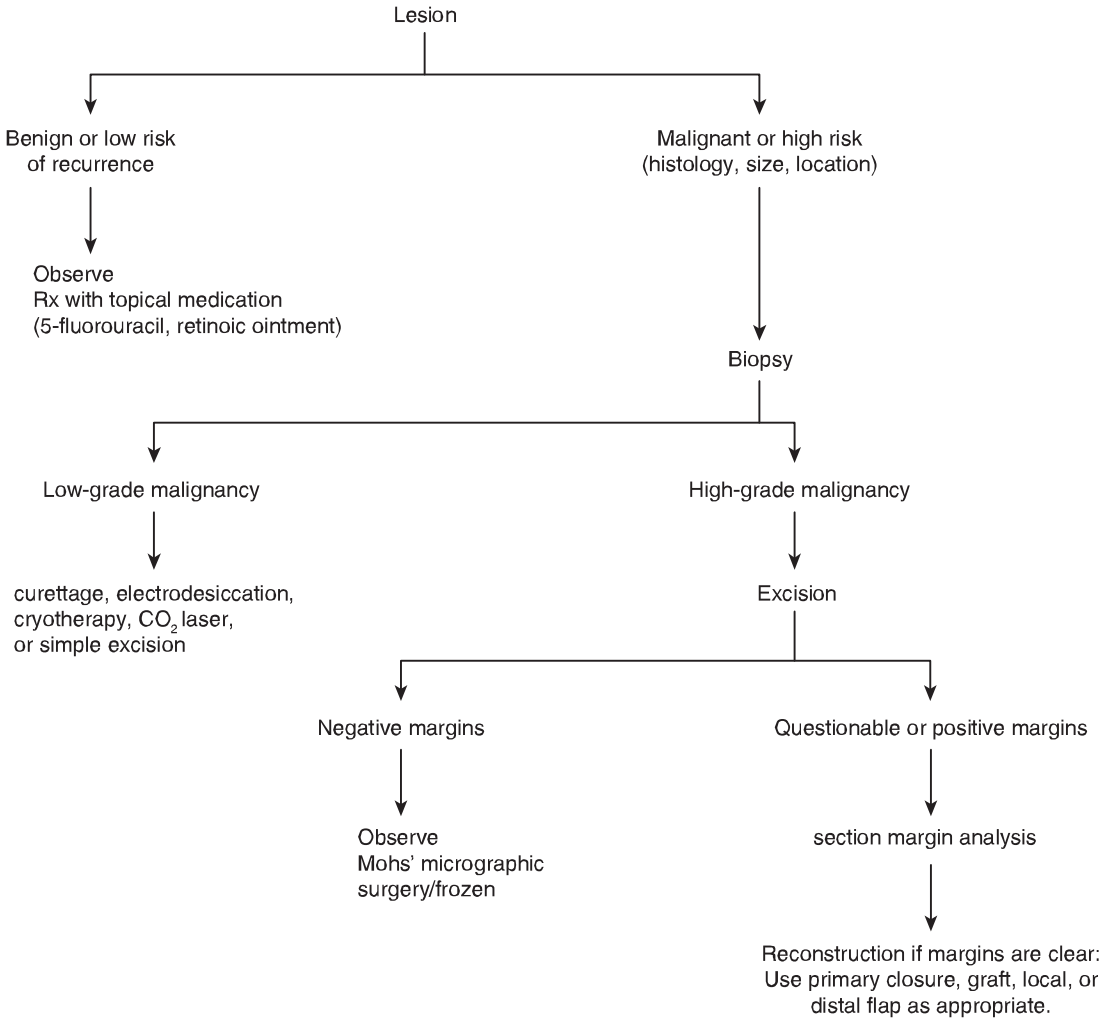
In addition to functional restoration, anatomic, pathologic, and cosmetic considerations influence the surgeon's choice of reconstructive method. Basic to any flap reconstruction is the secondary tissue deficit that, when closed, results in increased tension on the surrounding local tissue. Scar contraction has the potential to distort and create a greater deformity. The use of a skin graft decreases this likelihood by harvesting tissue where there is an abundance, usually some distance from the defect, and substituting this tissue for the resected tumor.

Anatomic considerations control surgical options by imposing constraints such as symmetry, facial landmarks and structures, and the lack of availability of adequate local or adjacent tissue. All flaps create a secondary defect that must be attended to in some manner. This is most often

TABLE 113.3 TREATMENT BASAL CELL CARCINOMA

Treatment Method	Success Rate (%)
Electrosurgery	81–97
Excisional surgery	86–97
Cryosurgery	83–96
Radiation surgery	90–93
Mohs surgery	97–99

TABLE 113.4 TREATMENT CUTANEOUS MALIGNANCIES



done by primary closure, but the surgeon can use another flap or a graft.

Pathologic considerations influence reconstructive choices. The defects related to certain histologic tumor types might best be covered with a skin graft rather than have potential tumor hidden by a thick flap. Questionable margins are another factor that might prompt a more conservative choice. Tumors located in areas known clinically to be more virulent (e.g., medial canthus, nasal spine, external ear canal) might best not be reconstructed with a thick flap. Squamous cell carcinomas of the skin are usually more aggressive and infiltrative than basal cell carcinomas, and this affects their management. An exception to this is the morphea type of basal cell carcinoma, which is infiltrative. Its iceberg-like subdermal extension may make elaborate reconstructive efforts futile and perhaps devastating for the patient. It is wise to defer immediate reconstruction and allow healing by second intention or cover the defect with a skin graft. When the recipient bed has a marginal blood supply, delayed skin grafting is recommended. The wound area is allowed to granulate for 21 days. Then a 1- to 2-mm circumferential strip is removed, followed by cross-hatching of the area. A thick (0.45- to 0.5-mm) split-thickness skin graft is placed. If further reconstruction is needed, it can be undertaken when the patient is confirmed to be tumor free, usually after a period of observation of 1 to 2 years.

Planning Reconstruction

In designing local flap reconstruction, the surgeon must first consider the effects on adjacent tissues and structures. It is essential that the tissue to be moved into the defect is lax and abundant enough to close the surgical void. The donor site must also be closed, usually primarily, without unacceptable consequences to adjacent tissues or structures. Utmost in the surgeon's mind must be the placement

of incisions. Closure lines should be in skin creases, facial structural demarcations, or relaxed skin tension lines. The tension and direction of maximal pull must not distort, create asymmetry, or result in an unacceptable scar. The ultimate contracture of the resulting scars should not create a deformity.

A review of our surgical cases indicates that the most common management after resection is advancement and primary closure. Obviously, this technique is propitious for most small lesions. For those requiring a more sophisticated form of reconstruction, there are several reliable reconstructive options. Reconstruction options and techniques are discussed in Chapters 162, 166, and 169.

Additional Considerations

In dealing with facial cutaneous malignancies, the temptation to avoid disfigurement is great. Unfortunately, this often results in an inadequate excision, dooming the patient to recurrence and quite possibly a much worse prognosis. Perhaps the most important lesson that the Mohs technique has taught us is the insidious behavior of some cutaneous malignancies. Therefore, margins must always be checked and histology confirmed. Questionable margins should not be reconstructed primarily but instead reconstructed at a later date once margin status has been confirmed on permanent histopathologic analysis.

What may originally be considered a simple excision is occasionally complicated by positive margins. The surgeon must be flexible. If the patient is under local anesthesia, general anesthesia may be needed. If the patient was not aware of the extent of the resection and subsequent repair, the surgeon should stage the surgery and discuss with the patient what may be involved. In considering reconstruction, function is always more important than cosmesis. The surgeon should avoid designing flaps that adversely affect function (i.e., cheek flap producing ectropion).

Regional nodal metastasis from cutaneous basal cell carcinoma is rare, occurring in up to 0.5% of patients (33). Nodal metastasis from cutaneous squamous cell carcinoma occurs in up to 12.5% of patients (34). Thus, in dealing with squamous cell carcinoma, regional lymph nodes must be carefully evaluated. Regional nodal metastasis from cutaneous malignancies in the head and neck most frequently involve the parotid nodes followed by upper cervical nodes. For cutaneous lesions larger than 3 cm, neck dissections or adjuvant therapy should be considered. It is mandatory to follow all patients with cutaneous malignancies, and biopsies should be performed for suspicious areas. Follow-up of patients with basal cell carcinoma should be every 6 months for 5 years as just over one-third of patients will develop a second primary basal cell carcinoma within 5 years. In many patients with skin cancers, constant vigilance is the key to a successful outcome. Potential problems and complications that can occur when managing these cutaneous malignancies are outlined in Table 113.5.

MERKEL CELL CARCINOMA

MCC is a rare but aggressive cutaneous malignancy with a mortality rate more than twice that of melanoma. The incidence of MCC is low relative to other cutaneous malignancies; however, the incidence has tripled from 1986 to 2001 representing an annual increase of 8% (35). MCC appears most frequently in those patients who are white with 95% of newly diagnosed MCC occurring in people over 50 years of age. Currently, approximately 1,500 cases of MCC are diagnosed per year (36).

TABLE 113.5 SUMMARY OF THE DIAGNOSIS, MANAGEMENT, AND COMPLICATIONS ASSOCIATED WITH CUTANEOUS MALIGNANCIES

Lesion	Diagnosis	Treatment	Closure	Problems or Complications
Superficial basal cell carcinoma	History of sun exposure, red scaly patches, occasionally central ulceration, rolled border	Small: electrodissection and curettage, cryosurgery, excisional biopsy	Primary if excised	Lesion recurs; large excision with frozen section or Mohs surgery
Morpheaform basal cell carcinoma	Macular rough patch, skip lesions, extension down natural fascial planes	Resection often to bone, including periosteum, frozen sections of deep layers	Delay reconstruction if margins are uncertain	Recurrence common; primary excision is aggressive, possible role for adjuvant therapy
Squamous cell carcinoma	Erythematous and patchy, usually history of actinic keratosis, friable	Evaluate regional nodes, neck dissection and postoperative radiation if indicated	Local flap, graft, or distant flap	Recurrent and large lesions; requires large en bloc resection; failure to identify lymph node involvement

Merkel cells, described by Friedrich Merkel in 1875, are large pale cells found in the basal layer of the epidermis that resemble cells of the diffuse neuroendocrine system and function as mechanoreceptors. Indeed it has been demonstrated that Merkel cells are neural crest in origin. Ultrastructurally Merkel cells are characterized by having projections and cytoplasmic dense core granules facing nerve terminals. Merkel cells are highly specific for cytokeratins to include CK-20 as is MCC; thus, MCC is thought to arise from Merkel cells.

MCC most commonly presents in the head and neck as well as the extremities. Indeed 70% to 90% of case of MCC present in these areas. MCC has a propensity to metastasize to regional lymph node basins with regional disease found in 52% to 59% of patients (37). In the clinically N0 necks, 32% have been found to have microscopic evidence of metastasis (38). Distant metastasis is found in 32% to 34% of cases to include, in order of highest frequency, distant skin, lung, central nervous system, bone, and liver (37). Risk factors implicated in the development of MCC include age greater than 50 years, white skin, suppressed immune system, and overexposure to sunlight/UV radiation to include UVB radiation. Merkel cell Polyomarvirus has been identified in some cases of MCC; however, its precise role in MCC remains to be determined.

MCC characteristically presents in an elderly white individual of either sex. The clinical presentation of the lesion itself can be rather nonspecific; however, a common presentation involves the presentations of a rapidly enlarging, nonulcerative, violaceous, nodular cutaneous, or subcutaneous lesion. Indeed on clinical presentation, MCC is rarely suspected and the diagnosis is only made after biopsy. Light microscopy reveals a small blue cell tumor, and the diagnosis is confirmed with immunohistochemistry using CK-20 (Fig. 113.10). In the head and neck, the periorbital/cheek areas have been reported as the most common sites of involvement. On presentation, 25% of patients have palpable regional adenopathy, and 5% have distant metastatic disease.

With the diagnosis of MCC established via histopathologic analysis of biopsy specimens, workup includes a complete evaluation of the skin and regional lymph nodes. Imaging consists of CT scan, MRI, and PET scanning where appropriate. Primary treatment depends on the staging of MCC as defined by the AJCC (Table 113.6). For lesions where pretreatment staging does not indicate regional or distant metastasis, wide local excision and lymph node assessment is appropriate. Margins ranging from 1 to 2 cm have been advised as well as the use of intraoperative margin analysis to ensure negative resection margins. It has been reported that in the N0 neck, elective lymph node dissection decreased regional recurrence rates and improved survival (39). Pathologic nodal staging is associated with improved survival and a decrease in nodal recurrence. Typically, sentinel node biopsy is performed, and if positive, neck dissection is then performed to optimize the treatment. Postoperative radiation to the primary tumor bed and lymphatics is appropriate to minimize postoperative recurrence. Chemotherapy is typically reserved for those patients with distant metastatic disease.

Despite the method of treatment, the overall recurrence rate ranges from 40% to 75% with over 90% of recurrences occurring within 2 years of the initial diagnosis of MCC. The overall 5-year survival is 30% to 64%; however, those who have developed distant metastasis have an 11% 2-year survival rate (40). Median survival for patients with regional nodal metastatic disease is reported as 11 months.

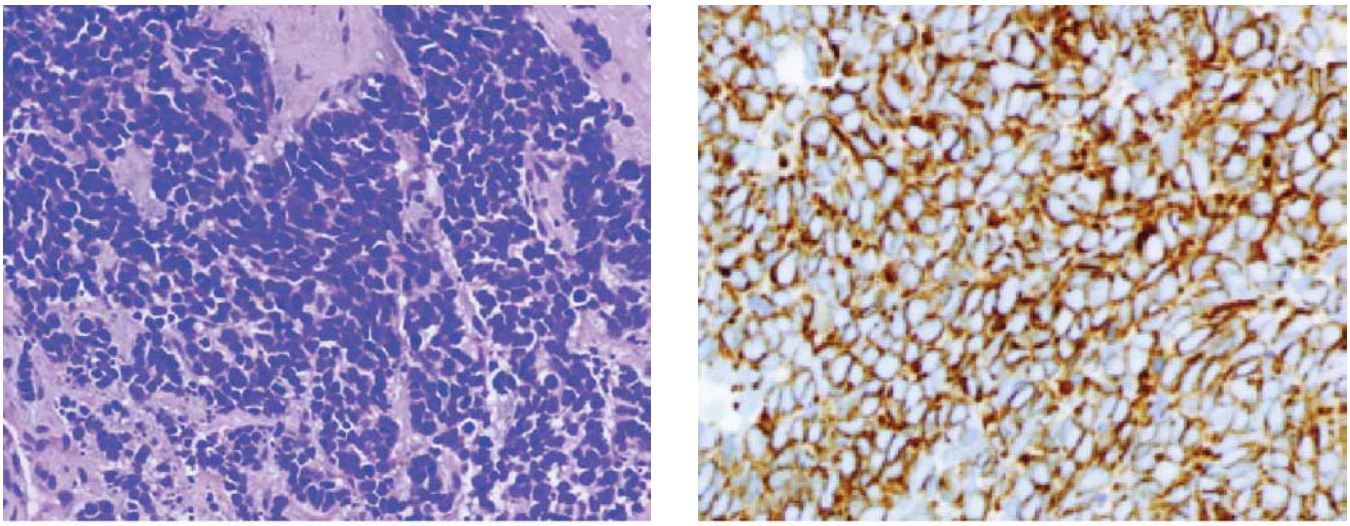


Figure 113.10 **A**: H & E staining of MCC demonstrating diffuse atypical blue cells with minimal cytoplasm and many mitoses. **B**: MCC positive demonstrating a paranuclear dot staining pattern with CK-20.

TABLE 113.6 AJCC CLASSIFICATION FOR MCC

Primary tumor (T)
- TX: Primary tumor cannot be assessed.
- T0: No evidence of primary tumor
- Tis: Carcinoma *in situ*
- T1: Tumor 2 cm or less in greatest dimension
- T2: Tumor >2 cm but not more than 5 cm in greatest dimension
- T3: Tumor >5 cm in greatest dimension
- T4: Tumor invades bone, muscle, fascia, or cartilage

Regional lymph nodes (N)
- NX: Nodes cannot be assessed.
- N0: No regional lymph node metastasis
- cN0: Nodes negative by clinical exam
- pN0: Nodes negative by pathologic exam
- N1: Regional lymph node metastasis
- N1a: Micrometastasis as seen on sentinel node biopsy or elective neck dissection
- N1b: Macrometastasis as seen on clinical exam and confirmed by pathologic exam
- N2: In transit metastasis

Distant metastasis (M)
- M0: No distant metastasis
- M1: Distant metastasis beyond regional nodal basin
- M1a: Metastasis to skin, subcutaneous tissues, or distant lymph nodes
- M1b: Lung metastasis
- M1c: Metastasis to other visceral sites

HIGHLIGHTS

- Sun exposure is associated with all forms of skin cancer.
- Unlike other forms of basal cell cancer, the morphea type is particularly difficult to excise because of indistinct margins, skip lesions, and a propensity for deep invasion.
- *De novo* squamous cell cancer tends to be far more aggressive locally and metastatically than cancer that develops after actinic changes.
- High-risk features of cutaneous carcinoma include thickness more than 2 mm, perineural invasion, ear or non–hair-bearing lip involvement, and poorly differentiated or undifferentiated pathology.
- Premalignant and low-grade lesions can be managed by topical chemotherapy (i.e., 5-fluorouracil), electrodesiccation and curettage, or CO_2 laser. All other lesions should be excised with clear margins to maximize success.
- Consider excising additional tissue to incorporate a complete facial unit if more than one-third is involved. This produces a more cosmetic and symmetric repair.
- If confronted with indistinct deep margins or a high probability of recurrence, consider skin grafting and observation for 6 to 12 months.
- Planned reconstruction should never limit oncologic resection.
- If possible, place incisions in a facial crease, hair-bearing areas, junctions of facial units, and parallel to relaxed skin tension lines.
- If using a local facial flap, consider the donor site defect and its effect on functional structures (e.g., eyelid, mouth).
- For MCC, sentinel node biopsy is appropriate if adenopathy is not clinically present.

Malignant Melanoma of the Head and Neck Region

114

Aaron J. Berger *Jeffrey N. Myers* *Andrew J. Nemechek* *Mike Yao*

The incidence of cutaneous malignant melanoma (CMM) continues to increase at a remarkable rate, and mortality from this disease also continues to rise. Despite our best attempts to understand the molecular basis of CMM, only recently have some of the critical molecular determinants of this disease been uncovered and used as a basis for new medical treatments. Thus, successful treatment of this disease relies heavily upon the surgeon. In this chapter, we will review some of the recent developments in the staging, evaluation, and treatment of CMM and present guidelines for treatment and management of melanoma of the head and neck.

EPIDEMIOLOGY

Despite an overall modest decrease in cancer incidence and cancer-related deaths over the past 20 years (largely related to lung, colon, breast, and prostate cancers), melanoma incidence rates and deaths continue to rise yearly. In the United States alone for 2013, it is estimated that 76,690 new melanoma cases will be diagnosed, and 9,480 deaths will be attributed to melanoma (1). While melanoma accounts for roughly 4% of all skin cancers, it is responsible for more than 77% of skin cancer deaths.

The major risk factors for development of cutaneous melanoma include fair complexion, tendency to sunburn easily, large congenital nevi (greater than 20 cm), presence of atypical/dysplastic nevi (2,3), a personal history of skin cancer (melanoma or otherwise) (4–7), genetic predisposition (8), and immunosuppression (9). Head and neck melanomas occur more commonly in men (2:1), with a median age at diagnosis of 55 years, and a range of 12 to 92 years (10).

Epidemiologic studies demonstrate higher rates of melanoma in those living in geographic areas that are exposed to intense sunlight (i.e., Australia). This finding and investigations in the laboratory demonstrate that exposure to ultraviolet light plays a major role in the pathogenesis of melanoma, and UV-A and UV-B radiation have both been implicated. This is further supported by the lower rates of melanoma reported in people whose skin natively has more pigmentation, and the incidence of melanoma is approximately 10 times higher in whites than in blacks in the same geographic region (11).

Although the combined head and neck region accounts for only 9% of body surface area, 15% to 30% of all melanomas arise within the head and neck (12,13). Multiple factors may contribute to this anatomic predilection for the skin of the head and neck, including higher levels of sun exposure and melanocyte content of the skin that is two- to threefold higher than other regions (14). Of note, melanomas arising on the face and scalp are associated with higher rates of local recurrence and regional lymph node disease than melanomas arising in other parts of the body.

CLINICAL PRESENTATION AND DIAGNOSIS

The classic hallmark finding that raises suspicion for malignant melanoma is the presence of a pigmented lesion that changes over a period of weeks to months. Lesions that change substantially in size or color over time should prompt medical attention. Other features of pigmented lesions, which should alert one to the possibility of a malignant process, include changes in diameter or height, variations in border, color, ulceration, itching, pain, and bleeding (15). Melanomas also may show signs of regression with involution of a primary lesion, which is often manifested by a "halo" lesion with a central area of decreased pigmentation. However, the clinical diagnosis of this disease may not always be straightforward; not all melanomas are pigmented. As many as 10% of melanomas

may lack melanin, some may resemble other cutaneous lesions such as basal cell carcinoma, and some tumors may not have a surface component. Patients also may be seen initially with metastasis to cervical lymph nodes with no identifiable primary tumor.

Once a suspicion of melanoma exists, relevant historic factors associated with increased risk of developing this disease should be ascertained. These factors include a history of childhood sun exposure with episodes of severe sunburns and a family history of cutaneous malignancies, including melanomas. Other types of pigmented lesions are important to note as well. These include junctional or acquired nevi that are found in the skin of most adults and are generally smaller than 5 mm. Dysplastic nevi tend to be larger and have irregular borders with variation in color. The identification of a dysplastic nevus should prompt dermatologic evaluation and excision because of an increased risk of developing a malignant melanoma within these lesions.

When a patient's skin lesion is suggestive of malignant melanoma by both history and physical examination, biopsy is performed. The clinician should document clearly the presence or absence of ulceration before biopsy, as this plays a role in staging. The technique for obtaining tissue for pathologic analysis has been the subject of considerable debate. A properly performed biopsy not only establishes a diagnosis but also provides critical prognostic data and assists in formulating a specific treatment plan. The type of biopsy is dictated by factors such as the size of the lesion and its anatomic location in relation to vital structures in the head, face, and neck. The site of origin of a primary melanoma in the head and neck also can be of prognostic significance, because lesions of the scalp and neck are associated with a worse prognosis than are melanomas of the face. Excisional biopsies are the favored technique to obtain tissue for diagnosis, and several studies have demonstrated an association between decreased survival and incisional or manipulative biopsies (16). Excision is performed with a narrow margin of normal-appearing tissue and should include subcutaneous fat for complete evaluation of the depth.

After excisional biopsy, the specimen is oriented and discussed with the pathologist. If the lesion's size or other anatomic or cosmetic constraints preclude excision, incisional or punch biopsy techniques are acceptable alternatives. Shave biopsies are acceptable, but should only be performed by experienced practitioners to ensure that the biopsy fully assesses the thickness of the lesion, or in cases with low suspicion. All biopsy techniques should sample the most representative portion of the lesion. Punch biopsy may include sampling the most raised area of the lesion or an area with the most pigmentation. Lesions with variable heights, colors, and borders may require biopsies of multiple areas to be performed for accurate and proper diagnosis. Traditional stains such as hematoxylin–eosin are used. The immunohistochemical stains S-100, HMB-45, and melan-A have helped standardize pathologic evaluation of cutaneous lesions (Fig. 114.2).

Fine-needle aspiration and curettage techniques have no role in evaluation of suspected invasive cutaneous melanoma, as they are inadequate in providing precise information regarding the depth of invasion. It should also be clearly stated that the initial excisional biopsy with negative margins is not considered adequate therapy for invasive melanoma but does allow re-excision with the opportunity to perform lymphatic mapping and sentinel lymph node biopsy (SLNB) at the time of re-excision.

MELANOMA SUBTYPES

Melanoma is divided into four distinct clinicopathologic subtypes: lentigo maligna melanoma (LMM), superficial spreading, nodular, and acral lentiginous melanoma. These lesions demonstrate either a radial (intraepithelial) or vertical (intradermal) growth phase or a combination of the two. Radial growth is circumferential in nature and confined to the dermal–epidermal junction. The vertical growth phase (intradermal) demonstrates invasion through the dermal–epidermal junction. The radial growth phase may indicate a lesion's capacity for growth and invasion into the papillary dermis. These lesions may lack metastatic potential. Conversely, cells in the vertical growth phase may represent a clonal change in cells with a growth advantage over neighboring cells, resulting in the clone's ability to invade and metastasize.

Cutaneous melanomas may mimic a host of other pathologic cutaneous lesions.

Differential diagnosis includes seborrheic keratosis, benign nevi (including junctional, compound, and dermal), hemangioma, blue nevi, pyogenic granuloma, and pigmented basal cell carcinoma.

Lentigo maligna (LM), also known as melanoma *in situ*, is a premalignant pigmented lesion that frequently develops in the head and neck region of elderly patients (Fig. 114.1A). Known historically as Hutchinson melanotic freckle, these lesions are associated with solar skin damage and feature atypical melanocytes, which spread radially along the dermal–epidermal junction, exhibit focal nesting, and occasionally extend along skin appendages into the dermis. Up to 5% of LMs or melanomas in situ progress to invasive LMM. LMM lesions should be excised with 0.5- to 1.0-cm margins, although prediction of tumor margins can prove difficult. This is the least common type of cutaneous melanoma and accounts for between 6% and 10% of melanoma lesions. Its growth is characterized by a slow radial phase that may take up to 10 years to progress. At first, they are quite slow to invade deeply, and affected patients have a better prognosis when compared with those with other forms of melanoma.

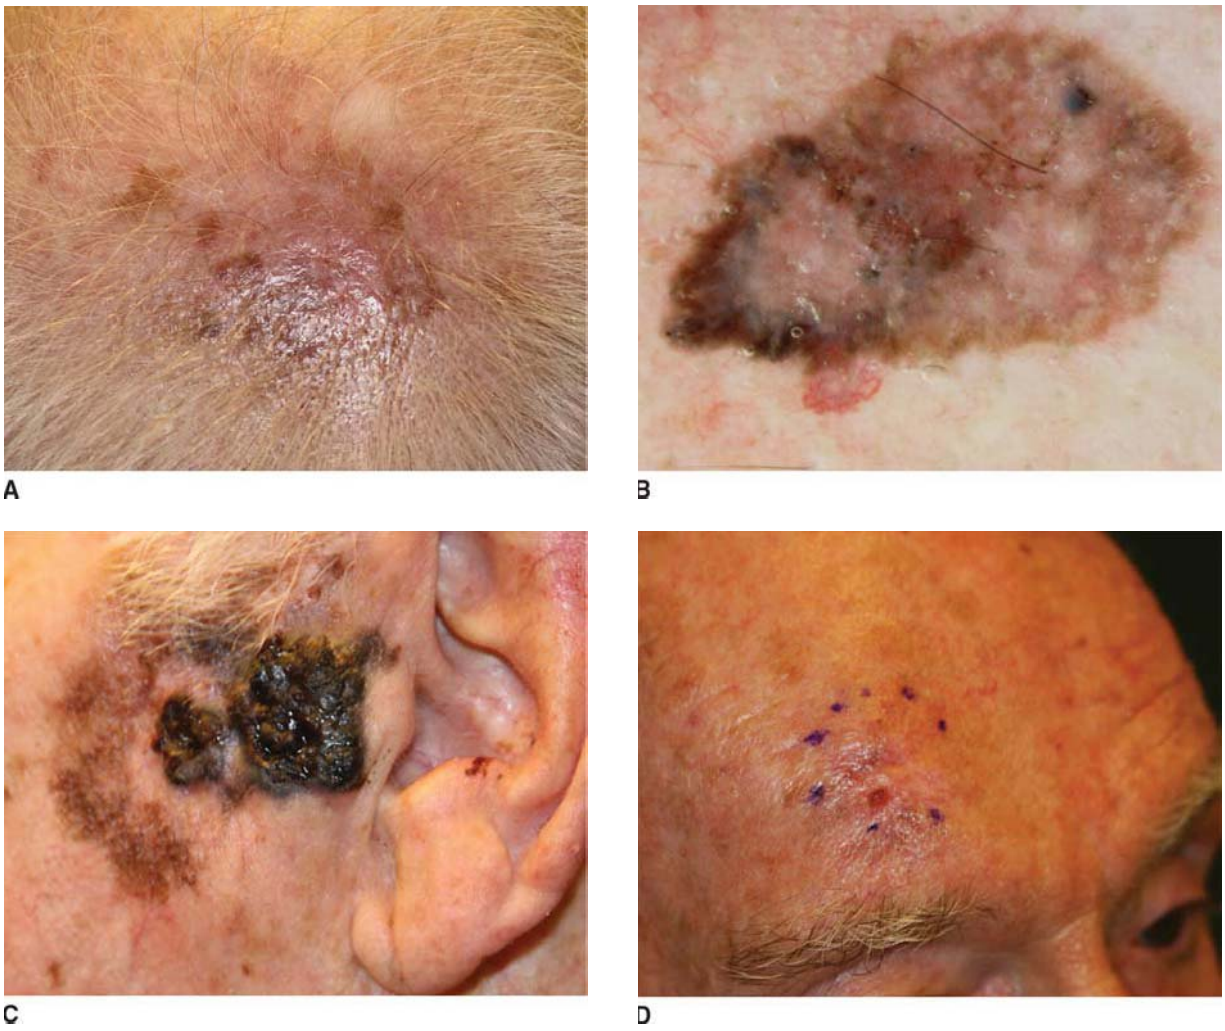

Figure 114.1 Photographs of the different subtypes of melanoma. **A:** Lentigo maligna invasive melanoma, Breslow depth 1.35 mm, Clark's level IV, no ulceration, mitotic index of 4, sentinel lymph nodes negative. **B:** Superficial spreading melanoma, Breslow depth 1.36 mm, Clark's level III, no ulceration, mitotic index of 5, sentinel lymph nodes negative. **C:** Nodular melanoma, Breslow depth of at least 3.9 mm, no ulceration, mitotic index of 4, sentinel lymph node negative. Case confounded by concurrent chronic lymphocytic leukemia. **D:** Desmoplastic melanoma, Breslow depth of 9 mm, Clark's level V, ulcerated, mitotic index of 5, sentinel lymph nodes negative. An SLNB was performed because the initial biopsy showed a spindle cell melanoma that was not thought to be a desmoplastic melanoma.

Superficial spreading melanoma represents the most common type of melanoma and comprises between 65% and 75% of cases (Fig. 114.1B). These lesions may demonstrate a wide variety of colors, including pink, blue–gray, brown, tan, and black. They also may demonstrate radial growth for 5 to 7 years and then become invasive, an event frequently heralded by ulceration and bleeding. High cure rates have been reported when these lesions are clinically detected in the radial growth phase. Spontaneous regression of superficial spreading melanomas also has been reported.

Acral lentiginous is the most common type of melanoma seen in the African American population. Because these lesions commonly occur on the soles of the feet, surfaces of the hand, and oral/anogenital mucosa, head and neck surgeons less commonly encounter them.

Nodular melanoma comprises between 10% and 15% of all melanomas and may affect areas of both exposed and non–sun-exposed areas of the skin (Fig. 114.1C). They tend to develop in patients older than 50 years. Nodular melanoma is considered to be the most invasive of the cutaneous melanomas, and affected patients have the poorest prognosis.

Desmoplastic melanoma is a histologic variant of melanoma that accounts for fewer than 1% of melanoma cases overall (Fig. 114.1D). However, as many as 75% of these tumors occur in the head and neck region. Clinically, desmoplastic melanomas may be amelanotic, a feature that impedes early recognition and often leads to significant delays in diagnosis and treatment. Another important characteristic feature of these lesions is their neurotropism.

This predisposes them to perineural invasion and spread that often accounts for local recurrence despite histologically "negative margins" with recurrence rates reported between 23% and 48% (17–22). Therefore, it is suggested that wider resection margins be taken around a desmoplastic tumor and that adjuvant radiation is often recommended after definitive excision. Multiple studies have demonstrated a lower rate of regional nodal spread in patients with desmoplastic melanoma as compared to other histologic subtypes of melanoma (23–27). The lower rate of positive sentinel lymph nodes has made the role of SLNB in this population less widely recommended (25). However, a distinction needs to be made between those lesions which are purely desmoplastic and are associated with a low rate of nodal metastasis and those that have a combination of desmoplastic and a more conventional melanoma histology which spread to lymph nodes at the higher frequency associated with the nondesmoplastic histology (25,26). Therefore, SLNB can be recommended in the combined desmoplastic cases, which meet other criteria for performing the biopsy such as depth of invasion, number of mitoses, and/or ulceration.

MUCOSAL MELANOMA

A relatively rare entity, mucosal melanoma deserves special mention. Primary melanoma may arise in the mucosa of the respiratory, alimentary, and genitourinary tracts, as they all contain melanocytes. Mucosal melanoma accounts for 1% to 2% of all melanomas, with the majority being found in the head and neck region (28). More than 50% of reported cases arise within the nasal cavity. Other affected areas include the paranasal sinuses, nasopharynx, oral cavity, and oropharynx. Esophageal mucosa can also be affected. Nasal obstruction is the most common presenting symptom for sinonasal lesions. However, a significant number of mucosal melanomas may be asymptomatic until they have progressed to an advanced stage, which contributes to the poor prognosis of patients with this diagnosis. Stern and colleagues (29) at the M.D. Anderson Cancer Center found an average of 9 months between the first onset of symptoms and physician intervention. In addition to delay in diagnosis, the poorer prognosis associated with mucosal melanomas may also be related to an inherently more aggressive behavior of mucosal melanomas, or earlier dissemination, because of the rich lymphatic and vascular supply of the mucosa.

The differential diagnosis includes vascular lesions, angiomas, and dental amalgam tattoos. It is not uncommon for the characteristic melanosis to be absent in mucosal melanoma lesions. Biopsy is usually confirmatory, and immunohistochemistry may be used to assist in diagnosis. Desmoplastic variants of mucosal melanoma have been described in the head and neck (30). No studies have conclusively demonstrated that depth of invasion is of prognostic importance in mucosal melanoma.

The majority of these patients have a poor prognosis. These tumors have a high rate of local recurrence, which is typically a harbinger of disseminated disease, and most of these patients die from complications related to distant metastases.

Anatomic constraints frequently preclude the use of excisional biopsy techniques in most patients with mucosal melanoma. Although wide local excision is the mainstay of therapy, radiation therapy has been used as a primary modality and postoperative adjuvant therapy with unclear benefit (31–33). It should especially be considered in situations when adequate resection margin is not possible, where it may help prevent local recurrence (34).

Patients may experience multiple local recurrences and ultimately die of a combination of uncontrolled local and distant disease. Five-year survival rates for mucosal melanoma range between 10% and 45% (35–39).

MELANOMA STAGING SYSTEM

The staging of malignant melanoma has evolved over the past half century in efforts to more reliably determine prognosis and to identify the most appropriate treatment schemes. Clark and Breslow made significant contributions to the microscopic grading of primary cutaneous melanoma. Clark (40) described five levels of anatomic invasion through the layers of the skin. In the Breslow system (41), the maximum thickness of melanomas is used as a prognostic indicator.

The current staging system for melanoma developed by the American Joint Committee on Cancer (AJCC) and adopted by the International Union for Cancer Control, relies upon assessment of the primary tumor (T), regional lymph nodes (N), and distant metastatic sites (M). The seventh, and most recent, edition of this staging system is based upon long-term analysis of over 38,900 patients with cutaneous melanoma (42) (Table 114.1).

Primary Tumor

Tumor thickness, presence or absence of ulceration, and mitotic rate are the histopathologic details factored into staging, as they have been demonstrated to correlate closely with prognosis. Clark level has clinical utility in the evaluation and treatment of patients with thin melanomas, and thus, is only included in the staging of melanomas less than or equal to 1 mm in thickness.

Regional Nodal Staging

Regional nodal status is the most powerful predictor of survival for patients with melanoma (43) and has led to the widespread adoption of SLNB in the evaluation of patients with primary cutaneous melanomas. For patients with clinically detectable lymph nodes on presentation, regional imaging (CT or MRI) as well as fine-needle aspiration

TABLE 114.1 CUTANEOUS MELANOMA TNM STAGING

Melanoma TNM Classification

T Classification	Thickness	Ulceration Status
T_{is}	Not applicable	Not applicable
T1	≤1.0 mm	A: w/o ulceration and mitosis <1/mm^2
		B: with ulceration or mitosis ≥1/mm^2
T2	1.01–2.0 mm	A: w/o ulceration
		B: with ulceration
T3	2.01–4.0 mm	A: w/o ulceration
		B: with ulceration
T4	>4.0 mm	A: w/o ulceration
		B: with ulceration
N Classification	**Number of Metastatic Nodes**	**Nodal Metastatic Mass**
N1	One node	A: micrometastasis[a]
		B: macrometastasis[b]
N2	—Two to three nodes	A: micrometastasis[a]
		B: macrometastasis[b]
		C: in-transit met(s)/satellite(s) *without* metastatic nodes
N3	Four or more metastatic nodes, or matted nodes, or in-transit met(s)/ satellite(s) *with* metastatic node(s)	
M Classification	**Site**	**Serum LDH**
M1a	Distant skin, subcutaneous, or nodal metastases	Normal
M1b	Lung metastases	Normal
M1c	All other visceral metastases	Normal
	Any distant metastasis	Elevated

[a]Micrometastases are diagnosed after sentinel or elective lymphadenectomy.
[b]Macrometastases are defined as clinically detectable nodal metastases confirmed by therapeutic lymphadenectomy or when nodal metastasis exhibits gross extracapsular extension.

may be performed to confirm the presence of melanoma; if found, therapeutic lymph node dissection and systemic staging are recommended (Fig. 114.2). The extent of dissection remains controversial and will be addressed later in this chapter.

The decision to perform SLNB is typically based upon characteristics of the primary tumor, as the risk of regional metastasis is known to correlate with tumor thickness and ulceration (44–48); high mitotic rate and younger patient age have also been associated with SLN positivity rates (49–51). With respect to SLN status, patients with T1 lesions have a 3% to 5% risk of SLN positivity; T2, 8% to 12%; T3, 23% to 27%; and T4, 24% to 44% (46,50,52).

When reporting the pathologic nodal status after SLNB or a more comprehensive lymphadenectomy, it is important to include the number of nodes involved (53), micro- versus macrometastases (53), and the presence or absence of in-transit metastases. In-transit metastases are a unique manifestation of intralymphatic tumor dissemination, characterized by the presence of melanoma in either cutaneous or subcutaneous tissue situated between the primary tumor and the draining regional lymph node basin (54). In early stage disease, these develop in 2% to 13% of patients (55,56), and based on poor patient outcomes associated with their presence, they are considered equivalent to the presence of significant nodal disease (Table 114.1).

The prognosis for patients with microscopic metastases found at the time of SLNB (67% 5-year survival) is better than for patients with macroscopic metastases detected clinically (43% 5-year survival) (57). For patients with microscopic metastases, the number of tumor containing nodes is the most important prognostic indicator followed by the mitotic rate (57). For patients with macroscopic metastases, the number of nodes, primary ulceration, and patient age are the most important prognostic factors (57). Buzaid et al. (58) showed that the number of lymph nodes involved with regional metastases is more predictive of treatment outcomes than is the size of lymph nodes harboring metastatic disease.

In the head and neck, lateralized tumors may drain into the primary echelon nodal basins, including preauricular, parotid, postauricular, suboccipital, posterior cervical, anterior cervical (external or internal jugular), and supraclavicular nodal groups. Nodal drainage basins in the

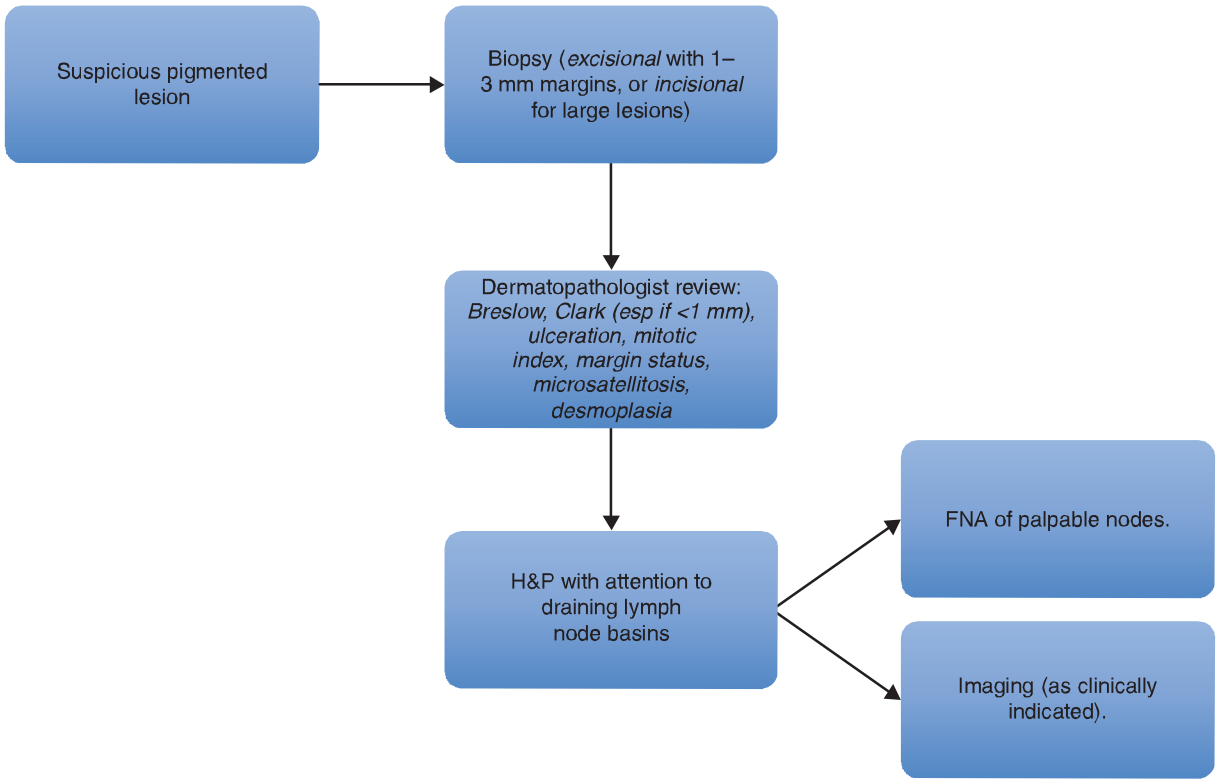

Figure 114.2 Initial management of cutaneous melanoma (Adapted from NCCN). H&P, History and Physical Examination; FNA, Fine-needle aspiration.

head and neck are less predictable when compared with trunk and extremity sites. Although some areas on the scalp, face, and ears may have predictable lymphatic drainage, bilateral or contralateral metastases are not uncommon, and ambiguous drainage patterns can be seen in up to 55% of patients (59). Preoperative and intraoperative lymphoscintigraphy helps to precisely define an individual's pattern of lymphatic drainage in primary melanomas of the head and neck region (60).

Metastatic Workup

The National Comprehensive Cancer Network (NCCN) guidelines for melanoma do not recommend routine use of imaging studies such as CT, MRI, or PET scans for the systemic staging of patients with thin melanomas (stage I and II) since the risk of distant metastasis is exceedingly low in this group of patients (61). For patients with thin melanomas with adverse features such as positive deep margins, lymphovascular invasion, or mitotic rate greater than 1 per mm^2, imaging is recommended only to investigate specific signs or symptoms that may be attributable to a metastatic lesion.

For patients with stage III melanomas (metastatic disease in a lymph node, satellite, or in-transit metastases), the NCCN guidelines do not make specific recommendations and leave the workup to the discretion of the treating physician. Without any signs or symptoms, the likelihood of finding an occult metastatic lesion with screening CT or PET scan is low.

For stage IV (distant metastases), the NCCN guidelines recommend an LDH level plus chest x-ray and/or chest CT (Fig. 114.3). A brain MRI or CT scan with contrast should be performed if the patients have even minimal suggestions of symptoms or physical findings of brain involvement or if the results would affect treatment decisions. LDH levels have been shown to correlate with melanoma-specific survival (62). Nevertheless, in our practices, in order to help select and prioritize treatments for patients with Stage III or IV disease, we will often perform systemic imaging to include and brain MRI and either a PET/CT or CT of the head and neck, chest, abdomen, and pelvis. As an example, a patient presenting with regional nodal metastatic disease found to have distant metastatic disease on systemic imaging might be offered systemic treatment rather than surgery and radiation as initial treatment. Thus, we find imaging quite helpful in these instances to make informed treatment decisions.

DETECTION OF OCCULT LYMPH NODE DISEASE

As stated previously, the most powerful predictor of survival is lymph node status. In patients with lesions less than 0.75 mm in depth, lymph node observation is appropriate. Patients with lesions between 0.76–1.0 mm in depth, without ulceration and less than 1 mitosis per mm^2

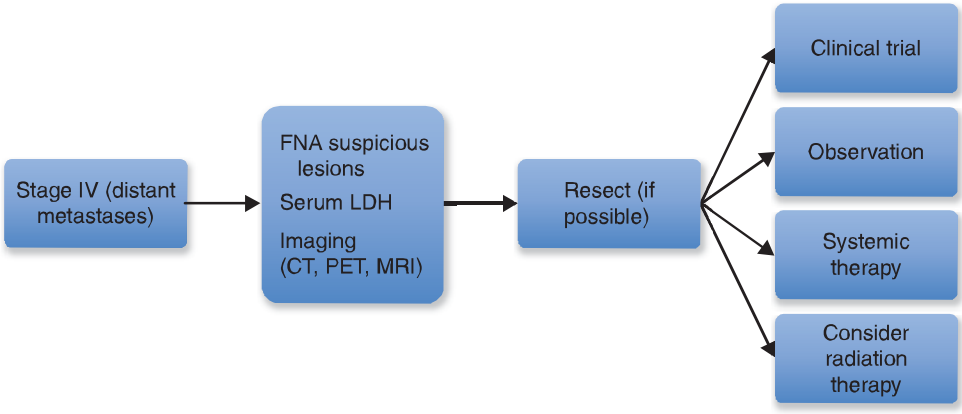

Figure 114.3 Management of metastatic melanoma (Adapted from NCCN).

should consider lymph node evaluation. Patients with lesions between 0.76–1.0 mm in depth with ulceration or ≥1 mitosis per mm^2 or with lesions >1 mm with any characteristic should be offered lymph node evaluation. Of the two main ways of evaluating for occult lymph node metastases, SLNB has supplanted elective lymph node dissection (ELND) as the preferred method.

The rationale for determination of nodal status is to appropriately stage patients and to identify patients who may benefit from regional therapy with surgery, radiation, or both to improve locoregional control. The goal is to also identify patients at greater risk for systemic recurrence who could potentially benefit from systemic adjuvant therapy.

Elective Lymph Node Dissection

The utility of ELND in the initial management of patients with CMM of intermediate-thickness or thicker lesions is questionable in the current era of SLNB. In terms of using ELND to attempt surgical cure, four prospective randomized clinical trials failed to show a benefit from ELND in melanoma (63–66). However, data from the World Health Organization (WHO) Melanoma group Trial 14 and the Intergroup Melanoma Surgical Trial suggest that certain subgroups of patients may benefit from ELND (44,67,68). In particular, patients in the WHO study with truncal melanoma greater than 1.5 mm thick and microscopic regional nodal disease had improved survival compared to those patients in whom lymph node dissection was delayed until they developed palpable lymphadenopathy (5-year survival 48.2% vs. 26.9%, $P = 0.04$). In the intergroup study, patients younger than 60, with nonulcerated primary lesions 1 to 2 mm thick, had a survival benefit from ELND. While these studies demonstrate survival benefits in select groups of melanoma patients with clinically undetectable disease, the majority of patients (80% to 85%) will not have occult metastases.

The development of SLNB has enhanced the sensitivity and specificity of lymph node biopsy, and it has replaced ELND, a procedure with greater potential morbidity and disability, in the *initial* assessment of regional metastatic disease in patients with CMM of the head and neck region.

Sentinel Lymph Node Identification and Biopsy

Seminal work by Dr. Donald Morton (14) and others has supported the hypothesis that, within each nodal basin, an orderly progression of lymphatic drainage is found from a first-echelon or sentinel node to nodes of lower echelons. This implies that if one can identify the sentinel lymph node in a basin at risk for spread from a melanoma and find it to be free of metastasis, then the remainder of nodes in that basin should also be free of metastatic tumor. This concept has been subsequently supported in a number of trials for non–head and neck CMM. Universal adoption of SLNB for CMM of the head and neck was somewhat delayed secondary to the belief that nodal drainage patterns in the head and neck region might be too complex to make SLNB feasible. Eicher et al. were among the first to dispel this notion (69), demonstrating SLNs in 98% of patients in whom SLNB was performed in the context of a regional lymphadenectomy in patients with intermediate-thickness cutaneous melanomas in the head and neck region. No patients were found to have a positive non-SLN when the SLN was negative. Overall, studies reflect that the predictive value of a negative SLN approaches 99% and that the SLNB procedure has a low false-negative rate (less than 4%) (70,71); however, this rate may be slightly higher in head and neck melanomas as compared to the trunk or extremities (72). Studies of SLNB for patients with head and neck primary melanomas report a range of regional recurrence from 2% to 8% in patients who had negative SLN (67,70,72).

Patients with melanomas ≤0.75 mm in depth with or without adverse characteristics are not offered sentinel lymph node biopsy. Patients with melanomas 0.76–1.0 mm in depth without ulceration and <1 mitosis per mm^2 should consider SLNB. Patients with melanomas 0.76–1.0 mm in depth with ulceration or ≥1 mitosis per mm^2, or >1 mm in depth with any characteristic should be offered SLNB (61) (Fig. 114.4).

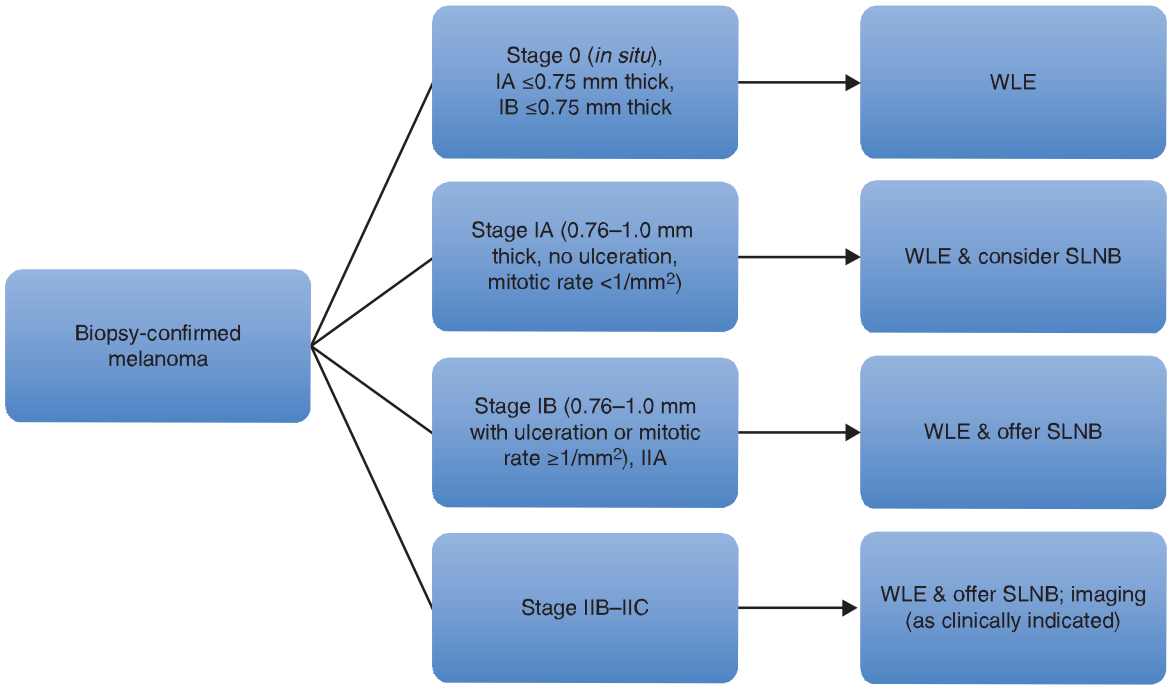

Figure 114.4 Surgical management of cutaneous melanoma (Adapted from NCCN). WLE, wide local excision (see Primary Resection section for suggested margin of resection); SLNB, sentinel lymph node biopsy; imaging modalities to consider: Chest x-ray, CT ± PET, MRI.

Technical Considerations

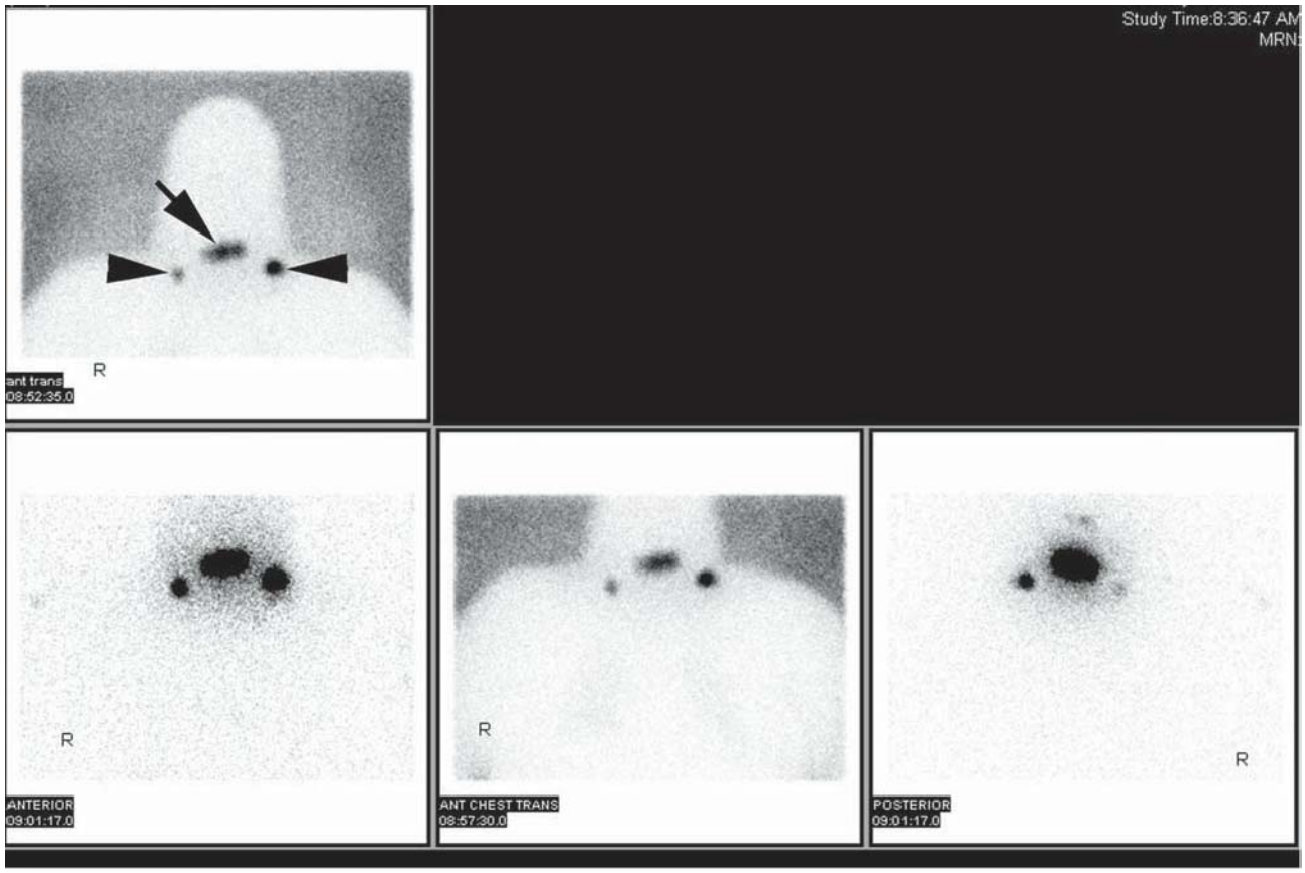
Localization and mapping of sentinel lymph nodes typically involves preoperative cutaneous lymphoscintigraphy as well as intraoperative localization of lymph nodes with vital blue dye and handheld gamma probe detection of lymph nodes harboring technetium-99m (^{99}Tc)-labeled sulfur colloid. SLNB is usually performed at the time of wide excision of the primary tumor. Preoperative lymphoscintigraphy involves intradermal (not subcutaneous) injection of ^{99}Tc-labeled sulfur colloid divided into four quadrants around the melanoma. SPECT imaging (single photon emission computed tomography) of the draining radioactive colloid identifies the regional nodal basins at risk, and, in some cases, the number and location of SLNs within the basin. Intraoperative injection of blue dye and ^{99}Tc-labeled sulfur colloid intradermally around the intact tumor/biopsy site is taken up by the lymphatic system, and the afferent lymphatic channels and SLNs are identified by the uptake of blue dye and radioactive signal (using handheld gamma probe). The addition of radiocolloid to blue dye increases the surgeon's ability to identify the SLN from 84% to 85% accuracy with blue dye alone to 96% to 99% (45). By performing the lymphoscintigraphy the morning of surgery, the radioactivity from the lymphoscintigraphy can be used for intraoperative localization, and a second injection of the radioactive colloid is not needed. If the delay between lymphoscintigraphy and SLNB is more than a few hours, a second injection of the radiolabelled sulfur colloid is performed (73–75).

Lymphazurin (1% isosulfan blue, US Surgical Corp, Norwalk, CT) was the first blue dye to be approved by the FDA for lymphangiography and is considered the gold standard dye for SLNB (76). However, due to shortages and anaphylactic reactions to the isosulfan blue, other blue dyes such as methylene blue have been successfully used (77).

In the head and neck, lymphatic basins can overlap with the primary tumor site making identification of the SLN difficult. Rasgon (78) advocated the use of lower levels of radioactivity (0.1 to 0.6 mCi) for lymphoscintigraphy and SLNB. We have had similar problems with radioactivity from ear, cheek, or neck melanomas obscuring evaluation of the underlying lymph nodes. As a result, in these areas, we have lowered the injected level of radioactivity from 1 to 0.4 mCi. Another effective strategy for dealing with this "shine-through" from the primary injection obscuring the sentinel lymph nodes nearby is to remove the primary tumor prior to sentinel node identification.

More recently, SPECT–CT has been used to aid in identification of sentinel lymph nodes in the head and neck, providing higher sensitivity for SLN detection and detailed anatomic localization (79,80) (Fig. 114.5). This technique has proven particularly useful in determining the extent of parotid gland LN involvement, assisting the surgeon in determining the necessary extent of parotid dissection (81). Another area in which this imaging adjunct has been useful is discerning whether high cervical lymph nodes are in the external or internal jugular chains, facilitating preoperative counseling about incisions and potential risk to vital structures such as the spinal accessory nerve.

For the SLNB to be accurate, all true SLNs, regardless of location, must be identified and harvested, since the



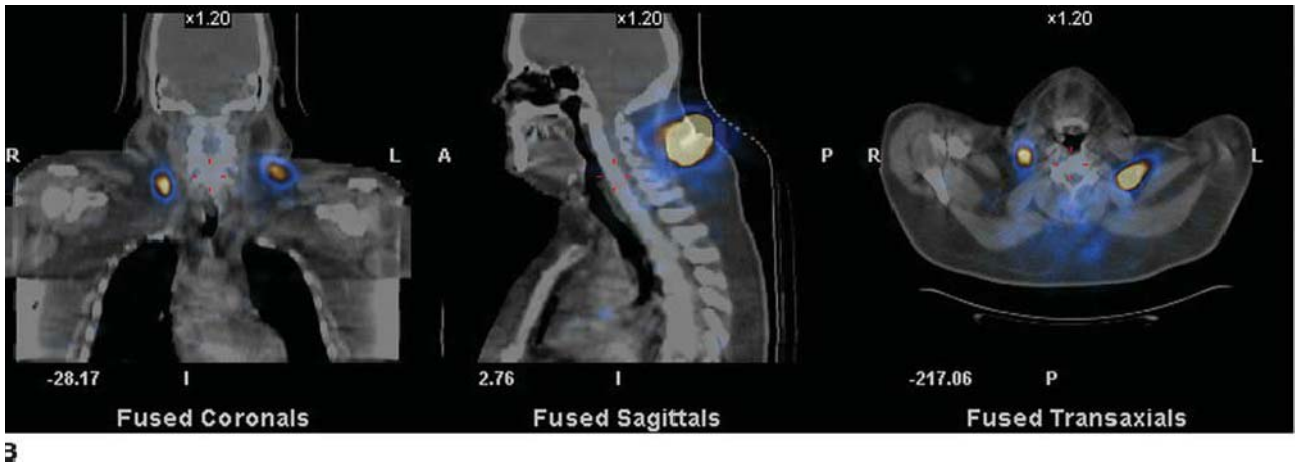


Figure 114.5 Patient with superficial spreading type melanoma of the posterior neck. **A:** Lymphoscintigraphy showing the injection site (*large arrow*). The sentinel lymph nodes are seen laterally in the neck bilaterally (*arrowhead*). **B:** SPECT/CT showing much improved anatomic detail of the radioactive lymph nodes in the supraclavicular fossa bilaterally. SLNB successfully identified three sentinel lymph nodes. Two sentinel lymph nodes on the left and one on the right all harbored metastatic disease. Subsequent bilateral neck dissections did not reveal any metastatic disease in the nonsentinel lymph nodes.

histologic status of one draining basin does not predict the status of other basins in patients with melanomas that drain to multiple regional basins. Eicher et al. (69) found that head and neck primary melanomas drain to an average of 2.2 nodal basins per patient, with drainage to nonadjacent nodal basins in 42% of patients. Reynolds et al. (82) performed an extensive review of lymphoscintigraphy results from 929 patients with head and neck melanoma, demonstrating that the lymphatic drainage patterns in the head and neck are not always predictable. O'Brien et al. (59), at the Sydney Melanoma Unit, performed lymphatic mapping in the treatment of head and neck

melanoma in 97 patients. The authors found a high rate (34%) of disagreement between clinically predicted lymphatic drainage pathways in the head and neck region and those demonstrated on lymphoscintigraphy. Their analysis also revealed a large number of SLNs for each patient: 13 patients had a single SLN, 33 patients had two SLNs, 3 had three SLNs, 15 had four SLNs, and 6 had five SLNs, indicating some of the complexity of lymphatic mapping in the head and neck region.

We recommend removing lymph nodes identified with the handheld gamma probe until all lymph nodes with counts per minute greater than 10% of the counts per minute found in the lymph node with the highest uptake of the radiolabelled sulfur colloid (83,84). Abou-Nukta and Ariyan reported that removing the three hottest lymph nodes and all of the blue lymph nodes detected 100% of the positive SLNs. In addition, 98% of the positive SLNs in their study had radioactivity counts greater than 30% of the hottest lymph node. They have suggested that the removal of lymph nodes with radioactivity less than 30% of the hottest lymph node is unnecessary (85).

Pathologic Analysis of SLNs

An additional benefit of SLNB is that it can focus a more extensive evaluation of lymph nodes at risk for subclinical metastases. Workers at the M.D. Anderson Cancer Center have shown that analysis of serial sections of an SLN can increase the sensitivity in detection of nodal metastases, thereby improving the selection of patients who receive regional and systemic treatment (86). The use of frozen sections for evaluation of an SLN is not recommended because false negatives have been reported, secondary to inferior quality relative to permanent sections. Immunohistochemistry for S-100, HMB-45, MART-1/melan-A, or, more recently, the reverse transcriptase polymerase chain reaction (RT-PCR) is required since hematoxylin and eosin alone will miss up to 12% of positive nodes (87). It is important to note that in the new AJCC staging system, immunohistochemically detected SLN metastases are formally considered evidence of node-positive disease (88). With respect to RT-PCR analysis of SLN, it remains investigational and should not be used outside of a clinical trial to direct further therapy (89).

The role of SLNB continues to be refined in the management of CMM of the head and neck region. The complexity of lymphatic drainage patterns and the frequent need to remove SLNs from the parotid gland, placing the facial nerve at risk, initially made head and neck surgical oncologists somewhat slow to adapt this method. Multiple centers have reviewed their experience with lymphatic mapping by using preoperative lymphoscintigraphy and intraoperative blue-dye localization and a handheld gamma probe (75,86). The University of Michigan group reported no facial nerve injuries in 19 patients with SLNs removed from the parotid gland (90), and this technique of removing parotid nodes without performing a complete parotidectomy has become widely adopted. The low false-negative rate of lymphatic mapping lends further support for the use of this method for staging the regional lymphatics (91). Data from these studies suggest that lymphatic mapping by using the combination of blue dye and a handheld gamma probe is an effective method for ruling out regional metastases in patients with melanoma and identifying patients who might benefit from further lymph node dissection, radiation, and/or systemic adjuvant therapy.

Potential Therapeutic Benefit from SLNB

In an effort to determine the impact of SLNB on survival, Morton et al. (92) performed a prospective analysis of 1,269 patients with intermediate stage melanoma (1.2- to 3.5-mm depth) and no lymphadenopathy. The patients were randomly assigned to receive wide excision and postoperative observation of regional lymph nodes, or wide excision and SLNB with immediate lymphadenectomy if nodal micrometastases were detected. Five-year melanoma-specific survival was not significantly different between the two groups (87.1% vs. 86.6%; $P = 0.58$). However, the group performed several subgroup analyses and clearly demonstrated that SLNB provides important prognostic information, identifying patients with microscopic nodal metastases, a median of 16 months earlier than presentation of clinically evident nodal metastases (92). Comparison between patients who underwent immediate lymphadenectomy for positive SLN and patients who underwent delayed lymphadenectomy for clinically detected nodal relapse, 5-year melanoma-specific survival, was significantly better in the SLN group (72.3% vs. 52.4%; $P = 0.004$) (92).

The value of SLNB lies in its ability to improve staging accuracy and, in turn, the ability to obtain regional disease control early, as melanoma-specific survival is better when lymphadenectomy is performed in patients with *microscopic* nodal burden than in patients with multiple nodal metastases (53,93–95). The presumption is that once nodal disease becomes clinically evident (palpable), metastatic deposits may already be present at distant sites.

While primarily advocated for patients with intermediate-thickness melanomas, SLNB should not be omitted from the workup of patients with thick (greater than 4 mm) melanomas, as it remains a prognostically powerful tool in this patient cohort (96–100).

TREATMENT: PRIMARY RESECTION

After an appropriate preoperative workup, therapeutic options are discussed with the patient. Surgical resection has been the mainstay of therapy in the treatment of primary cutaneous melanoma in the head and neck. Treatment includes resection of the primary melanoma or previous biopsy site with a rim of normal-appearing tissue surrounding it.

The minimal resection margin necessary for adequate resection has been the topic of debate. Historically, 5-cm excision margins were suggested, based on the propensity of melanomas to recur in areas adjacent to the primary site, although no survival advantage could be demonstrated. Based on subsequent retrospective analyses, it was suggested that narrower resection margins might be appropriate for thin or intermediate-thickness lesions (101). Recent randomized trials concluded that local and regional control rates and survival were not different when excisions with large (5-cm) margins, and those using more conservative (2-cm) margins were compared (102).

In a collaborative review, investigators at the University of Texas M.D. Anderson Cancer Center and the Moffitt Cancer Center found no increase in local recurrence rates or worse survival rates in patients when thick primary melanomas (larger than 4 mm) were excised with a margin of 10 mm or less (103). Of note, a recent Cochrane review of surgical excision margins for primary cutaneous melanoma (including five randomized controlled trials) was unable to demonstrate a statistically significant difference in overall survival between narrow and wide excision margins (104).

According to the NCCN, current guidelines for adequate resection margins of cutaneous melanoma are the following (which may be modified to accommodate individual anatomic or functional considerations) (61):

In Situ (T_{is})	0.5 cm
≤1 mm (T1)	1 cm
1.01–2.0 mm (T2)	1–2 cm
2.01–4.0 mm (T3)	2 cm
>4 mm (T4)	2 cm

Frequently, in the head and neck, proximity of structures such as the eyes, nose, ears, and circumoral anatomy effectively limits the borders for excision. Excisions are carried out in a full-thickness fashion down to underlying fascia such that all margins, including those that are deeply invaded, may be effectively evaluated.

Significant controversy exists regarding the use of frozen section for evaluation and diagnosis. Zitelli et al. (105) and other Mohs surgeons have reported that frozen sections of analysis for surgical margins of melanoma had sensitivity and specificity of 100% and 90%, respectively. However, many dermatopathologists believe that the use of frozen sections is inadequate to distinguish the margins of pigmented lesions. Therefore, we recommend control of margins by permanent-section pathologic analysis and often delay reconstruction until margin analysis has been completed. However, Mohs' surgery may be useful for extensive contiguous disease such as large, clinically ill-defined *in situ* melanoma of the lentigo maligna type. Alternatively, for some of these lesions, with positive surgical margins showing *in situ* disease, topical imiquimod or radiotherapy may be considered (61).

Methods of reconstruction after resection for melanoma are beyond the scope of this chapter. However, most lesions can be closed either primarily with the use of local advancement flaps or with the use of skin-grafting techniques. Skin grafting may allow closer surveillance for earlier detection of recurrent disease, and may also serve as a bridge to later definitive flap reconstruction.

Though more rare than cutaneous melanoma, mucosal melanoma deserves some mention in this section. While early detection is unlikely because of the occult anatomic locations, diagnosis must be established through full-thickness biopsy if possible. If the size or location of the lesion precludes excisional biopsy, incisional biopsy should include a representative sample from the border of the lesion, to assist the pathologist in differentiating a primary mucosal melanoma from mucosal melanoma metastasis. The primary approach to treatment of mucosal melanoma is wide surgical resection, for which the 5-year overall survival is only 13% to 22% (106,107). As a result of these poor outcomes and concern regarding adequate resection, radiotherapy and chemotherapy are often pursued as adjuvant therapies in the treatment of mucosal melanoma.

LYMPHADENECTOMY: THERAPEUTIC NECK DISSECTION AND PAROTIDECTOMY

For patients with clinically positive lymph nodes, neck dissection is indicated (Fig. 114.6). However, the extent of neck dissection remains an area of controversy but ranges from removal of gross disease by selective lymphadenectomy to radical neck dissection and its modifications.

Studies from Memorial Sloan-Kettering Cancer Center, the Melanoma Unit in Sydney, Australia, and Duke University have investigated the effect of neck dissection on outcome for patients with melanoma (108,109). Shah and colleagues (110) concluded that in the presence of clinically positive lymph nodes, a comprehensive neck dissection should be carried out. The type of neck dissection was tailored to the site of the primary tumor. For instance, in patients with melanomas of the face, ear, and anterior scalp, dissection of the parotid gland and lymph node levels I through IV was carried out. Patients with lesions in the postauricular and posterior scalp and neck required dissections of levels II through V. A complete discussion as to type and technique of neck dissection can be found elsewhere in this chapter.

For patients with positive SLNs, treatment options include observation, completion lymphadenectomy, and/or radiation therapy. In approximately 20% of SLN-positive patients, completion lymphadenectomy reveals additional melanoma-containing lymph nodes (111). Thus, completion lymphadenectomy is highly recommended for patients with positive SLN to ensure regional control. However, the multicenter selective lymphadenectomy trial (MSLT–II), which is currently in progress, is

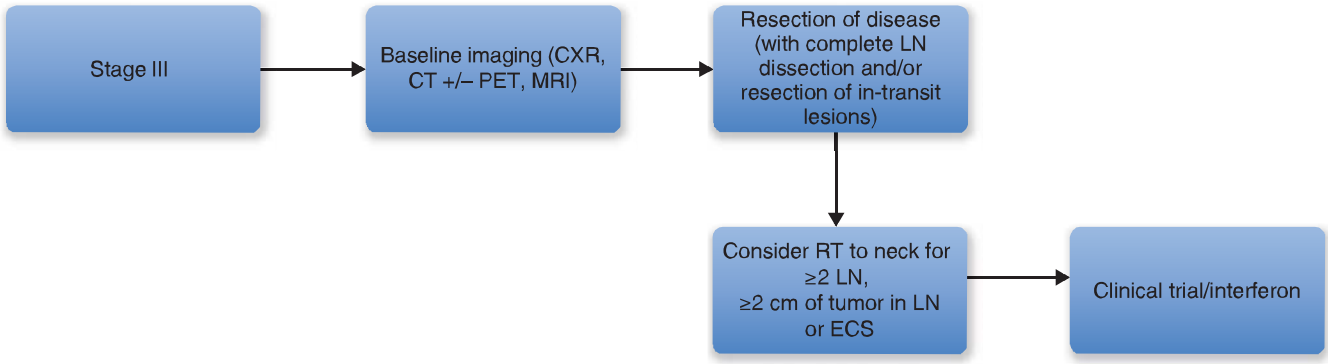

Figure 114.6 Management of node-positive melanoma (Adapted from NCCN). LN, lymph node; ECS, extra ≥2 cm tumor within lymph node capsular spread.

investigating the use of serial nodal ultrasound to identify those SLN-positive patients who will need completion lymphadenectomy, sparing up to 80% of patients a potentially unnecessary operation (112). The use of radiation therapy for SLN-positive patients will be addressed later in this chapter.

RADIOTHERAPY

Like many issues important to the treatment of malignant melanoma, radiotherapy, both as the primary modality of therapy and in the adjuvant setting, has sparked much controversy in the past century. Conflicting reports as to its efficacy included investigators unabashedly stating that malignant melanoma cells were radioresistant. However, groundbreaking work by Barranco et al. (113) found that cultured malignant melanoma cells differ from other types of tumor cells in their radiosensitivity. The observed radioresistance of melanoma could be overcome by increasing the individual dose fraction. These studies have helped form the basis for clinical practice, and subsequent studies helped to determine the ideal fraction size and total therapeutic dose that effectively treats melanoma.

Radiotherapy is not generally recommended for the primary treatment of CMM. However, in some exceptional circumstances, its use is advocated. In patients who are poor candidates for surgical resection, radiotherapy may offer an acceptable alternative.

For those patients with extensive facial LM melanoma that precludes adequate surgical resection based on functional or cosmetic considerations, radiotherapy has been used and has provided excellent outcomes (114). However, more recently, advances in topical therapies such as imiquimod are supplanting radiation therapy in the nonsurgical treatment of LMM.

In prospective nonrandomized clinical trials carried out at The University of Texas M.D. Anderson Cancer, three subgroups of patients were studied (115). The first group had primary lesions thicker than 1.5 mm or had lesions extending to Clark level IV or V and received elective radiation after a wide local resection. The second group had palpable lymphadenopathy and received radiation in the adjuvant setting after excision of primary lesions coupled with a therapeutic neck dissection (selective or modified radical). The last group of patients underwent radiation after therapeutic neck dissection for regionally recurrent melanoma. Hypofractionated radiotherapy was delivered in five fractions of 6 Gy, twice weekly, to a total dose of 30 Gy. Theoretically, the large radiation fractions were used to overcome the melanoma radioresistance. Only 6 of 174 patients developed recurrence above the clavicles, but 58 patients developed distant metastases. The 5-year survival rate was 47%, and the local–regional control rate was 88% for all patients. The 5-year survival rates compared favorably with historical controls, and the radiation side effects were tolerable. These studies formed the basis for the use of hypofractionated radiation in melanoma.

Later studies from this group evaluated the outcome of patients with clinically apparent cervical lymph node metastases from malignant melanoma managed with surgical resection and adjuvant radiation (116). After 10-year follow-up, the group demonstrated a 94% regional control rate. Radiation-related complications for the patients were rare and manageable (116). The same group evaluated the utility of radiation therapy alone in the treatment of 36 patients with positive SLNB (*in lieu* of completion lymphadenectomy) and demonstrated 93% regional control over 5 years (117).

The Trans Tasman Radiation Oncology Group and Australia and New Zealand Melanoma Trials Group reported on a prospective study of radiation versus observation after lymphadenectomy on patients from 16 different centers (118). Inclusion criteria included greater than or equal to one parotid, greater than or equal to two cervical or axillary, or greater than or equal to three groin-positive nodes; extra nodal spread of tumor; or minimum metastatic node diameter of 3 cm (neck or axilla) or 4 cm (groin). Radiation was given as 2.4 Gy in 20 fractions over 4 weeks. There was a statistically significant improvement in lymph node field control with radiotherapy: 20 of 109

radiation and 34 of 108 observation patients relapsed regionally (P = 0.04). Despite improved local regional control, the overall survival was better in the observation group (47 months median survival) versus the radiation group (31 months median survival) although this was not statistically significant (P = 0.14). These data have raised concerns about possible deleterious effects of radiation as a contributor to the development of distant metastases. This question remains to be answered.

The NCCN recommends adjuvant radiation for patients with desmoplastic melanoma with narrow margins, recurrent disease, extensive neurotropism, gross nodal extracapsular extension, ≥2 lymph nodes, ≥2 cm of tumor in a lymph node, or unresectable nodal, satellite or in-transit disease (Fig. 114.6). Additionally, radiotherapy should be considered after excision of mucosal melanomas, which may or may not be amenable to complete excision (32,120).

SYSTEMIC THERAPY

Two major indications exist for systemic therapy in the management of patients with CMM. The first indication is the *adjuvant* treatment of patients who have completed locoregional therapy and have no evidence of local, regional, or systemic disease but who are thought to be at high risk for systemic relapse. The second indication for systemic treatment is the presence of distant metastases. A number of systemic therapy options are available to treat patients with either of these indications, including single-agent or multiple-agent chemotherapy, biochemotherapy, or strategies using immune modulation.

A number of clinical studies have been designed to evaluate the role of systemic adjuvant therapies for patients who have completed local–regional treatment and who are believed to be at high risk for the development of distant metastatic disease. Although no universal definition exists for the high-risk patient, a number of studies have accrued patients with primary lesions that are ulcerated, more than 4 mm in depth or Clark level IV, or those patients with satellitosis, in-transit disease, or nodal metastases. It is well established that the prognosis of patients with metastatic melanoma is poor; those with liver, brain, or bone metastasis have a median survival of only 3 to 4 months.

Interferon

Interferon alfa is one of the most well-studied agents for the systemic adjuvant therapy of CMM arising from all sites (121,122). However, it has yet to be shown unequivocally to improve overall survival for these patients. The interferons are a family of proteins that have both immunostimulatory and antiangiogenic activity and have excellent preclinical antitumor activity in a number of systems. Interferons enhance phagocytosis and free radical production in macrophages and increase activity of natural killer cells.

A prospective, randomized, clinical trial of high-dose interferon alfa-2b in the treatment of patients with high-risk melanoma was conducted by the Eastern Cooperative Oncology Group (122). High risk was defined as thick melanomas greater than 4 mm in Breslow depth and lymph node involvement by melanoma. High-risk patients were given high-dose interferon alfa-2b, 20 MU/m^2/d intravenously for 4 weeks. This was followed by 10 MU/m^2/d, administered subcutaneously, 3 days weekly for the remainder of the year. An increase in survival of 2.8 to 3.8 years was observed, and the recurrence-free survival ranged from 1 month to 1.7 years. The survival advantages were statistically significant in patients with regional lymph node metastasis. Most patients experienced significant toxicity that included chills, fevers, myalgias, and other constitutional symptoms including fatigue and anorexia. A follow-up trial of high- and low-dose interferon alfa-2b in high-risk melanoma, E1690, was reported by the intergroup (121). This study did not confirm the earlier improvement in overall survival but did demonstrate a dose-dependent improvement in 5-year recurrence-free survival rates from 35% to 44%. This is the 9% improvement in survival that many practitioners quote when discussing this treatment with patients.

The EORTC protocol 18,991 randomized 1,256 patients with stage III melanoma that had been completely resected to either observation or treatment with pegylated interferon alfa for an intended duration of 5 years. Four-year relapse-free survival was significantly better in the interferon group compared to the observation group (45.6% vs. 38.9%), but there was no significant effect of pegylated interferon on overall survival (123). Of note, a recent study (124) demonstrated that the appearance of autoantibodies or clinical manifestations of autoimmunity (i.e., vitiligo) during treatment with interferon alfa-2b is associated with statistically significant improvements in relapse-free survival and overall survival, though this has been disputed by others (125).

Low-dose and intermediate-dose trials of interferon alfa (EORTC 18952 and AIM HIGH Study) did not show improvement in progression-free or overall survival (126,127). Currently, when interferon is recommended as adjuvant therapy, only the high-dose regimens are recommended.

Recently, the Hellenic Cooperative Oncology Group reported on a prospective randomized study of 4 weeks of high-dose induction interferon (15 MU/m^2/d) versus the same induction regimen followed by 11 months of lower dose interferon (10 MU/m^2/d three times a week) (128). They found no difference in relapse-free survival (24.1 vs. 27.9 months [P = 0.9]) and median overall survival (64.4 vs. 65.3 months [P = 0.49]) (128). There were more side effects in the group with prolonged therapy. These findings were encouraging that a shorter treatment might be equally efficacious; however, subsequently, the Eastern Cooperative Oncology Group (ECOG) trial 1697: Phase III

Randomized Study of Four Weeks High Dose IFN-A2B in Stage T2B NO, T3A-B NO, T4A-B NO, and T1-4, N1A, 2A (microscopic) melanoma compared 1 month of high-dose interferon to observation. This study was halted in October of 2010 after the third interim analysis because there was no evidence of benefit in the interferon treatment group and no meaningful possibility that the study would show a benefit. These results have not been published yet, but based on the limited information that is publicly available, only treating with 1 month of interferon is not advisable.

The NCCN guidelines recommend consideration of the use of high-dose interferon alfa for treatment of patients with stage IIB (2.01 to 4 mm thick with ulceration or greater than 4 mm thick without ulceration), IIC (greater than 4.0 mm thick with ulceration), III (lymph node, in-transit, or satellite metastases), or IV (distant metastatic) disease.

Tumor Vaccines

Tumor vaccines are another widely studied strategy for systemic adjuvant therapy of the high-risk melanoma patient, and a variety of different immunization approaches have been used. These studies are predicated on several clinical observations and lines of basic investigation that indicate that the immune system can eradicate melanoma cells and that immune stimulation can overcome immune tolerance to tumor antigens to enhance the immune surveillance of tumor cells. Although a comprehensive review of available vaccine strategies is beyond the scope of this chapter, some of the more encouraging studies are discussed.

Ganglioside GM2, an antigen overexpressed by many melanoma cells, given in combination with Bacille Calmette-Guérin (BCG) or other immune adjuvants, was developed by Dr. Alan Haughton and colleagues at Memorial Sloan-Kettering Cancer Center. Initial clinical trials suggested promising results (129); however, further studies failed to show clinical benefit of this adjuvant treatment. Kirkwood et al. (130) reported their experience comparing high-dose interferon alfa-2b and GM-2 ganglioside vaccine for patients with resected melanoma, demonstrating superior performance of interferon. Additionally, a randomized Phase III trial (EORTC 18961) of adjuvant GM2-KLH21 in 1,314 patients with stage II melanoma was closed early by the data monitoring committee because of inferior survival in the vaccine arm (131).

Investigators at the John Wayne Cancer Center developed a polyvalent melanoma cell vaccine capable of inducing humoral- and cell-mediated immune responses to melanoma-specific antigens (132,133). Dr. Steven Rosenberg and coinvestigators at the surgery branch of the National Cancer Institute have identified other cancer vaccines by using specific peptide antigens recognized by autologous tumor-specific T-cell clone reactivity (134). These peptide vaccines are most often administered with cytokine or cellular immune adjuvants such as dendritic cells. DiFronzo et al. (135) demonstrated that enhanced humoral responses in patients treated with polyvalent vaccines resulted in limited but improved disease-free survival. Schwartzentruber et al. (136) showed increased survival of 17.8 months compared to 11.1 months in treatment with a vaccine (gp100:209-217(210M)) and interleukin-2 (IL-2) as compared to IL-2 alone. It is difficult to advocate any of the current vaccine strategies over another. Therefore, we recommend that patients with high-risk melanoma be enrolled into prospective trials to test these adjuvant therapeutic strategies.

Interleukin-2

Interleukin-2 (IL-2) was approved by the Food and Drug administration (FDA) for treatment of metastatic melanoma in 1998. High-dose intravenous bolus IL-2 treatment resulted in overall objective response rates of about 17% (137). In a highly selected patient population (n = 270), IL-2 was able to induce durable complete responses (median response duration over 59 months) in approximately 6% of patients and partial responses in 10% of patients with metastatic melanoma, albeit with high levels of toxicity (138,139). A recent study demonstrated increased response rate in metastatic melanoma when IL-2 was given with the 210M peptide vaccine (22%) compared to IL-2 (13%) alone (140).

Ipilimumab

Despite many preclinical and clinical studies evaluating multiple cytokines, vaccines, antibodies, and other types of immune modulation, alone or in combination with chemotherapy, only *IL-2* for metastatic disease and *interferon alfa* for surgical adjuvant treatment have demonstrated sufficient success to warrant approval by regulatory authorities (138,141). Nevertheless, there has been continued optimism that immune modulation can become an effective treatment for patients with melanoma driven largely by key advances in tumor immunobiology, including the potential to manipulate and disrupt immune activation checkpoints and tumor defense mechanisms; newer approaches to antigen presentation for immune activation; refinements to procedures for antigen-specific T-cell expansion; gene transfer to alter lymphocyte specificity and function; and the potential for discovery of improved predictive biomarkers to select patients for individual treatments (142).

Along these lines, Hodi et al. induced antitumor immunity in patients with metastatic melanoma using ipilimumab, an antibody directed against the cytotoxic T-lymphocyte-associated antigen CTLA-4 (143). CTLA-4 is an immune checkpoint molecule that downregulates T-cell activation, and blocking this molecule is known to promote antitumor immunity (143). In their multicenter clinical trial, patients with metastatic melanoma were randomly assigned to receive either an anti–CTLA-4 agent (ipilimumab), a vaccine based on a melanoma antigen, or a combination of the anti–CTLA-4 agent and the vaccine. An improvement in overall survival, as well as an improvement in progression-free survival and best overall response rate, was seen in the patients who received anti–CTLA-4 therapy, as compared with the patients who received the

vaccine only (143). Of note, the side effect profile of ipilimumab deserves mention, as 60% of patients suffered adverse events, mostly immune related. However, this randomized, controlled trial showed that there was a significant improvement in overall survival among melanoma patients treated with ipilimumab. Robert et al. (144) showed improved survival of 20.8% from 12.2% at 3 years for patients treated with ipilimumab plus dacarbazine versus dacarbazine alone. Based on these trials, ipilimumab is a preferred therapy option for advanced or metastatic melanoma in the NCCN guidelines.

Chemotherapeutic Agents

Chemotherapy regimens using single-agent dacarbazine (DTIC) or combinations such as bis(2-chloroethyl)nitrosourea (BCNU), cisplatin, lomustine, and hydroxyurea have been reported. The trials comparing DTIC alone or in combination with other agents have shown a significant though brief improvement in survival (145). Unfortunately, there is little consensus regarding a standardized chemotherapeutic regimen for metastatic melanoma. According to the NCCN, dacarbazine remains a standard of care in community practice and has been used as a standard for comparing the efficacy of new regimens (61,146). Dacarbazine and temozolomide have been shown to have similar response rates (~10% to 20%) and survival (147); median response duration with these drugs is 3 to 4 months (145,147). Temozolomide can cross the "blood–brain barrier," making it an attractive agent for treating melanoma, which has a propensity for metastasis to the brain.

Combination chemotherapy regimens such as CVD (dacarbazine plus cisplatin and vinblastine) or the Dartmouth regimen (dacarbazine, carmustine, cisplatin, and tamoxifen) initially reported higher response rates (148,149), but subsequent clinical trials have not replicated these high response rates (150). Paclitaxel alone or in combination with carboplatin may provide clinical benefit to some patients with metastatic melanoma; however, the duration of clinical benefit is short (2 to 7 months) (151,152).

Molecularly Targeted Therapy of Melanoma

Recent groundbreaking work has been reported on molecularly targeted chemotherapy in melanoma. In 2002, it was demonstrated that approximately 50% of human melanomas harbor an activating mutation in BRAF, in which glutamic acid is substituted for valine (the V600E mutation) (153). BRAF is an upstream component of the growth-promoting mitogen-activated protein (MAP) kinase pathway. It has been established that melanoma cells containing mutant BRAF are dependent on MAP kinase signaling for their growth and survival (154). These findings suggested the possibility that melanoma may be amenable to targeted therapy. Initial studies performed with sorafenib, a multikinase anti-BRAF agent, were disappointing showing no difference between standard chemotherapy and the addition of sorafenib (155,156). However, vemurafenib (PLX4032 Plexxikon; RG7204, Roche Pharmaceuticals), a potent inhibitor of BRAF with the V600E mutation, has been shown to be remarkably successful therapeutic option in properly selected patients (157). Eighty-one percent of patients with metastatic melanomas harboring the activating mutation in BRAF (V600E) had a response—complete or partial tumor regression—to treatment with vemurafenib in a multicenter, phase 1 and 2, dose escalation trial. Responses were observed at all sites of disease, including bone, liver, and small bowel.

A phase 3 randomized clinical trial comparing vemurafenib with dacarbazine in 675 patients with previously untreated, metastatic melanoma with the BRAF V600E mutation showed improved 6 month survival of 84% versus 64% in the vemurafenib versus the dacarbazine group (158). Response rates were 48% for vemurafenib and 5% for dacarbazine (158). Endpoints for improved survival with vemurafenib were met at the interim analysis and patients were recommended to crossover from dacarbazine to vemurafenib.

It seems clear that melanomas can be categorized by specific molecular changes that drive their proliferation (159); targeting the activated pathways in individual tumors may lead to tumor regression and possible cure. This type of personalized cancer therapy will likely play a prominent role in the care of patients with melanoma and other cancers in the coming decade.

Biochemotherapy

Another approach to systemic treatment of melanoma includes the use of biochemotherapy in which conventional chemotherapeutic drugs are combined with the biologically active agents interferon alfa and IL-2. In single institutional phase II trials, biochemotherapy (cisplatin, vinblastine, dacarbazine, interferon alfa, and IL-2) produced an overall response rate of 27% to 64% and a complete response rate of 15% to 21% in patients with metastatic melanoma (160–162). A report of a small phase III randomized trial comparing sequential biochemotherapy (dacarbazine, cisplatin, vinblastine with IL-2, and interferon alfa administered on a distinct schedule) with combined cisplatin, vinblastine, and dacarbazine (CVD) showed response rates of 48% for the biochemotherapy regimen compared to 25% for CVD alone; median survival for patients treated with biochemotherapy was 11.9 versus 9.2 months for CVD (163). In a phase III randomized intergroup trial (E3695), biochemotherapy (cisplatin, vinblastine, dacarbazine, IL-2, and interferon alfa-2b) produced a slightly higher response rate and progression-free survival than CVD alone, but it was not associated with either improved quality of response or overall survival in patients with metastatic melanoma (164). Biochemotherapy was substantially more toxic than CVD. Additional attempts to decrease toxicity of biochemotherapy by administering subcutaneous outpatient IL-2 did not show a substantial benefit of biochemotherapy versus chemotherapy alone (165–167). Notably, a recent meta-analysis demonstrated

that although biochemotherapy seemed to improve overall response rates, there was no survival benefit for patients with metastatic melanoma (168). Some current studies are focused on the use of IL-2 given with melanoma peptide antigens or melanoma-specific in vitro expanded autologous tumor-infiltrating lymphocytes. A combination of systemic therapies such as interferon alfa, IL-2, cisplatin, dacarbazine, and tamoxifen also has been reported to have activity in patients with metastatic disease (169).

Nevertheless, given the overall poor performance of agents in this cohort of patients, continued basic and translational research is warranted to identify active agents for these unfortunate patients. Preemptive strategies are also being developed. Because a majority of patients with CMM have some identifiable risk factor (i.e., sun exposure), chemoprevention using carotenoids and inhibitors of cyclooxygenase-2 (COX-2), vascular endothelial growth factor (VEGF) receptor, and cytochrome P-450 is actively being investigated (170). Outcomes of this work are much anticipated.

SURVEILLANCE

With the rapidly increasing rate of melanoma worldwide, the importance of surveillance of even benign-appearing lesions is understood. The importance of dermatologic evaluation, photo documentation, and close follow-up cannot be overstated. In patients with a diagnosed malignant melanoma, between 55% and 70% of recurrences appear within the first 2 years of therapy, and up to 80% of recurrences will be diagnosed in the first 3 years after treatment. Those with regional metastasis at presentation may have clinically evident tumor recurrences within 24 months. The time to recurrence also correlates with primary tumor thickness, ulceration, and increasing patient age. Screening is typically by physical examination, liver-function serology, and chest x-ray, which will detect most of these recurrences; therefore, routine screening with CT of the head, chest, and abdomen is not recommended. In general, the use of chest x-rays and liver serology is known to have an extremely low yield (171). The utility of PET or PET–CT imaging for the surveillance of affected patients is still under investigation. Additionally, the prospect of using specific serum screening tools such as tyrosinase mRNA detected by RT-PCR is both clinically exciting and ethically challenging (172).

The National Cancer Institute reported a consensus statement on the follow-up evaluation of patients with early melanoma. Most patients without a family history and no atypical nevi should have follow-up evaluations every 6 months for the first 2 years.

Thereafter, yearly follow-up is appropriate. Those with a family history or atypical nevi are followed up every 3 months. The recommended surveillance for patients without any evidence of disease after treatment for CMM is shown in Figure 114.7 (173).

CONCLUSION

The incidence and mortality rate of CMM are rapidly increasing worldwide. Features of the history and physical examination that are suggestive of malignant melanoma include changes in size or color, sensation of the lesion, and variations in color and margin, and thickness. The presence of ulceration also is quite important. When a suggestive lesion is encountered, excisional biopsy is recommended, and should include subcutaneous fat for complete evaluation of lesion depth. Biopsy techniques that do not evaluate depth, such as fine-needle aspiration and

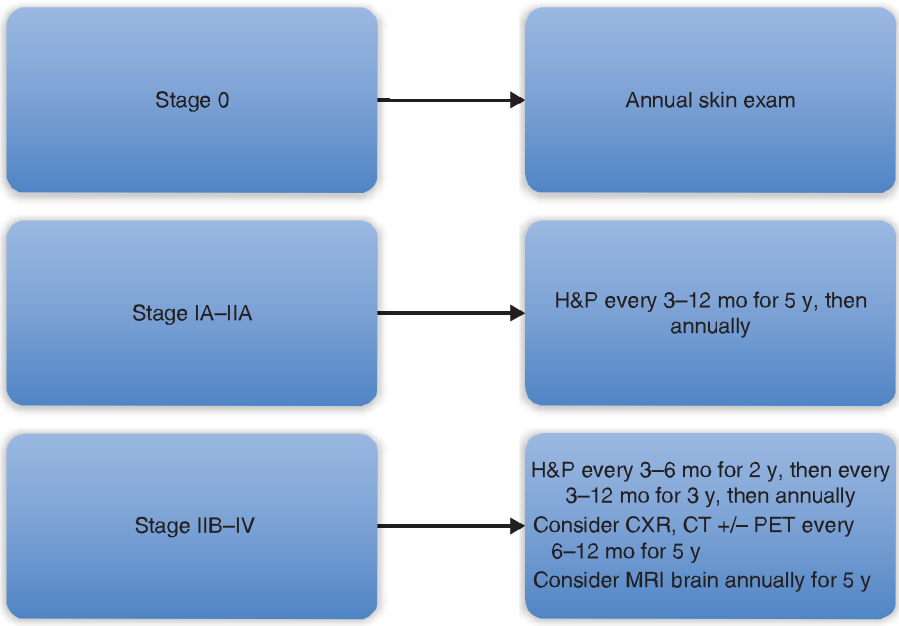

Figure 114.7 Surveillance recommendations (Adapted from NCCN).

curettage, have no role in evaluation in suspected melanoma. Once invasive melanoma is diagnosed, histologic type is assessed, and lesion thickness is established. Tumor thickness (Breslow), level of invasion (Clark), presence of ulceration and microscopic satellitosis, and number of mitoses are prognostically important and aid the clinician in the decision to perform SLNB. Staging in relation to the presence of regional and distant metastasis is established by physical examination, liver function serology, and chest radiograph in stage I and II disease. Additionally, imaging of the brain, head, neck, chest, and abdomen is recommended for patients with stage III and IV disease.

Lymphoscintigraphy with SLNB provides an adjunctive method of identifying SLNs and defining routes of lymphatic spread, especially in patients with primary tumors located in the midline that have predicted drainage basins that are ambiguous or include both parotid glands. After staging, a treatment strategy is formulated. For melanomas less than 0.75 mm in thickness and with no evidence of regional metastasis, surgical excision is carried out with close surveillance thereafter. Current recommendations for adequate resection margins, dependent on anatomic constraints, range from 0.5 to 2 cm, depending on the thickness of the primary lesion. For patients with lesions more than 0.75 mm thick without regional metastasis, excision is offered, along with SLNB. Once SLNB is performed, serial sectioning of the lymph node(s) with immunohistochemical evaluation is carried out on histologically negative SLNs to increase the sensitivity of pathologic identification of metastases.

In patients with regional lymph nodes that are found to be pathologically positive, therapeutic lymphadenectomy and/or radiotherapy is offered.

Patients with clinically positive lymph nodes should undergo excision of the primary lesion and a therapeutic neck dissection that may be modified to preserve neurovascular structures. Parotidectomy is performed if parotid lymph nodes are included in nodal drainage basins. These patients also should be evaluated for systemic therapy, as should those who have or develop distant metastasis. The use of systemic therapy includes chemotherapy, bioimmunotherapy, vaccination, and more recently, molecularly targeted therapy, all of which can be used to treat metastatic disease or in the adjuvant setting for patients without evidence of disease who are at high risk for systemic failure. The importance of treating these patients within the confines of thoughtfully designed, prospective clinical trials cannot be overemphasized.

The number of patients affected with melanoma is increasing. However, survival rates are improving because of early-detection programs and heightened awareness of the general population. It is hoped that this heightened awareness, coupled with progress made in improved pathologic description and staging and the use of systemic therapies, including immune modulation and molecularly targeted therapy, will result in continued improvement in our ability to cure patients with this disease.

HIGHLIGHTS

- Melanoma is divided into four distinct clinicopathologic subtypes: LMM, superficial spreading, nodular, and acral lentiginous melanoma. Desmoplastic melanomas are a fifth, less common subtype of melanoma that are characterized by perineural invasion, high local recurrence rates, and low rates of lymph node metastases.
- Histologic evaluation must include the following: Breslow depth/thickness, presence or absence of ulceration, and mitotic rate. Clark level may have clinical utility in the evaluation and treatment of patients with thin melanomas.
- Staging of melanoma includes the presence of satellite lesions, in-transit disease, the number (rather than the size of) involved lymph nodes, and distant metastases.
- Recommended excision margins for melanoma are dictated by Breslow depth. *In situ* melanoma requires a 0.5-cm margin of normal skin, lesions less than or equal to 1 mm in depth require a 1-cm margin, lesions 1.01 to 2.0 mm in depth require a 1- to 2-cm margin depending upon surrounding structures, and lesions greater than 2.01 mm in depth require a 2-cm margin.
- SLNB is considered or offered to patients with melanomas greater than 0.75 mm in thickness. The likelihood of a positive sentinel lymph node increases with the depth of the primary melanoma: T1 lesions have a 3% to 5% risk of SLN positivity; T2, 8% to 12%; T3, 23% to 27%; and T4, 24% to 44%.
- For patients with thin, nonulcerated primary tumors without evidence of regional or distant spread on physical examination (stages I and II), chest radiograph and liver function tests compose the recommended workup. For patients with regional or systemic metastases or both, a comprehensive staging workup should include MRI of the brain and contrast-enhanced CT of the neck, chest, abdomen, and pelvis. PET imaging has been used to aid in detecting regional and distant metastasis.
- Adjuvant radiation therapy should be considered for patients with desmoplastic melanoma with narrow margins, recurrent disease, extensive neurotropism, gross nodal extracapsular extension, ≥2 lymph nodes, ≥2 cm of tumor in a lymph node, or unresectable nodal, satellite or in-transit disease.
- Patients with high-risk primary tumors, regional metastasis, or distant metastases should be evaluated for systemic adjuvant therapies. Interferon alfa, ipilimumab, vemurafenib and high-dose IL-2 are effective in this setting.

115 Salivary Gland Neoplasms

Young S. Oh *Matthew S. Russell* *David W. Eisele*

Neoplasms of the salivary glands represent a diverse group of benign and malignant tumors with varying degrees of behavior. Accurate pathologic diagnosis is key to the management of these lesions because of their varied clinical behaviors. The otolaryngologist-head and neck surgeon must understand the behavior of each tumor type to develop an appropriate treatment plan for a given patient.

ANATOMY AND PHYSIOLOGY

Salivary glands are divided into major and minor glands. The major salivary glands consist of the paired parotid, submandibular, and sublingual glands. The minor salivary glands consist of 600 to 1,000 glands distributed throughout the upper aerodigestive tract. The World Health Organization histologic classification scheme for salivary gland tumors is presented in Table 115.1.

The incidence rate for salivary gland neoplasms is near 1/100,000 with little variance over the last several decades. Approximately 70% of salivary gland tumors originate in the parotid gland. Of parotid gland tumors, approximately 75% to 80% are benign. About 10% of salivary gland tumors arise from the submandibular gland with the distribution of benign and malignant tumors being similar to the parotid gland. Finally, approximately 20% arise from the minor salivary glands, and a higher proportion (50% to 75%) of these neoplasms are malignant (1).

In adults, the vast majority of salivary gland tumors are benign. Malignancies make up 5% of all head and neck cancers and less than 0.5% of all cancers (2). The most common benign tumor for all salivary glands is the pleomorphic adenoma. Tables 115.2 to 115.4 list series in the literature detailing the distribution of neoplasms of the parotid, submandibular, and minor salivary glands, respectively (3–5).

Salivary gland tumors are far less common in the pediatric population. Only about 5% of all epithelial salivary gland tumors will occur in children and adolescents. Unlike adults, benign vascular and lymphatic tumors are the most common pediatric salivary gland masses (6). Infectious, inflammatory, and congenital conditions should also be considered in the differential diagnosis of pediatric salivary gland lesions. The majority of epithelial neoplasms in children are malignant (Tables 115.5 and 115.6) (7).

BENIGN NEOPLASMS

Pleomorphic Adenoma

Pleomorphic adenoma (benign mixed tumor) accounts for approximately 65% of all salivary gland tumors. These tumors are most often found in the parotid gland, followed by the submandibular gland, and the minor salivary glands. They also represent the most common tumor of each type of salivary gland.

Benign mixed tumor describes the mesenchymal and epithelial components of the tumor. The gross appearance is smooth and lobular with a well-defined capsule. Microscopically, the tumor consists of epithelial and mesenchymal elements. The epithelial component forms a trabecular pattern with a mesenchymal stroma (Fig. 115.1). The mesenchymal portion may be myxoid, chondroid, fibroid, or osteoid. The stroma varies from tumor to tumor and may have a combination of any of these tissue types within it. Histologically, encapsulation may be incomplete with pseudopod extensions of the tumor (8).

Historically, unacceptably high recurrence rates of 20% to 45% have been observed with simple tumor enucleation. Thus, complete surgical resection with an adequate margin of normal tissue is advocated. In the past, for the parotid gland, this constituted a complete superficial parotidectomy. Although this technique is highly effective, there can be some unwanted sequelae such as temporary or permanent facial nerve injury, cosmetic soft tissue defects, or Frey syndrome. Presently, tumor resection by partial parotidectomy

with facial nerve preservation is advocated. This procedure is defined as any parotidectomy in which less than the entire lobe or less than all the branches of the facial nerve are dissected. Lower rates of facial nerve weakness and Frey syndrome are observed with this approach (9).

Rarely, pleomorphic adenoma can metastasize and yet remain benign appearing histologically. Reported sites of metastases include bone, head and neck regions, lungs, and skin. When feasible, surgical resection of the metastatic site is the optimal treatment. Incomplete excision or

rupture of the primary is thought to be a risk factor for the development of distant metastases (10,11).

Warthin Tumor

Warthin tumor (papillary cystadenoma lymphomatosum) is the second most common benign salivary gland neoplasm constituting 5% to 6% of all benign tumors. The majority of Warthin tumors occur in the parotid gland. However, extraparotid sites can be involved as well, typically in the cervical lymph nodes (12). Smoking is a clear etiologic factor for this tumor. Classically, this is a tumor that occurs more commonly in men, but the incidence has increased in women. This is thought to be due to the increased relative rate of smoking in women. Rates of multicentricity for this tumor has been reported from 12% to 50% depending on the series (Fig. 115.2). Bilateral tumor can be seen in up to 12% of patients (13,14).

The gross appearance of the tumor is smooth with a well-defined capsule. Cut sections reveal multiple cystic spaces that can be filled with a thick, mucinous exudate. Microscopically, Warthin tumor has a characteristic appearance with a papillary epithelium with a lymphoid stroma projecting into cystic spaces (Fig. 115.3). The epithelium is a double layer of oxyphilic granular cells, with cells of the inner layer having the nuclei oriented toward the basement membrane. The cells in the outer layer have nuclei toward the cystic space.

Complete surgical excision is recommended. Tumor "recurrences" are thought to result from unrecognized multicentric tumors (13).

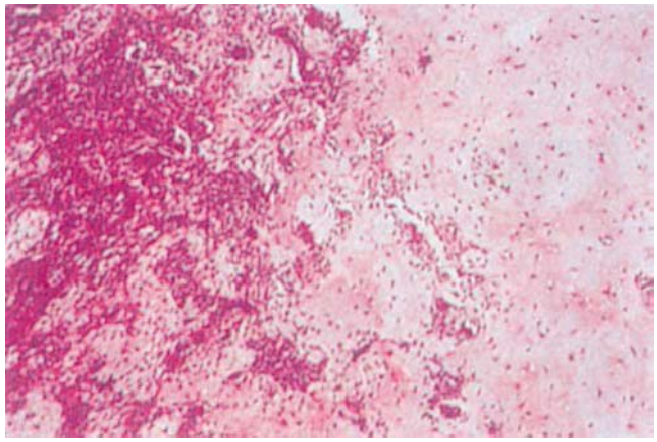

Figure 115.1 Pleomorphic adenoma. The histologic appearance shows characteristic epithelial and mesenchymal elements.

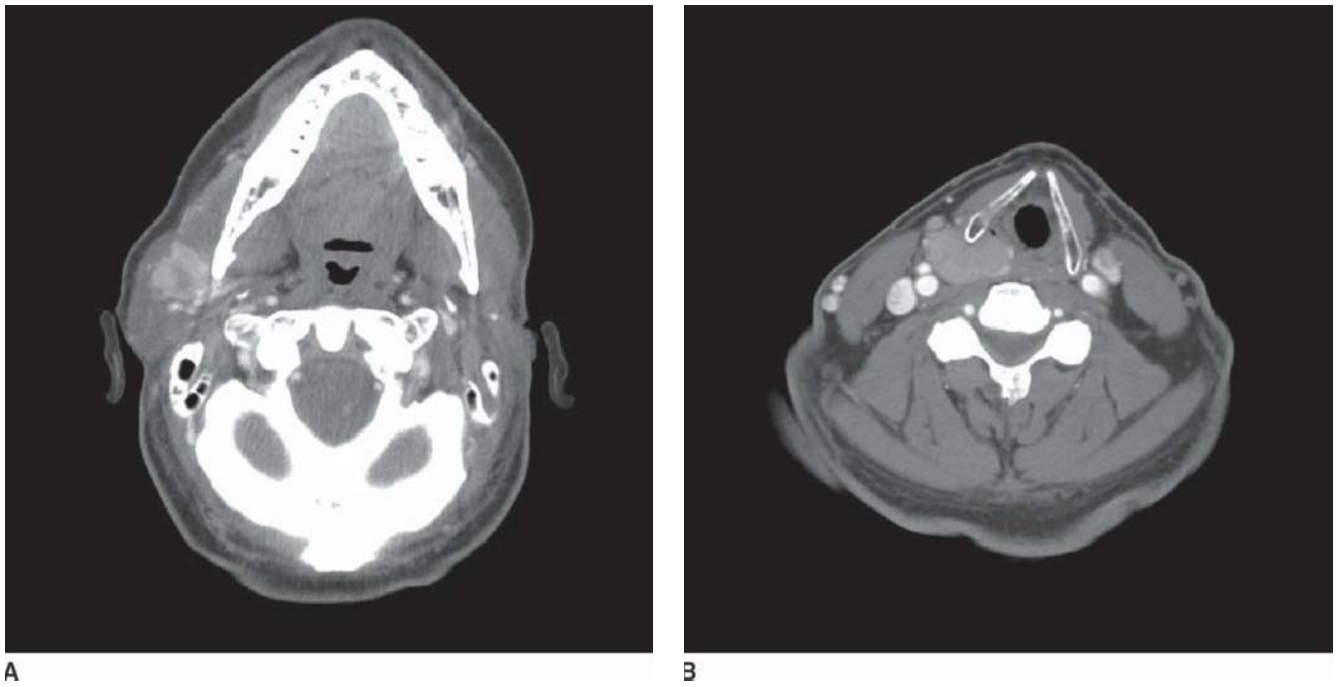

Figure 115.2 **A:** Axial contrast-enhanced CT shows a sharply marginated, heterogeneous attenuation lesion in the superficial lobe of the right parotid gland. **B:** Axial contrast-enhanced CT demonstrates a well-circumscribed enhancing mass, medial to the sternocleidomastoid muscle, which displaces the right thyroid cartilage anteriorly and laterally. This lesion proved to be an additional focus of Warthin tumor.

Oncocytoma

Oncocytoma is an uncommon salivary gland tumor that accounts for about 1% of all salivary gland neoplasms (15). It occurs almost exclusively in the parotid gland. This tumor occurs most frequently in the fifth and sixth decades of life and with equal distribution between men and women (16). Oncocytoma usually presents as a painless mass in the superficial lobe of the parotid gland.

These tumors are noncystic, firm, and rubbery. Microscopically, these neoplasms are composed of brown, plump, granular eosinophilic cells with small indented nuclei (Fig. 115.4). A mitochondria-filled cystoplasm is a characteristic finding on electron microscopy. Malignant degeneration is rare. A possible explanation for these tumors is an acquired genetic defect leading to mitochondrial dysfunction; however, an exact molecular mechanism has not been established (17). Immunohistochemical studies have found that oncocytoma demonstrated positive reactivity to CK5/6, CK8/18, CK19, and EMA. It was negative to S100 and SMA (16).

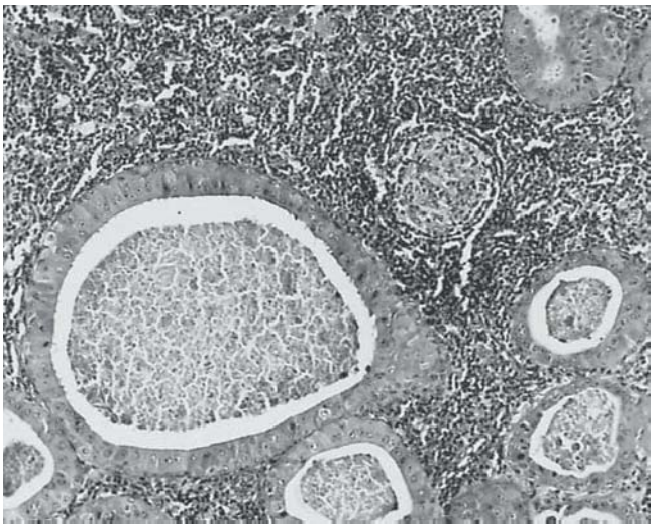

Figure 115.3 Warthin tumor. Lymphoid stroma and double-layered epithelium surround the cystic spaces.

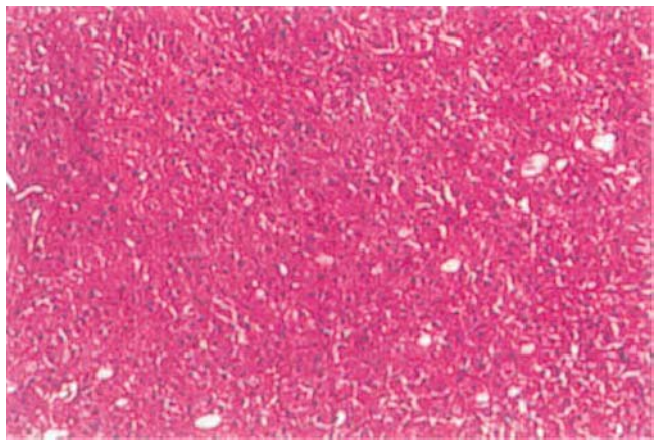

Figure 115.4 Oncocytoma. The histologic appearance is that of typical plump, granular eosinophilic cells.

Complete tumor resection is the treatment of choice for oncocytoma.

Basal Cell Adenoma

Basal cell adenoma represents about 2% to 3% of all salivary gland tumors. It usually occurs in the sixth to seventh decades of life, and it occurs most often in the parotid gland. The remainder are divided between the submandibular and the minor salivary glands. It affects more women than men (18).

These tumors are well circumscribed and encapsulated. The membranous histologic variant can be multinodular. Microscopically, it can demonstrate four different histologic patterns. The solid pattern consists of sheets of basaloid cells. The tubular pattern consists of small ductules linked by the basaloid cells. The trabecular pattern has plexiform bands of the tumor cells. Finally, the membranous pattern consists of differing sizes of islands of basaloid cells. The membranous pattern can show multicentric tumor patterns and has a higher rate of recurrence after surgery (18).

Basal cell adenoma is considered a benign, nonaggressive tumor. Treatment consists of complete surgical resection with a margin of normal tissue.

MALIGNANT NEOPLASMS

Mucoepidermoid Carcinoma

Mucoepidermoid carcinoma is the most common malignant neoplasm of the salivary glands. It presents most frequently in the parotid gland, for which it is the most common malignant tumor. It is the second most common malignant tumor of the submandibular gland. Mucoepidermoid carcinoma constitutes approximately 30% to 35% of all malignant tumors of the salivary glands (19,20). This is a cancer that usually occurs between the third and sixth decades of life with a slight predominance in women.

Mucoepidermoid carcinomas are usually classified as low-grade or high-grade tumors. However, some pathologists also include an intermediate grade. Low-grade tumors have a higher proportion of mucous cells to epidermoid cells. These lesions behave more like benign neoplasms but in rare cases are capable of local invasion and metastasis. High-grade tumors have a higher proportion of epidermoid cells and may be difficult to differentiate from squamous cell carcinoma. High-grade lesions are aggressive tumors with a high propensity for metastasis. Intermediate-grade lesions have been found to behave like high-grade tumors. Thus, the grade and stage of these neoplasms are important prognostic variables (21).

Low-grade tumors are usually small and partially encapsulated. High-grade neoplasms are usually larger and locally invasive. On cut sections, low-grade mucoepidermoid carcinoma may contain mucinous fluid, whereas high-grade tumors are typically solid. Microscopically, low-grade mucoepidermoid carcinoma demonstrates aggregates of mucoid cells separated by strands of epidermal cells (Fig. 115.5). High-grade tumors have few mucoid elements, and the epidermoid cells predominate (Fig. 115.6).

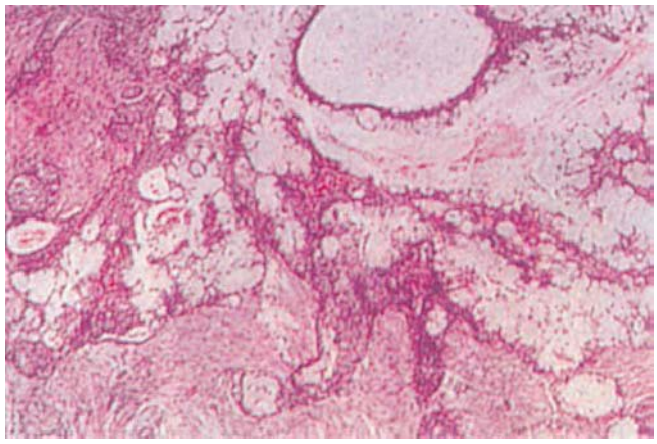

Figure 115.5 Low-grade mucoepidermoid carcinoma. Note the epithelial and glandular elements.

The treatment of this cancer depends on the grade and stage of the tumor. For small, low-grade cancers, complete surgical resection is recommended. Elective treatment of the neck is not recommended for in the clinically N0 neck because of the incidence of occult nodal involvement is very low (21). If the surgical margins are clear and there are no adverse pathologic features, adjuvant radiation therapy is not recommended. Prognosis for this cancer is excellent with locoregional recurrence rates of 10% and 5-year overall survival of 97% (22).

For high-grade tumors, the treatment is tailored to the extent of the disease. As in low-grade disease, complete surgical resection of the primary site is recommended. If the tumor involves the parotid gland, the facial nerve is spared, if possible. Cervical nodal metastases are managed by a comprehensive neck dissection at the time of the resection of the primary. Occult metastases rates have been shown to be approximately 21%; therefore, an elective neck dissection can be considered in a patient with a clinically N0

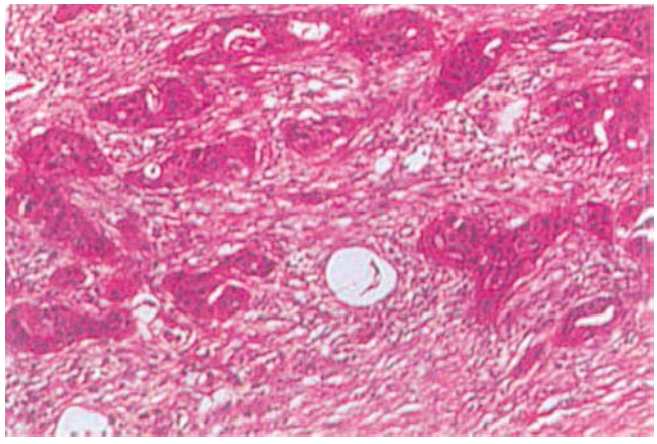

Figure 115.6 High-grade mucoepidermoid carcinoma. Note the relative lack of glandular elements.

neck (22). In most cases of high-grade mucoepidermoid carcinoma, adjuvant radiation therapy is recommended to improve locoregional control (23). High-grade mucoepidermoid carcinoma is an aggressive tumor with a poorer prognosis than the low-grade variant. Locoregional recurrence has been shown to occur 43.5% of the time with 3-year disease-free survival reported to be 55% and 5-year disease-free survival at 30% (21,24).

Adenoid Cystic Carcinoma

Adenoid cystic carcinoma accounts for approximately 10% of all salivary gland neoplasms. It is the second most common malignancy of the parotid gland but is the most common malignancy of the submandibular and minor salivary glands (25). Adenoid cystic carcinoma occurs with equal frequency in men and women, usually in the fifth decade of life. Facial paralysis and pain occur as initial symptoms in a small proportion of patients.

Adenoid cystic carcinoma has a contradictory clinical course. The tumor is slow growing, but its clinical course is relentless. Multiple local recurrences can occur despite adequate surgical intervention, and although regional metastatic spread is uncommon, distant spread, especially to the lungs, is common.

Grossly, the tumor is usually monolobular and either nonencapsulated or partially encapsulated. The mass often demonstrates infiltration of surrounding normal tissue. Microscopically, adenoid cystic carcinoma has a basaloid epithelium arranged in cylindric formations in an eosinophilic hyaline stroma (Fig. 115.7). Different histologic patterns have been identified including cribriform, solid, and tubular. The solid histologic pattern appears to have a worse prognosis in terms of distant metastases and long-term survival (26).

Perineural invasion is a typical feature of adenoid cystic carcinoma. This explains the difficulty in tumor eradication despite the appearance of complete tumor removal. Complete surgical excision and postoperative radiation therapy is recommended for the management of this tumor (27). For select small tumors that are completely excised, however, postoperative radiation therapy may not be needed (28).

There is evidence that fast neutron radiotherapy may be more effective than conventional photon radiation therapy as primary therapy for select adenoid cystic carcinomas that are not amenable to surgery (29,30).

Long-term follow-up is mandatory for these patients because of the slow, relentless disease progression. Recurrences have been shown to occur at an average of 63 months from the time of initial treatment (31). Thus, 5-year survival is not adequate to detail the outcomes of this malignancy. Ten-year overall survival has been reported to be from 55% to 64%. Recurrence rates can be broken down as 42% with distant metastases only, 39% with locoregional recurrences only, and 19% with both locoregional and distant disease (27,31).

Because of the low incidence of occult metastases, elective neck dissection for the N0 neck is not usually performed. However, the presence of nodal metastases at the time of diagnosis is an important prognostic factor because overall survival is significantly lowered when metastases are present (31).

Acinic Cell Carcinoma

Acinic cell carcinoma constitutes approximately 17% of all salivary gland cancers. Up to 98% of these occur in the parotid gland. It affects women more often than men and occurs in the fourth to sixth decade of life. The tumor can be multicentric in 2% to 5% of cases, and it can involve both parotid glands (32,33).

Grossly, this well-circumscribed tumor often has a fibrous capsule. There are two populations of cells: those resembling serous acinar cells of the salivary gland and those with a clear cytoplasm. Tumors occur in several configurations, including cystic, papillary, vacuolated, or follicular. There is often a lymphoid infiltrate, and cells are characteristically positive on periodic acid–Schiff staining (Fig. 115.8).

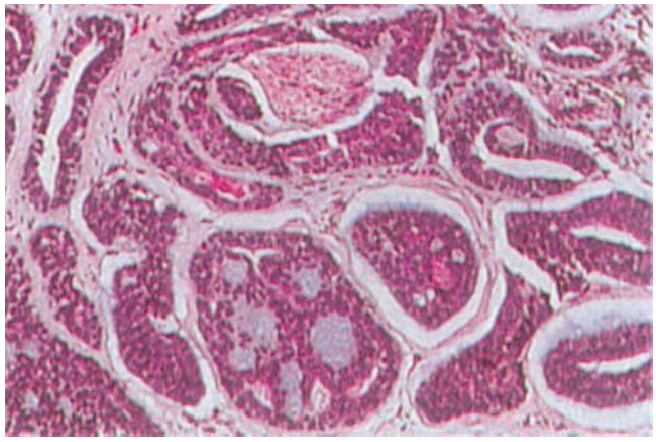

Figure 115.7 Adenoid cystic carcinoma, showing the characteristic histologic appearance with eosinophilic hyaline stroma and perineural invasion.

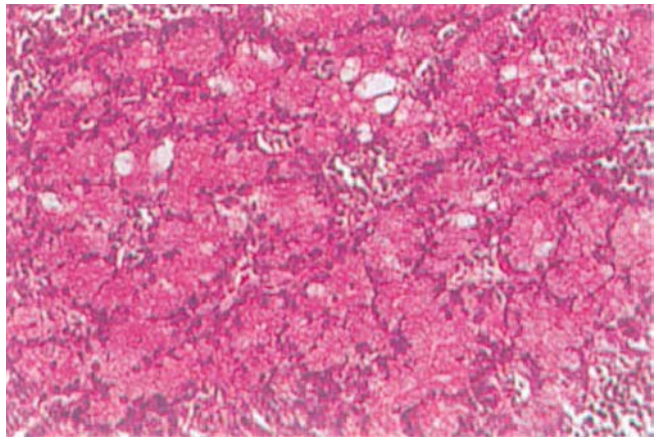

Figure 115.8 Acinic cell carcinoma. Note cells similar to serous acinar cells and cells with clear cytoplasm.

Treatment consists of complete surgical resection with adjuvant radiotherapy reserved for indicators of a poor prognosis (e.g., facial nerve involvement, neck metastases, and skin involvement). Elective treatment of the neck is indicated for high-grade cases of acinic cell carcinoma (32). Although acinic cell carcinoma is typically categorized as an indolent, slow-growing tumor, the average rate of recurrence has been found to be about 35% (32,33). Long term follow-up is mandatory because late local recurrences have been shown to occur many years after initial treatment. For low-grade lesions, 5- and 10-year disease-free survivals have been reported to be approximately 91% and 88%, respectively (34). Five-year overall survival for high-grade acinic cell carcinoma is much poorer at 33% (33).

Adenocarcinoma

Adenocarcinoma most commonly occurs in the minor salivary glands followed by the parotid gland. This neoplasm represents approximately 12% of malignant parotid neoplasms (35). Adenocarcinomas occur equally in both sexes and usually present as a palpable mass. They behave aggressively with a strong propensity to recur and metastasize.

Grossly, adenocarcinoma is firm or hard and attached to the surrounding tissue. Microscopically, the cylindric cells of variable height form papillae, acini, or solid masses. Most neoplasms produce mucus, which can be detected by mucicarmine stain. Adenocarcinoma can be differentiated from mucoepidermoid carcinoma by the lack of keratin staining. The degree of glandular formation has been used as a means of grading these tumors.

Complete surgical resection with postoperative radiation therapy is the recommended treatment for this high-grade malignancy. Five- and ten-year overall survivals are 52% and 36%, respectively (36).

Polymorphous Low-Grade Adenocarcinoma

Polymorphous low-grade adenocarcinoma (PLGA) occurs almost exclusively in the minor salivary glands. The neoplasm most commonly occurs in the palate, buccal mucosa, and the upper lip. Women are affected more commonly than men, and most of these neoplasms occur in the sixth decade of life. The typical presentation of this tumor is of a long-standing, asymptomatic mass on the palate (37).

Histologically, PLGA demonstrates a variable tumor cell differentiation and organization. Mitotic figures and necrosis are unusual features. Tumors typically have an infiltrative growth pattern with frequent perineural invasion. Typical histologic patterns include solid, trabecular, glandular, cribriform, fascicular, cord-like, and papillary. Because of this, careful pathologic diagnosis is mandatory as this neoplasm can be mistaken for pleomorphic adenoma or adenoid cystic carcinoma. Immunohistochemical staining has not been helpful in differentiating adenoid cystic carcinoma from polymorphous low-grade adenocarcinoma (38).

Treatment is wide local surgical excision. Cervical metastases are very uncommon, so a neck dissection is performed only for clinically positive nodes. In a recent review of the three largest series on PLGA, it was found that local recurrences occur anywhere from 10% to 33% of the time. These recurrences can occur up to 15 years after treatment. Even with recurrences, death from tumor progression is rare (39). In general, adjuvant radiotherapy is not recommended for this cancer (40).

Carcinoma Ex Pleomorphic Adenoma

Carcinoma ex pleomorphic adenoma represents a malignant tumor that has risen from a preexisting or recurrent pleomorphic adenoma. The malignant component and metastases from this tumor are purely epithelial in origin. This malignancy represents 2% to 5% of all salivary gland tumors. Rarely, the malignancy can take the form in which the tumor contains both mesenchymal and epithelial components.

Grossly, the tumors are firm with minimal encapsulation. The lesion is widely infiltrative with regions of necrosis and hemorrhage. Microscopically, the malignant neoplasm arises in a background that is characteristic of a benign mixed tumor (Fig. 115.9). Neurovascular invasion and necrosis are frequent findings. The malignant portion of the tumor can take the form of an adenocarcinoma, salivary duct carcinoma, adenosquamous carcinoma, undifferentiated carcinoma, or other malignancy (41). The tumor can also be classified as noninvasive (*in situ*), minimally invasive (less than 1.5 mm), or invasive (greater than 1.5 mm). The majority of these neoplasms are invasive (41,42).

The diagnosis may be confusing because of the differing proportions of benign and malignant elements of the

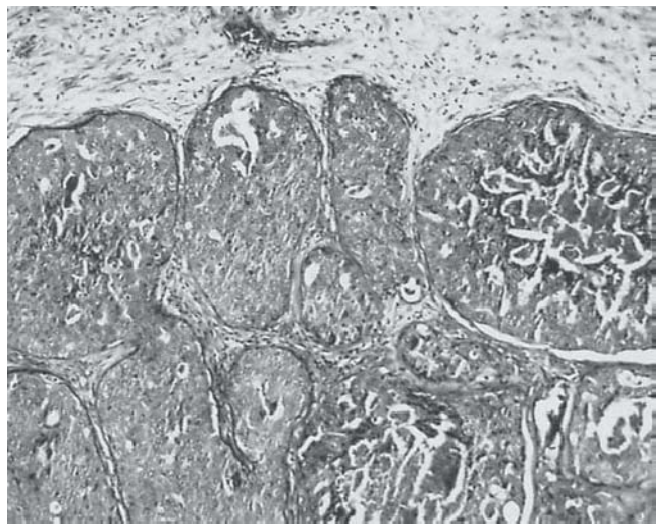

Figure 115.9 Carcinoma ex pleomorphic adenoma is seen in a preexisting pleomorphic adenoma.

tumor. Most cases, however, will have predominantly the malignant component (41,42).

Local and distant metastases are common with this tumor when compared to other salivary gland malignancies. Elective treatment of the neck is recommended because rates of occult metastases have been shown to be about 20%. The recurrence rate is 32% with most occurring in the first year following treatment. Overall survival is 48% at 5 years.

Nodal status is a major determinant of overall survival. In one study, patients who were N+ had 5-year survival at 16% compared to 67% of patients who were N0 (43). Other prognostic factors include pathologic stage, tumor size, grade, proportion of cancer, and extent of invasion (41). Complete surgical resection with postoperative radiation therapy is the recommended treatment for this high-grade malignancy (43).

Primary Squamous Cell Carcinoma

Primary squamous cell carcinoma of the salivary glands represents a rare neoplasm that constitutes less than 1% of all salivary gland cancers (44). This malignancy occurs more often in the submandibular gland than the parotid gland. Rarely, this tumor can also occur in the minor salivary glands (45). Proper diagnosis of squamous cell carcinoma requires exclusion of contiguous spread of a squamous cell carcinoma into the gland, metastases to the gland, high-grade mucoepidermoid carcinoma, and metastatic squamous cell carcinoma from a cutaneous primary.

These tumors usually present as firm indurated masses and occur more commonly in men, usually in the seventh decade of life. Histologically, these tumors reveal intracellular keratinization, intercellular bridges, and keratin pearl formation. However, they do not produce mucus (45). There is a high incidence of regional and distant metastases. Therapy consists of complete surgical resection and postoperative radiation therapy. The prognosis for squamous cell carcinoma of the salivary gland is fair with 5-year disease-free survival at 33% (44).

Undifferentiated Carcinoma

Undifferentiated carcinoma is a rare salivary gland malignancy. These tumors can be further subtyped as small cell undifferentiated carcinoma (SCUC), large cell undifferentiated carcinoma (LCUC), and lymphoepithelial carcinoma (LEC). The vast majority of these tumors occur in the parotid gland.

There is a high incidence of these tumors in Southeast China and among the Inuit Eskimos of North America where the presence of the Epstein-Barr virus (EBV) is more widespread. Studies have shown that the LEC subtype is strongly associated with EBV whereas the LCUC and the SCUC are not. However, even in these endemic geographic areas, the incidence of this malignancy is still very uncommon. A recent study from Taiwan reported 16 cases of LEC and 12 cases of large cell over nearly 30 years (46).

Overall survival is excellent for LEC with 5-year survival being 85%. However, survival is worse in LCUC with overall 2-year survival being 36%.

Salivary Duct Carcinoma

Salivary duct carcinoma is a rare but aggressive malignancy of the salivary glands. It affects primarily men in the seventh decade of life. The majority occur in the parotid gland (78%), followed by the submandibular gland, and then the minor salivary glands (47).

The tumor is poorly circumscribed and unencapsulated. Cut sections are white-tan and solid, often with cystic areas and necrosis. Microscopically, salivary duct carcinoma resembles high-grade breast carcinoma. Classic examples show Roman bridge structures. Comedonecrosis is often seen. The constituent cells have eosinophilic cytoplasm and exhibit moderate to marked nuclear pleomorphism (Fig. 115.10).

In a recent series, cervical metastases were present in 56% of patients at the time of initial diagnosis. Local recurrence occurred in 48% of patients with an average time to recurrence being 17.4 months. Distant metastases occurred also in 48% of patients with an average time of onset being 29 months after initial treatment. The average time of survival was found to be about 56 months (47).

Immunohistochemical studies reveal a similarity of this cancer and infiltrating ductal carcinoma. Approximately 20% of these tumors are strongly positive for HER2/neu. Having HER2/neu positivity is associated with a poorer prognosis with 5-year survival of 0% for strongly positive tumors compared to 11% for weakly positive cancers (47). Recommended treatment is wide surgical resection with ipsilateral neck dissection followed by adjuvant radiotherapy. Preliminary findings on the use of trastuzumab as a

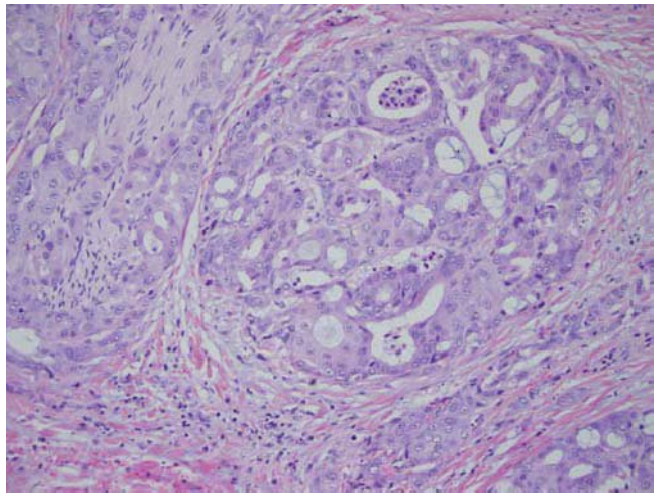

Figure 115.10 Salivary duct carcinoma. The tumor has cribriform architecture with mucin in small glandular spaces. Upper left hand portion of the image shows tumor wrapping around a nerve.

palliative chemotherapeutic agent has been reported in the case of recurrent salivary duct carcinoma (48).

Sarcoma

Sarcomas arising in the parotid gland are rare (49). These aggressive malignancies occur more commonly in men than in women and usually present as an enlarging, yet painless mass. Rhabdomyosarcoma and fibrosarcoma are the most common histopathologic subtypes. Diagnosis of a primary sarcoma requires the exclusion of metastatic spread of the sarcoma to the gland or glandular invasion from local soft tissues. Primary sarcomas behave like other soft tissue sarcomas, and the prognosis correlates with tumor size, type, and degree of histopathologic differentiation (49).

Lymphoma

Primary lymphoma occurs uncommonly in the salivary glands. When present, it usually affects the parotid gland more commonly than the other glands. Lymphoma occurs frequently in patients who have chronic autoimmune diseases such as Sjogren syndrome. Mucosa-associated lymphoid tissue lymphomas are the most common form of primary lymphoma (50). Primary lymphoma usually runs an indolent course with a favorable prognosis (51).

ASSESSMENT AND DIAGNOSIS

Etiologic Factors

Etiologic factors for salivary gland neoplasms are not well understood. Tobacco use has been clearly associated with the risk of developing Warthin tumor. There is no increased risk of developing other salivary gland neoplasms from tobacco use (52). Also, alcohol consumption has not been shown to increase the risk of developing salivary gland tumors (53).

Studies have examined viruses such as the EBV as etiologic factors and, except for LEC, there has not been a demonstrated role for viral infection as a factor in the pathogenesis of salivary gland neoplasms (54).

Low-dose radiation is considered a risk factor for the development of salivary gland neoplasms. A wide range in the dosage of radiation and age of exposure has been seen. This suggests that exposure at any age and any dose may predispose one to the development of a salivary gland tumor (55). The most common malignant radiation-related tumors are mucoepidermoid carcinoma and adenocarcinoma (56).

History

Patients with salivary gland neoplasms usually present with asymptomatic masses. Benign parotid gland neoplasms typically occur in the region of the tail of the gland. Pain is unusual with benign neoplasms but can occur due to associated infection, hemorrhage, or cystic enlargement.

Figure 115.11 Low-grade polymorphous adenocarcinoma presenting as a smooth painless mass of the hard palate.

In malignant neoplasms, pain is usually indicative of neural invasion by the tumor and portends a worse prognosis than a malignant tumor that is not painful. However, pain is not a reliable indicator for malignancy.

Submandibular gland neoplasms present in a similar manner as parotid tumors. Minor salivary gland tumors usually present as nonulcerated, painless submucosal masses involving the oral cavity, typically the hard or soft palate (Fig. 115.11).

Patients with nasal and paranasal sinus neoplasms usually present with advanced symptoms such as nasal obstruction or epistaxis. In the upper aerodigestive tract, minor salivary gland tumors can cause hoarseness, respiratory complaints, or dysphagia, depending on the location. Sublingual gland tumors usually present as masses in the floor of the mouth and may have associated discomfort.

Tumors located in the parapharyngeal space (PPS) are usually asymptomatic and may be noted on routine oropharyngeal examination (Fig. 115.12) or as a neck mass. As

Figure 115.12 Pleomorphic adenoma of the PPS. Note the uvular deviation to the opposite site.

the tumor enlarges, alterations in speech and swallowing function may occur.

Physical Examination

In a patient with a salivary gland neoplasm, a thorough head and neck examination is indicated. Attention should be directed to the size, location, and mobility of the tumor. The presence or absence of tenderness to the mass should be noted. Facial nerve function should also be assessed. The presence of facial nerve paralysis should raise the suspicion of malignancy, although rarely, a benign tumor can cause facial nerve paralysis.

Fine Needle Aspiration Biopsy

Fine needle aspiration (FNA) biopsy of a salivary gland tumor is a simple and accurate aid for the diagnosis of salivary gland neoplasms. Its primary value is to establish the need for surgery, not to establish a definitive diagnosis. As such, it is helpful to avoid surgery in select patients with a reactive lymph node, lymphoma, or nonneoplastic disorders.

Adequate tissue sampling is necessary, and clinicopathologic correlation is important. Image guidance with ultrasound or computed tomography (CT) scan is sometimes helpful. FNA offers several advantages including the ability to obtain a definitive diagnosis of a neoplasm and to aid in preoperative patient counseling regarding extent of surgery, timing of surgery, and use of imaging studies (Table 115.7) (57).

Imaging

Head and neck imaging is discussed in detail in Chapter 11. Imaging of salivary gland tumors is important to help in the evaluation of malignant or recurrent tumors, suspected PPS involvement, or suspected involvement in structures that would indicate tumor unresectability. The primary modalities used are CT and magnetic resonance imaging (MRI).

MRI is the imaging modality of choice in evaluating salivary gland tumors. MRI is superior to CT in its soft tissue differentiation. Also, MRI can also provide valuable information on deep tissue invasion, bone marrow infiltration, and perineural spread of tumor (58). The superiority of its soft tissue definition allows MRI to be a useful tool in assessing the PPS. The periparotid fat strip separating the deep lobe of the parotid gland from the PPS is an important anatomic landmark and allows for the differentiation of deep lobe parotid tumors extending into the PPS from tumors that arise from ectopic salivary gland tissue.

CT is helpful in identifying bony erosion or invasion. In cases of minor salivary gland tumors or tumors arising in the paranasal sinuses, CT and MRI frequently provide complimentary information to assess the extent of invasion of the malignancy (Figs. 115.13 and 115.14).

Recently, ultrasound has been more utilized for the assessment of major salivary gland masses. Since the lateral

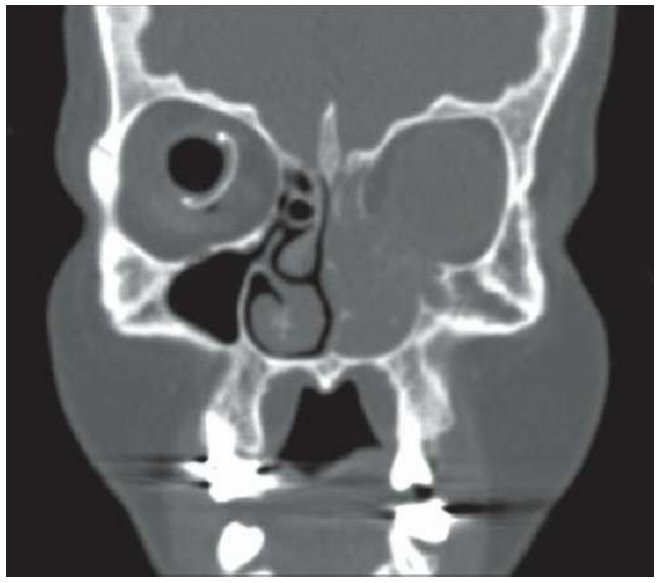

Figure 115.13 Coronal CT with bone windows demonstrates a large neoplasm in the left maxillary sinus with extension into the nasal cavity and orbit. Bone destruction is evident in the inferior orbital wall and a portion of the lateral wall of the left maxillary sinus.

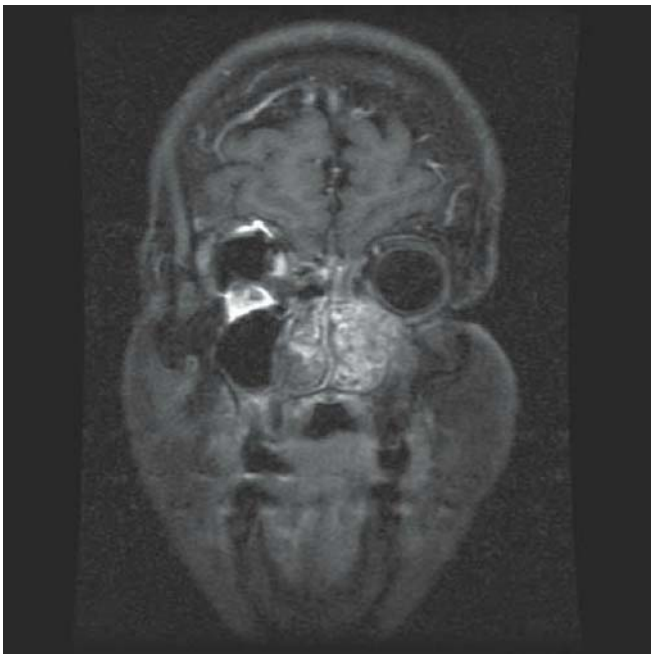

Figure 115.14 Coronal T1 fat-saturation MR image shows avid enhancement of the large neoplasm of the left maxillary sinus with extension in the orbit.

lobe of the parotid gland is a superficial structure, tumors of this lobe can be readily visualized with ultrasound. Advantages of ultrasound include relative low cost, ease of use, and the avoidance of ionizing radiation. A disadvantage of ultrasound, however, is that deep lobe tumors may not be accurately assessed. In some areas, ultrasound has replaced MRI and CT in preoperative imaging of benign parotid tumors (59). Accuracy in FNA has also been increased by using ultrasound to guide biopsy (60).

Fluorine-18 fluorodeoxyglucose positron emission tomography (PET) is uncommonly utilized to assess salivary gland neoplasms because many benign tumors and inflammatory conditions can be reported as falsely positive (61). It may provide additional information regarding the extent of disease for select malignant salivary gland neoplasms. A recent review reported a sensitivity of 74.4%, specificity of 100%, positive predictive value of 100%, and negative predictive value of 61.5% for combined PET/CT (62).

Diagnostic Surgery

Surgical biopsy of a parotid gland tumor should be avoided if possible. Excisional biopsy or tumor enucleation is associated with high rates of recurrence, particularly for pleomorphic adenoma. The standard surgical approach for parotid neoplasms is to perform complete surgical resection by parotidectomy with identification and preservation of the facial nerve. This ensures an adequate margin of tissue surrounding the tumor. This approach is diagnostic and curative in most cases. The facial nerve is identified to allow tumor excision and to avoid facial nerve injury. This technique has excellent rates of tumor control. However, risks of facial nerve paralysis (permanent vs. transient), cosmetic defects, and Frey syndrome still exist (63).

Some surgeons manage select parotid pleomorphic adenomas by careful extracapsular dissection. This surgical method is not the same as simple tumor enucleation. In this technique, the tumor is dissected with a thin cuff of normal parotid tissue around it (2 to 3 mm). Recent reports of this approach demonstrate low rates of tumor recurrence, facial nerve injury rates similar to standard parotid techniques, and low rate of Frey syndrome (64,65).

Staging

The AJCC staging system (2010) for major salivary gland malignancies is described in Table 115.8.

Differential Diagnosis

Normal anatomic structures can often be confused with salivary gland tumors. The masseter muscle, transverse process of the C1 vertebral body, and mandibular processes can mimic parotid lesions (Fig. 115.15). Inflammatory diseases, nutritional deficiencies, and infections can cause diffuse parotid enlargement. Parotid cysts are uncommon but may mimic tumor. Cystic lymphoepithelial lesions observed in patients who are positive for the human immunodeficiency virus or have Sjogren syndrome may be confused with tumor as well (Fig. 115.16).

Cutaneous malignancies can metastasize to the intraparotid lymph nodes. Melanoma and squamous cell carcinoma account for the majority of these metastatic tumors. Infraclavicular tumors such as lung, kidney, breast, and colorectal cancers can spread to the salivary glands.

Necrotizing sialometaplasia is a benign lesion of salivary tissue that may be confused with a minor salivary gland tumor. Other lesions of the palate that may be mistaken for a minor salivary gland tumor include mucus retention cyst, epidermoid cyst, fibroma, and a palatine torus.

MANAGEMENT

Surgery

The treatment of choice for most salivary gland neoplasms is complete surgical excision. Because most parotid tumors occur in the region of the tail of the gland and are superficial to the facial nerve, parotidectomy with identification and preservation of the facial nerve is diagnostic and curative in most cases. The tumor should be removed with an adequate margin of normal tissue to ensure complete tumor excision and, in the case of pleomorphic adenoma, to avoid tumor rupture and spillage.

❑ 3 grade system	❑ Grade II or 2
❑ 4 grade system	❑ Grade III or 3
❑ No 2, 3, or 4 grade system is available	❑ Grade IV or 4

General Notes:
For identification of special cases of TNM or pTNM classifications, the "m" suffix and "y," "r," and "a" prefixes are used. Although they do not affect the stage grouping, they indicate cases needing separate analysis.

m suffix indicates the presence of multiple primary tumors in a single site and is recorded in parentheses: pT(m)NM.

y prefix indicates those cases in which classification is performed during or following initial multimodality therapy. The cTNM or pTNM category is identified by a "y" prefix. The ycTNM or ypTNM categorizes the extent of tumor actually present at the time of that examination. The "y" categorization is not an estimate of tumor prior to multimodality therapy.

r prefix indicates a recurrent tumor when staged after a disease-free interval and is identified by the "r" prefix: rTNM.

a prefix designates the stage determined at autopsy: aTNM.

ADDITIONAL DESCRIPTORS

Lymphatic Vessel Invasion (L) and Venous Invasion (V) have been combined into Lymph-Vascular Invasion (LVI) for collection by cancer registrars. The College of American Pathologist (CAP) Checklist should be used as the primary source. Other sources may be used in the absence of a Checklist. Priority is given to positive results.

- ❑ Lymph-vascular Invasion Not Present (absent)/Not Identified
- ❑ Lymph-vascular Invasion Present/Identified
- ❑ Not Applicable
- ❑ Unknown/Indeterminate

Residual Tumor (R)

The absence or presence of residual tumor after treatment. In some cases treated with surgery and/or with neoadjuvant therapy there will be residual tumor at the primary site after treatment because of incomplete resection or local and regional disease that extends beyond the limit of ability of resection.

- ❑ RX Presence of residual tumor cannot be assessed
- ❑ R0 No residual tumor
- ❑ R1 Microscopic residual tumor
- ❑ R2 Macroscopic residual tumor

General Notes (continued):

surgical margins is data field recorded by registrars describing the surgical margins of the resected primary site specimen as determined only by the pathology report.

neoadjuvant treatment is radiation therapy or systemic therapy (consisting of chemotherapy, hormone therapy, or immunotherapy) administered prior to a definitive surgical procedure. If the surgical procedure is not performed, the administered therapy no longer meets the definition of neoadjuvant therapy.

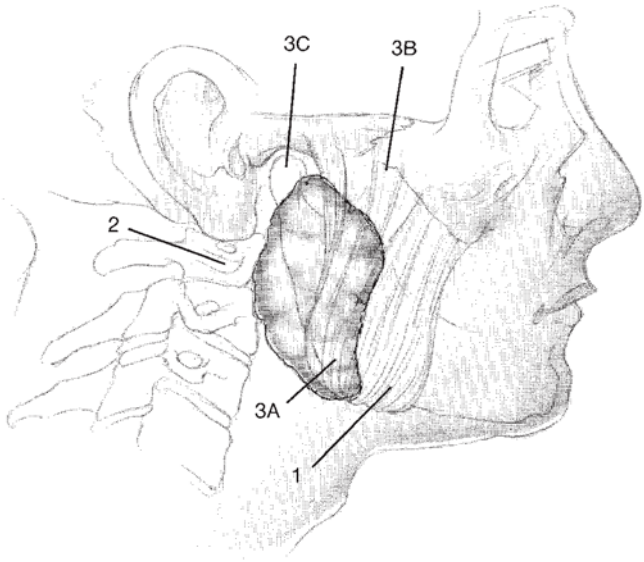

Figure 115.15 Normal anatomic structures are sometimes mistaken for parotid neoplasms. *1*, masseter; *2*, transverse process of C1; *3*, mandibular processes: *A*, angle; *B*, coronoid; *C*, condyle.

Complete excision by parotidectomy (Fig. 115.17) is considered adequate therapy for superficial low-grade malignancies (e.g., low-grade mucoepidermoid carcinoma and acinic cell carcinoma).

Complete surgical resection by parotidectomy is recommended for high-grade malignancies. The facial nerve is to be preserved if it functions normally and is not invaded by tumor. Facial nerve involvement by tumor requires facial nerve resection. Frozen sections are used to ensure negative nerve margins both proximally and distally. Immediate facial nerve grafting should be considered.

Figure 115.16 Fat-saturation T2-weighted magnetic resonance image demonstrates multiple cysts within the right parotid gland. This lesion is hyperintense on T2-weighted images.

During parotidectomy for malignancy, the neck is addressed with a comprehensive neck dissection for any known positive nodal disease. For the N0 neck, the role of elective neck dissection is controversial.

In general, high-grade tumors are more frequently associated with occult metastasis than low-grade tumors. Thus, malignancies such as high-grade mucoepidermoid or carcinoma ex pleomorphic adenoma have relatively high rates of occult disease. Other high-risk tumors include adenocarcinoma, primary squamous cell carcinoma, and salivary duct carcinoma. Low-risk tumors include low-grade mucoepidermoid carcinoma and acinic cell carcinoma. Although adenoid cystic carcinoma is considered a high-grade malignancy, it is associated with a low rate of occult metastases, and thus, elective neck dissection is not recommended for this cancer.

Some advocate that all salivary gland malignancies be managed with elective neck dissection of levels I, II, and III. A rationale is that in less than half the cases, the exact grade and histologic type of tumor is indeterminate prior to definitive resection (66).

There are also some who do not advocate elective neck dissection at all. Some suggest sampling the nodal tissue in levels I and II and making a decision based on frozen section whether or not to perform a neck dissection (67). A recent review on the management of the neck in salivary gland cancer summarizes the reasonable considerations for elective neck dissection as high-grade tumor, large tumor size, facial paralysis, extraglandular spread, age greater than 54, and perilymphatic invasion (68).

Parotidectomy Technique

The face and neck are prepared and draped with a transparent adhesive drape to allow for visualization of the face during the procedure. A preauricular incision is made extending inferiorly along the line of attachment of the ear lobule and curving into an upper neck crease. Alternatively, a modified face-lift incision can be used for selected patients. An anterior skin flap is elevated superficial to the parotid fascia. The flap is raised to the posterior border of the masseter muscle. The tail of the parotid is then dissected from the sternocleidomastoid muscle and the posterior branch of the greater auricular nerve is preserved if possible.

The digastric muscle is then exposed as the tail of the parotid is elevated. This serves as an important landmark in identifying the facial nerve. The second plane of dissection is then developed in the pretragal region. This space is opened with blunt dissection parallel to the course of the facial nerve. This exposes the tragal pointer and opens a plane from the zygoma superiorly to just above the styloid process inferiorly. With the tail and the pretragal portions of the parotid mobilized, the remaining parotid fascial

attachments to the mastoid are divided. The facial nerve is then identified using the exposed anatomic landmarks (Table 115.9).

If the main trunk of the facial nerve cannot be identified, then peripheral facial nerve branches can be dissected in a retrograde fashion. Alternatively, when there is significant scarring or distortion of the normal anatomy, a mastoidectomy can be performed and the facial nerve identified within the temporal bone.

After the main branch of the facial nerve is identified, individual facial nerve branches are followed peripherally and the gland is dissected off the nerve branches. After tumor removal, hemostasis is ensured and the wound closed over a closed-suction drain.

Total parotidectomy involves removal of parotid gland tissue both superficial and deep to the facial nerve. For deep lobe tumors, the facial nerve is exposed by removing the superficial lobe of the parotid gland. The deep lobe is then removed by first carefully mobilizing the branches of the facial nerve and removing the tissue deep to the nerve.

For parotid malignancies, the extent of the resection is determined by the extent of the disease. Frozen sections may guide the need for removal of any tissues that are invaded beyond the gland.

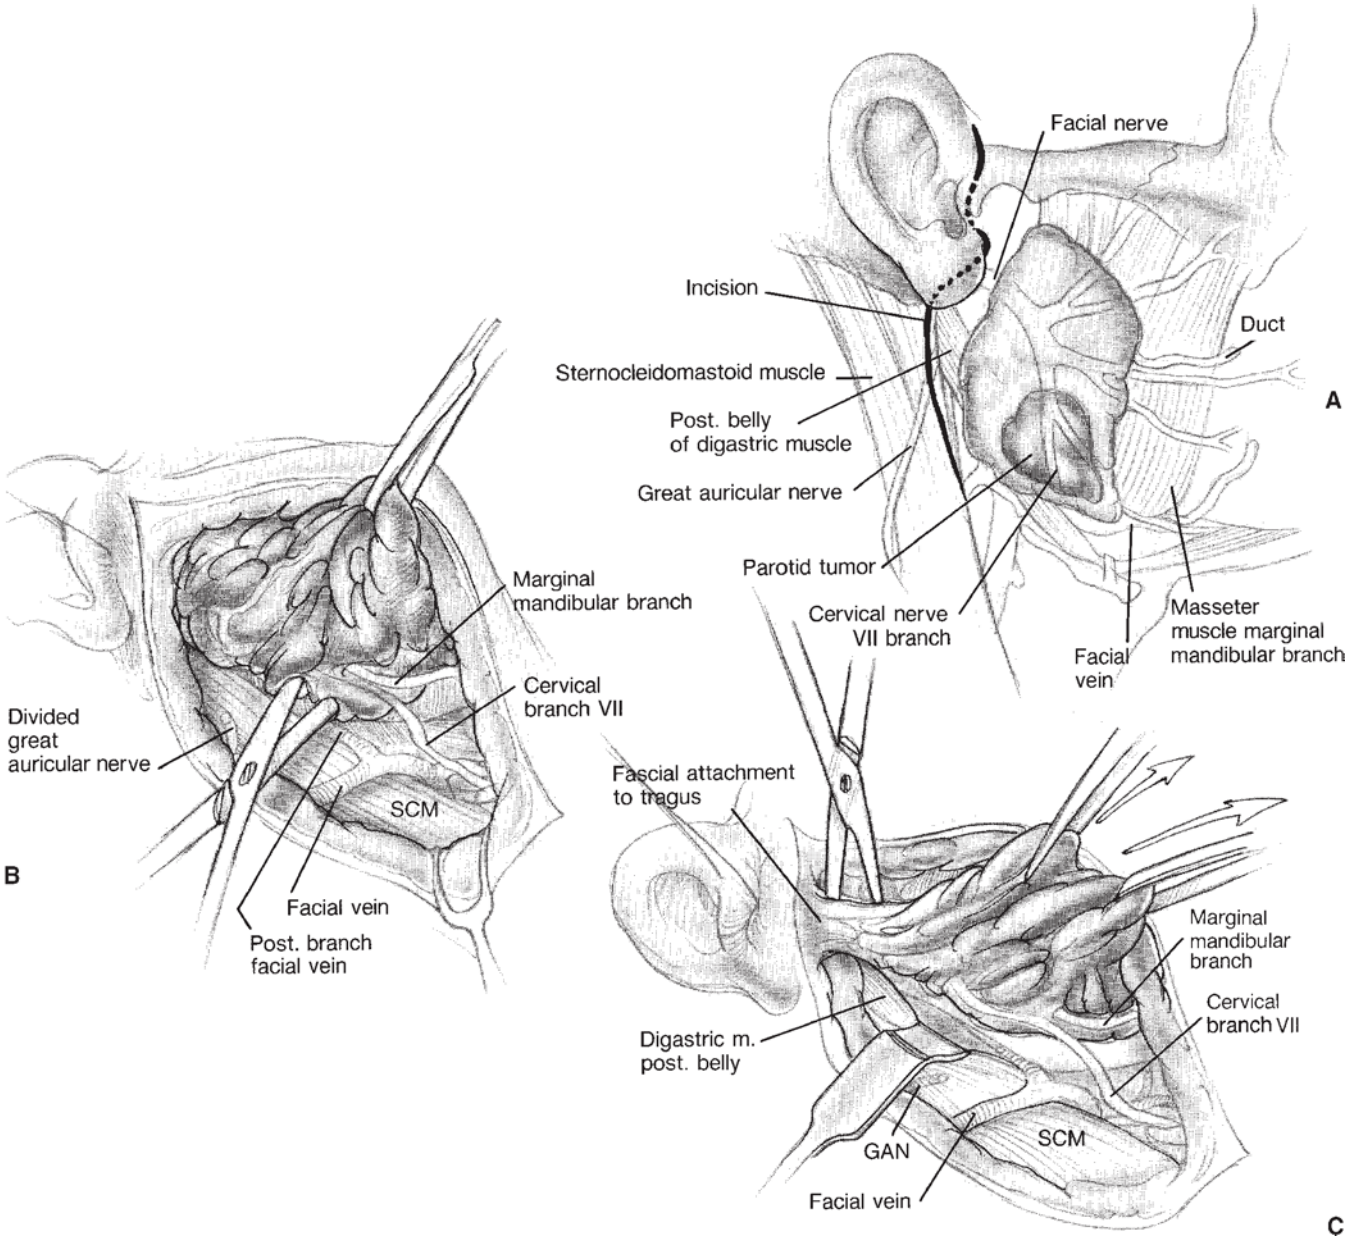

Figure 115.17 Techniques of parotidectomy. **A:** Anatomy of parotid area. **B:** Dissection of the inferior pole of the gland takes place before dissection of the facial nerve and its branches. **C:** Anterior retraction and blunt dissection above the main trunk of the facial nerve follows the mobilization of the inferior pole of the gland.

Surgical Treatment of Parapharyngeal Space Tumors

The PPS is located lateral to the pharynx and is shaped as an inverted pyramid with its base at the skull base and its apex at the hyoid bone. It is bounded posteriorly by the prevertebral fascia, medially by the pharyngeal constrictor muscles, and laterally by the mandibular ramus and the deep lobe of the parotid.

Parotid neoplasms may involve the PPS by two routes. Round tumors extend posterior to the stylomandibular ligament. Dumbbell tumors have waist-like constrictions that form as they penetrate between the mandible and the stylomandibular ligament (Figs. 115.18 and 115.19).

Most tumors of the PPS can be removed through a transcervical approach. The submandibular gland is then mobilized, which allows access to the anterior compartment of the PPS. Most PPS tumors can be bluntly dissected from the surrounding structures. This dissection must be done gently to avoid tumor rupture and seeding of the PPS.

If exposure needs to be increased, techniques such as division of the stylomandibular ligament and division of the stylohyoid and digastric muscles can enhance exposure (69). If additional exposure is required, a mandibulotomy may be needed. The mandibular osteotomies should be made in manner to preserve the inferior alveolar nerve.

For select benign tumors, a transoral approach to the PPS can be considered. Preoperative imaging is important in patient selection for this approach (70). Transoral biopsy of PPS tumors should be avoided. This carries risks of injury to the carotid artery, tumor spillage, seeding the tumor into the oropharyngeal tissues, and formation of adhesions. A transoral or image-guided FNA biopsy usually provides diagnostic information without these risks (71).

Surgical Treatment of Submandibular Gland Neoplasms

Tumors involving the submandibular gland are usually limited to the gland. For benign tumors, submandibular gland excision is therapeutic. Malignant tumors require complete surgical resection. Malignant tumors are usually confined to the gland, and thus, surgical resection is usually confined to the contents of the submandibular triangle. All nerves are preserved unless there is evidence of tumor involvement. For malignant tumors invading the surrounding tissue, the surgical resection is extended to

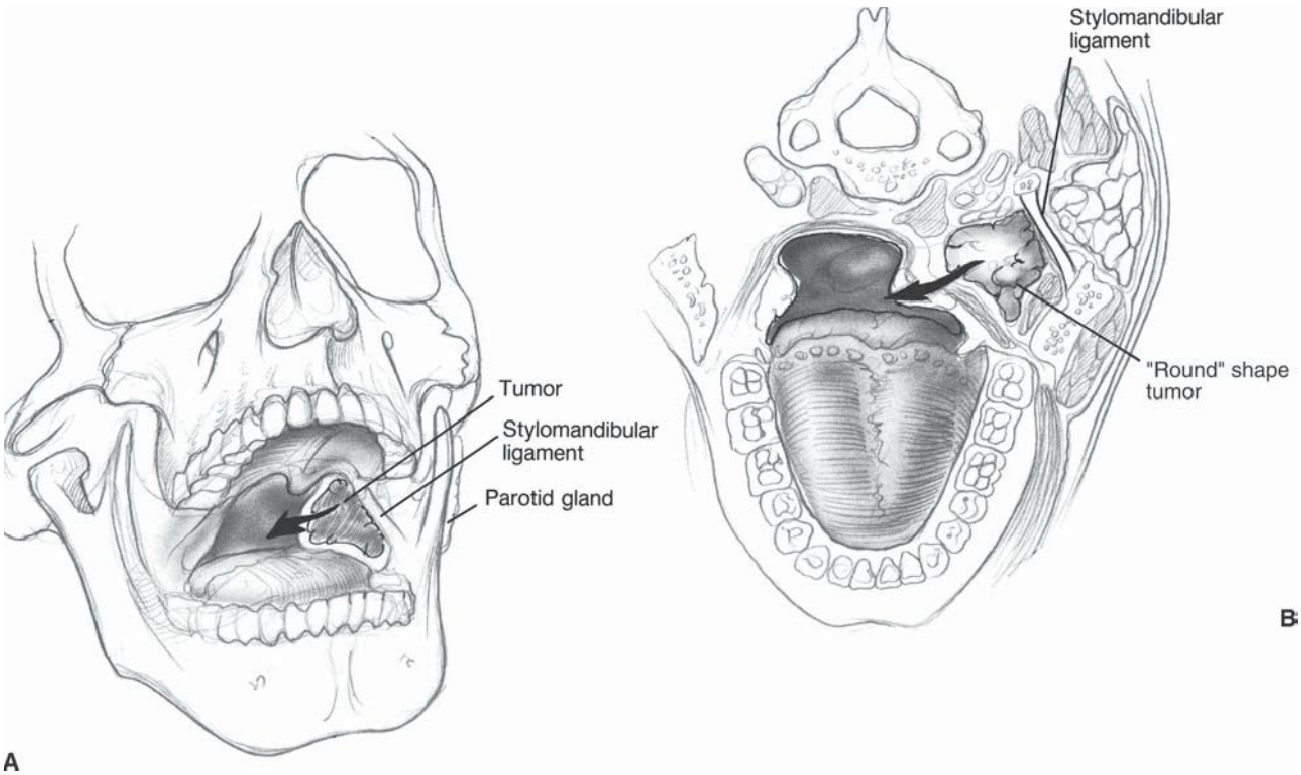

Figure 115.18 Round tumor involving the PPS. **A:** Three-fourths view. **B:** Axial view.

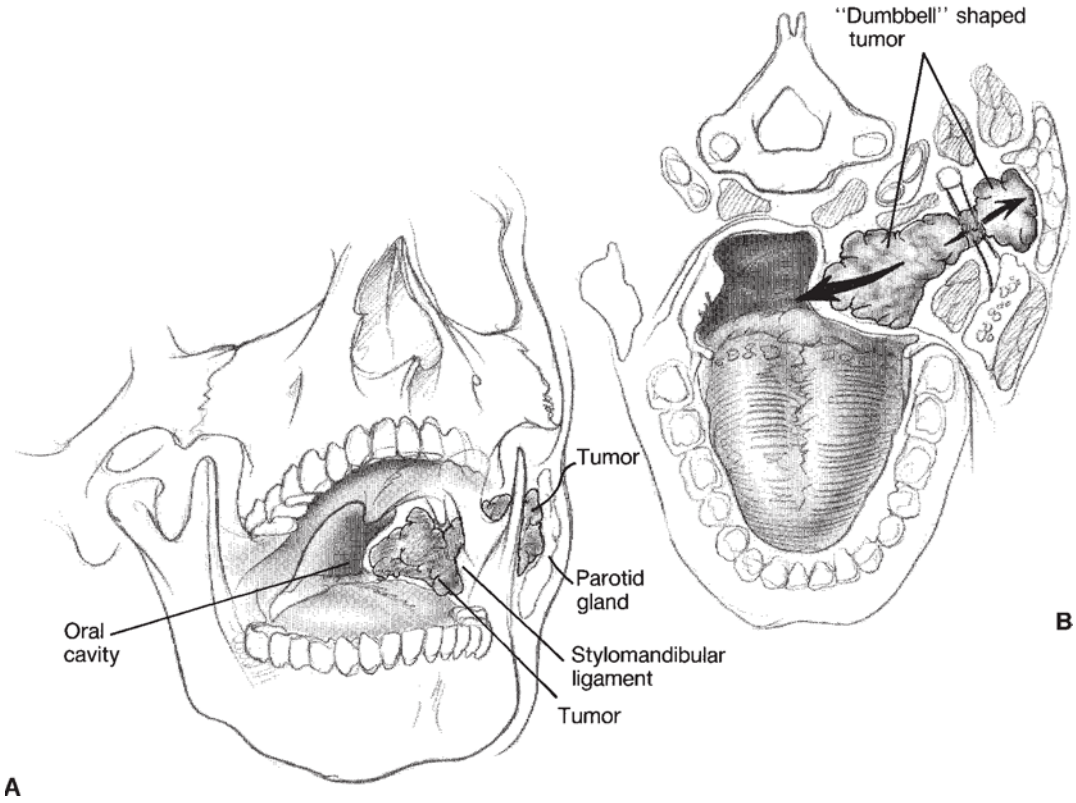

Figure 115.19 Dumbbell tumor involving the PPS. **A:** Three-fourths view. **B:** Axial view.

include the involved structures with an appropriate tumor-free margin. The involved structures may include the marginal mandibular branch of the facial nerve, the hypoglossal nerve, the lingual nerve, the mandible, the tongue, the floor of mouth, and the skin. The extent of surgical resection depends on the extent of the disease.

Submandibular Gland Excision Technique

The neck is prepared and draped in a sterile fashion. The incision is made below the inferior border of the mandible in a skin crease (Fig. 115.20). The incision is carried through the platysma muscle, and subplatysmal flaps are elevated with care to avoid injury to the marginal mandibular nerve. The Hayes Martin maneuver can be used to protect the marginal mandibular nerve at this point. The fascia overlying the submandibular gland is then incised and raised, exposing the gland itself. However, if enlarged facial nodes are present, the marginal mandibular nerve may need to be completely dissected and mobilized superiorly to ensure complete nodal removal. The dissection is then performed superiorly, and the facial artery is divided and ligated. The mylohyoid muscle is retracted anteriorly, and the gland is retracted posteroinferiorly, exposing the lingual nerve and Wharton duct. The submandibular ganglion is divided, freeing the lingual nerve. Wharton duct is then divided and ligated. The hypoglossal nerve runs superficial to the hyoglossus muscle. The hypoglossal nerve is preserved as the inferior border of the gland is dissected free. The facial artery is encountered again, and it is divided and ligated. After ensuring hemostasis, the wound is closed in layers over a drain.

Surgical Treatment of Minor Salivary Gland Neoplasms

Surgical therapy depends on the location and extent of disease. Complete surgical excision is therapeutic for benign tumors. Adenoid cystic carcinoma most commonly involves the oral cavity, nasal cavity, and paranasal sinuses. Adenocarcinomas most commonly involve the paranasal sinuses and nasal cavities. Malignant minor salivary gland tumors involving the larynx are usually adenoid cystic carcinoma or adenocarcinoma. The surgery for malignant minor salivary gland tumors may be extensive and may require maxillectomy, craniofacial resection, mandibulectomy, laryngectomy, or tracheal resection.

Radiation Therapy

Adjuvant radiation therapy has improved the locoregional control and survival for patients with carcinoma of the salivary glands (72). Indications for adjuvant radiotherapy include lymph node metastasis, high tumor grade, positive surgical margins and T3-T4 tumor stage (73). Although surgery remains the mainstay in the treatment of salivary gland malignancies, radiation therapy alone may be an

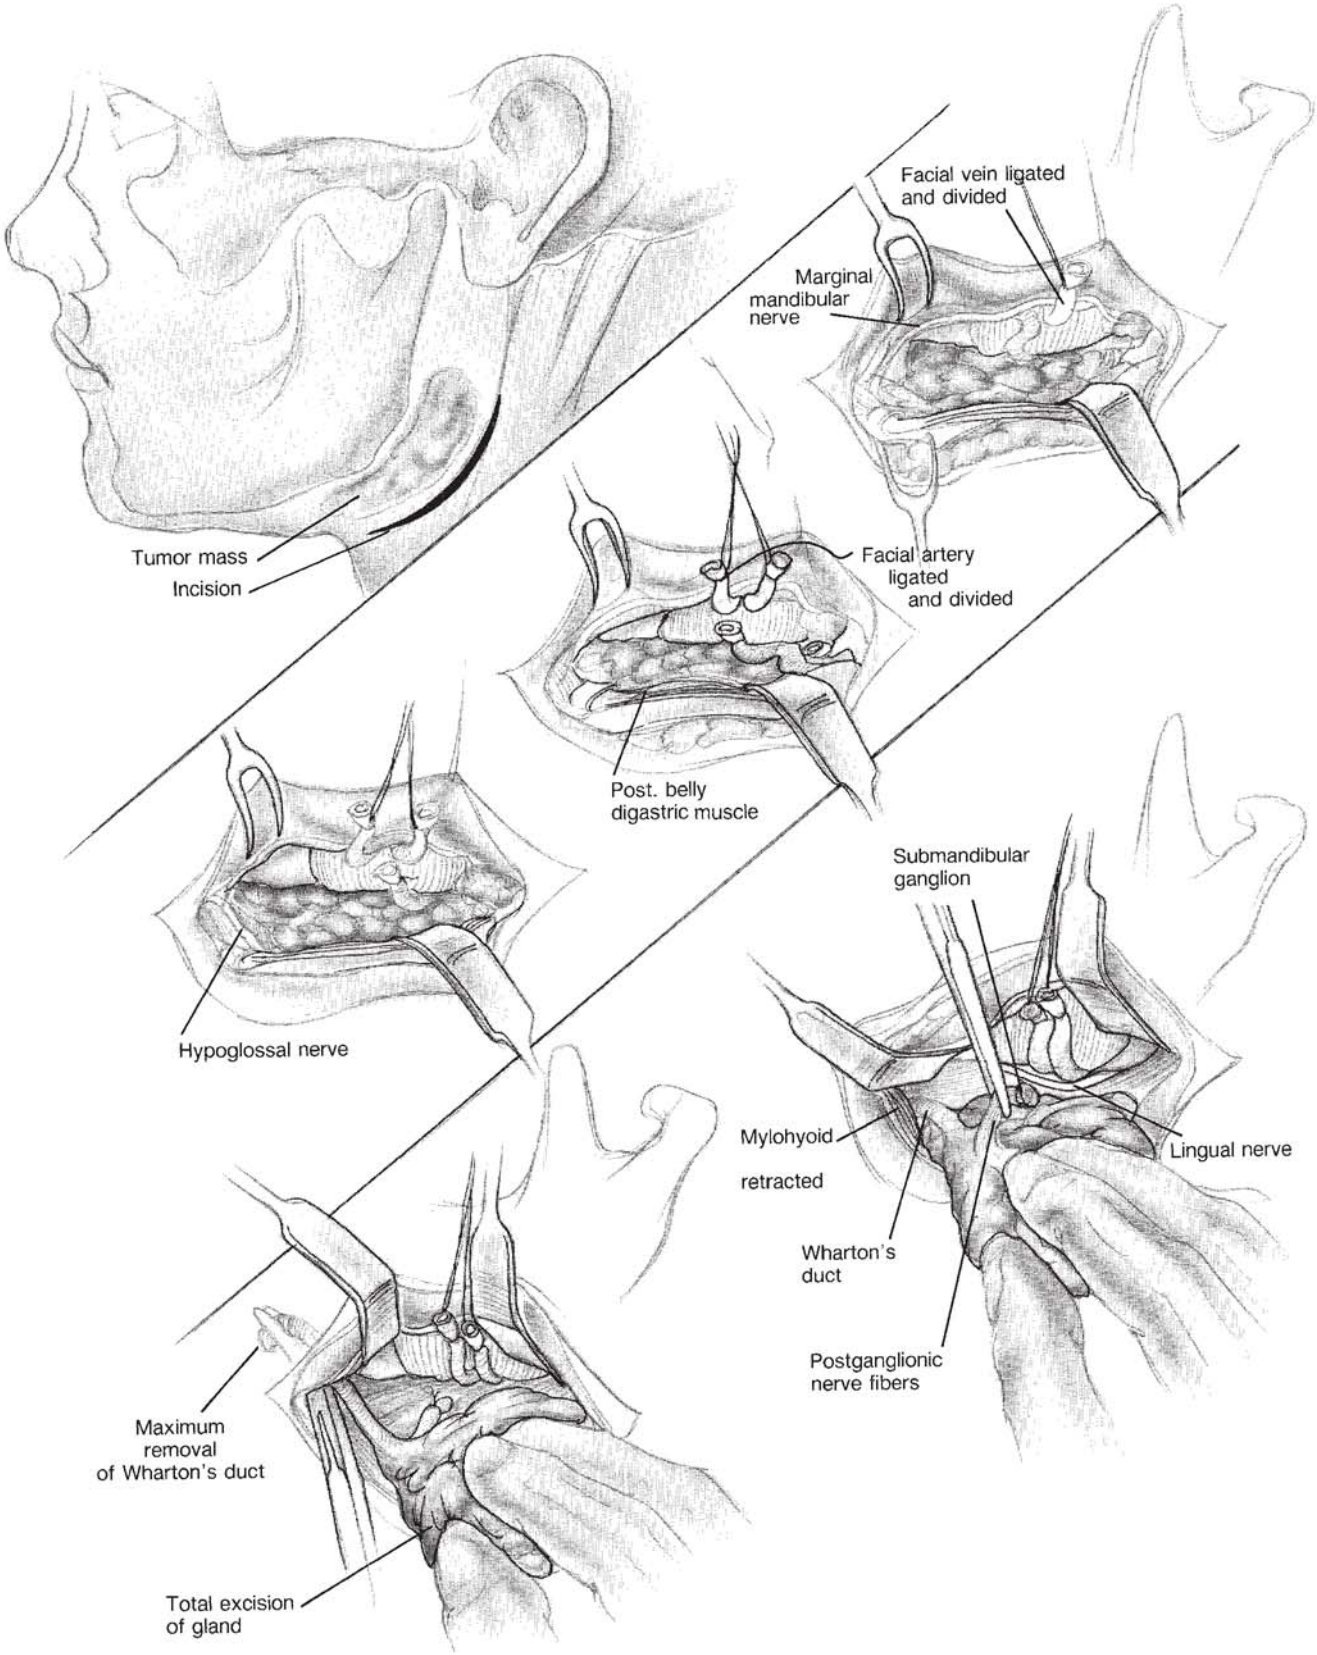

Figure 115.20 Technique for submandibular gland excision. See text for discussion.

option in cases where surgery is not possible or would result in unacceptable morbidity (74).

Adjuvant radiotherapy has been shown to be beneficial following resection of recurrent pleomorphic adenoma of the parotid, thus making it an option in selected cases (75). Fast neutron radiotherapy also shows promise as another modality for the treatment of recurrent pleomorphic adenoma (76).

Because of the proximity of important structures, it is difficult to deliver curative doses of radiation using conventional photons for tumors of the skull base or paranasal sinuses. Because of the radiobiologic properties of heavy particles, a larger dose of radiation can be delivered to the tumor while sparing the surrounding tissue. As mentioned earlier in this chapter, fast neutron radiotherapy may be more effective than conventional photon radiotherapy as the primary treatment modality in select cases of unresectable adenoid cystic carcinoma (29,30). In addition, conformal proton radiotherapy has shown promise in the treatment of adenoid cystic carcinoma of the skull base in cases of partial or incomplete resection of tumor (77).

Chemotherapy

Historically, the primary role for chemotherapy has been for palliation in the setting of symptomatic, unresectable disease. The role for chemotherapy continues to be investigated. At this point, there are very limited data for the role of chemotherapy in salivary gland cancer. It should be noted, however, that adenoid cystic carcinoma constitutes a large number of patients in these trials, thus making extrapolation of the outcomes to other malignancies difficult (1).

Single agent paclitaxel has been studied by the Eastern Cooperative Oncology Group. In their Phase II trial, they found a partial response rate in 26% of patients with mucoepidermoid carcinoma or adenocarcinoma but zero responders in those with adenoid cystic carcinoma. Median survival was 12.5 months (78). Gemcitabine combined with either cisplatin or carboplatin has also demonstrated modest response rates (79).

Small retrospective studies have demonstrated a potential benefit in adjuvant chemoradiation with platinum compounds (80). Currently, prospective studies are under way to determine its utility.

Development of therapeutic agents directed against specific molecular targets has also found its way in salivary gland cancers. No study thus far, however, has demonstrated meaningful responses, despite the overexpression of various markers in some neoplasms (Table 115.10).

COMPLICATIONS

Parotidectomy

There are both early and late complications of parotidectomy (Table 115.11). Partial or complete paralysis involving some or all branches of the facial nerve can occur as an early complication. Temporary facial nerve paralysis involving one or all branches of the nerve occurs in 10% to 30% of parotidectomies. Permanent facial nerve paralysis occurs in fewer than 3% of parotidectomies. The incidence of facial nerve paralysis is higher with total parotidectomy than with superficial parotidectomy. Facial nerve injury is also more common during reoperation for recurrent tumors. The nerve at most risk for injury during parotidectomy is the marginal mandibular branch. Temporary paresis usually resolves from weeks to months postoperatively. Complete nerve transection can occur during surgery and should be identified and immediately repaired.

TABLE 115.11 COMPLICATIONS OF PAROTIDECTOMY

Early	Late
Facial nerve paralysis	Frey syndrome
Bleeding	Recurrent tumor
Infection	Poor cosmesis
Skin flap necrosis	Soft tissue deficit
Trismus	Hypertrophic scar or keloid
Sialocele	
Seroma	

There are many factors that influence the risk of facial nerve injury. These include tumor size, location, type, extent of surgery, and reoperation. Mechanisms of injury include nerve transection, stretch, compression, thermal/electrical injury, and ischemia.

Continuous facial nerve monitoring has been gaining in popularity in recent years (81). In this technique, facial muscle electromyographic (EMG) activity is monitored. Commercially available, multichannel systems can track facial muscle activity and have a built-in pulse generator for nerve stimulation at varying strengths. Data for these systems are easy to interpret and do not require the presence of a neurophysiologic nerve monitoring team. Intraoperatively, the surgeon must be able to differentiate true EMG events from artifacts that are usually caused by contact of metal instruments on the operative field. Wave form analysis and the context in which the artifactual alert occurs can aid in differentiating these from true events.

The literature suggests a reduction in the rate of temporary facial nerve paresis and possible decreased operating time with facial nerve monitoring during parotidectomy. Studies to date, however, preclude conclusions regarding a benefit for permanent facial paralysis reduction due to lack of sufficient power (82,83). There are benefits to the use of the facial nerve monitor including minimizing trauma to the nerve during its dissection, improved ability to differentiate the facial nerve from nonnerve tissue, and alert to the surgeon regarding facial nerve proximity (84). The use of monitoring technology, however, should not replace the identification of the facial nerve using known anatomic landmarks.

Corticosteroids have been used by some surgeons in the hopes of avoiding postoperative paresis of the facial nerve by reducing edema and inflammation of the nerve. Studies, however, have failed to demonstrate a benefit of perioperative corticosteroids on facial nerve paresis rates (85).

Hemorrhage or hematoma is an uncommon complication and is usually related to incomplete hemostasis at the end of the procedure. Treatment consists of evacuation of the hematoma and surgical control of the bleeding vessels.

Infection is rare after parotidectomy and is avoided by the use of aseptic technique and careful handling of tissues. The rarity of infection is probably related to the rich vascular supply to this anatomic region. Treatment of infection consists of surgical drainage, if necessary, and antibiotics.

Skin-flap necrosis most commonly occurs in the distal tip of the postauricular skin flap. Care must be taken in designing this portion of the skin flap in avoiding this complication. Smoking, prior radiation therapy, and diabetes mellitus are risk factors for this complication.

Trismus may occur related to inflammation and fibrosis of the masseter muscle. This complication is usually mild and self-limited with jaw range of motion exercises.

Salivary fistula or sialocele is a relatively common complication after parotidectomy. This usually results from the cut edges of the remaining salivary gland leaking saliva and then collecting beneath the flap. This complication is usually self-limited when treated with needle aspirations. A chronic salivary fistula is rare.

Frey syndrome or gustatory sweating is a relatively common long-term complication of parotidectomy (Fig. 115.21). This is thought to occur as a result of aberrant

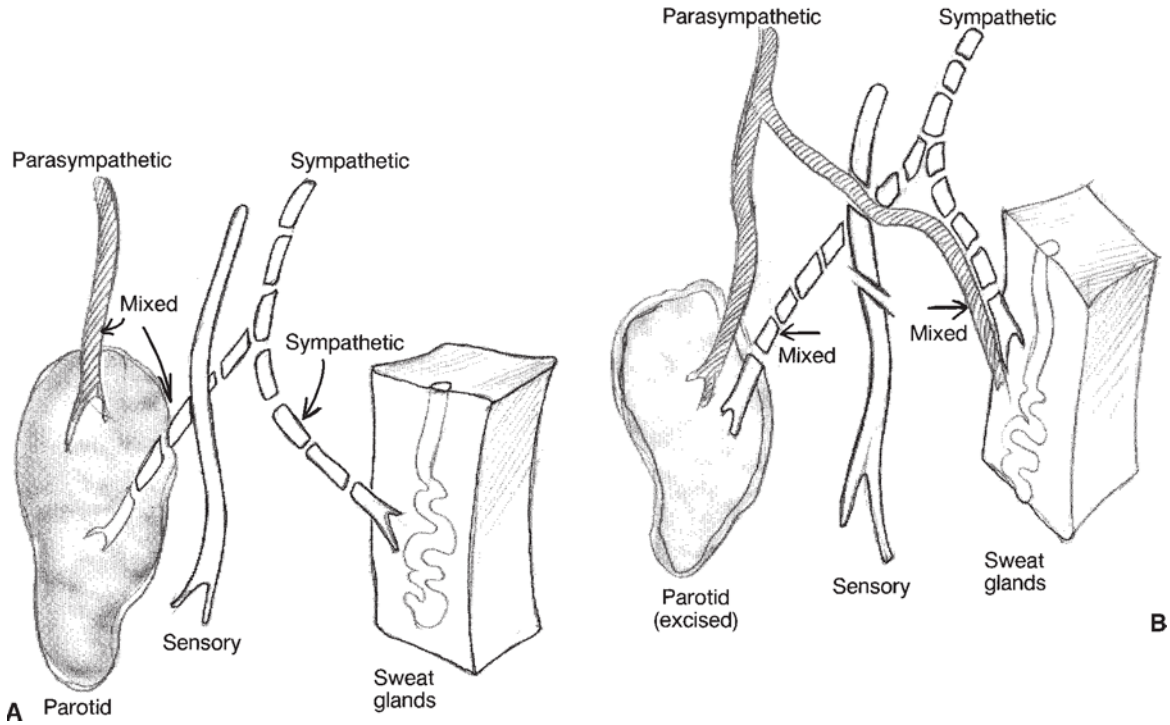

Figure 115.21 **A:** Normal innervation of parotid and sweat glands. **B:** Proposed mechanism of Frey syndrome.

regeneration of nerve fibers from the postganglionic secretomotor parasympathetic innervation of the parotid gland to the severed postganglionic sympathetic fibers that supply the sweat glands of the skin of the face. As a result, sweating or dermal flush occurs during salivary stimulation. Frey syndrome has been reported for 30% to 60% of patients undergoing parotidectomy. Only about 10% of patients, however, have symptomatic Frey syndrome.

Most patients with Frey syndrome do not seek therapy. Medical treatment of symptomatic Frey syndrome has included topical application of antiperspirant, topical anticholinergics, and injections of botulinum toxin, which provides excellent control for prolonged periods. Surgical techniques during parotidectomy that can reduce the risk of Frey syndrome include elevation of a thick skin flap and performance of partial parotidectomy (86). In addition, interpositional barriers such as fat, acellular dermal grafts, and muscle flaps have been used with success in the prevention of Frey syndrome (87–89). These surgical methods are uncommonly utilized presently due to the effectiveness of botulinum toxin therapy.

First bite syndrome can occur following deep lobe parotid and PPS neoplasms and manifests with recurrent severe pain with initial oral intake that subsides with successive bites. This problem is thought to result from interruption of the sympathetic innervation of the parotid gland with denervation supersensitivity of myoepithelial cell receptors. The severity of this condition usually diminishes over time. Severe cases may benefit from botulinum toxin injection of residual gland tissue.

Malignant and even benign tumors can recur. High-grade malignancies can have a high rate of recurrence despite combined therapy. Benign tumors such as pleomorphic adenoma, however, recur in less than 1% of patients who have proper surgery. Most recurrences occur after incomplete tumor resection or tumor spillage from tumor capsule rupture.

Recurrent pleomorphic adenoma is difficult to treat because they tend to be larger than suspected, lie at a deeper level than expected, and are multicentric (90). The treatment of recurrent pleomorphic adenoma consists of comprehensive resection of recurrent tumor nodules by revision parotidectomy with facial nerve preservation. A decrease in the rate of surgical control occurs with subsequent recurrences. Thus, postoperative radiation therapy may be recommended in certain cases to reduce the likelihood of recurrence following revision surgery. En bloc resection with immediate nerve grafting is necessary for recurrences encasing the facial nerve.

Submandibular Gland Excision

The complications of submandibular gland excision are listed in Table 115.12. Injury to the marginal mandibular branch of the facial nerve results in loss of lip depressor function. Temporary paresis of this nerve can occur from nerve stretch injury during retraction. Other nerves at risk include the hypoglossal nerve and lingual nerve resulting in ipsilateral tongue paralysis and anesthesia of the anterior two-thirds of the tongue, respectively.

TABLE 115.12 COMPLICATIONS OF SUBMANDIBULAR GLAND EXCISION

Hemorrhage
Infection
Marginal mandibular branch of facial nerve injury
Hypoglossal nerve injury
Lingual nerve injury
Poor scar formation

Hemorrhage, particularly from the facial artery, results in vigorous bleeding and can contribute to airway compromise. Wound re-exploration and control of hemorrhage is necessary. Infection is uncommon after submandibular gland excision.

PROGNOSTIC FACTORS

Histopathology

Many studies over the years have demonstrated that tumor histopathology is a strong prognostic factor in predicting the behavior of a malignancy. In general, low-grade tumors such as low-grade mucoepidermoid carcinoma or acinic cell carcinoma are usually well controlled with single-modality therapy. Whereas high-grade lesions such as high-grade mucoepidermoid carcinoma or salivary duct carcinoma require aggressive surgical treatment with adjuvant radiotherapy because they have a greater likelihood of metastasis and locoregional failure. An epidemiologic study was performed looking at data in the Swedish Cancer Society to look at the relative survival of different cancer types in the parotid and submandibular glands (Tables 115.13 and 115.14) (36). A classification scheme dividing tumors into low-risk and high-risk cancers is presented in Table 115.15 (91).

Tumor Size

Tumor size has been considered a major prognostic indicator for salivary gland malignancies with increased size resulting in poor prognosis and decreased survival (92,93). Increased tumor size also correlates with high rates of regional and distant metastases and increased rates of recurrence (95).

TABLE 115.13 RELATIVE SURVIVAL RATES FOR CANCER OF THE PAROTID

Tumor Type	5-y Survival (95% CI)	10-y Survival (95% CI)
Carcinoma ex pleomorphic	76 (69–82)	73 (65–81)
Adenoid cystic carcinoma	85 (79–90)	74 (66–82)
Acinic cell carcinoma	93 (88–98)	88 (80–95)
Mucoepidermoid carcinoma	82 (77–87)	80 (73–87)
Adenocarcinoma	63 (57–70)	55 (48–75)
Undifferentiated carcinoma	48 (40–56)	40 (25–61)

Adapted from Wahlberg P, Anderson H, Bjorklund A, et al. Carcinoma of the parotid and submandibular glands: a study of survival in 2465 patients. *Oral Oncol* 2002;38:706–713.

Facial Nerve Paralysis

Facial nerve paralysis associated with malignant tumors indicates a poor prognosis. Facial nerve paralysis is also associated with higher incidences of regional and distant metastases (95).

Regional Lymphatic Metastases

Regional lymph node metastases are associated with a poorer prognosis than for nonmetastatic disease (67,94). Factors associated with a higher risk of metastases have already been discussed earlier in the chapter. Other factors include tumor size, facial nerve paralysis, age of patient, histologic type, and grade of tumor.

Distant Metastases

Distant metastases indicate a poor prognosis. Distant metastases occur in approximately 20% of parotid malignancies, and they occur most frequently in adenoid cystic carcinoma and undifferentiated carcinoma. The most common sites for distant metastases are lung, bone, and brain. The length of survival after distant failure varies according to the tumor type. Some patients with adenoid cystic carcinoma may survive for many years due to slow tumor progression. The most important factors for predicting the development of distant metastases are the size of the tumor, presence or absence of regional metastases, and histologic type of tumor (93).

Location

There appears to be no difference in survival based on the location of a malignancy within the parotid gland, but PPS involvement by a malignancy is associated with a poor prognosis. In general, parotid malignancies have a better prognosis than salivary carcinomas arising in other locations.

For adenoid cystic carcinoma, tumors in the major salivary glands are associated with a better prognosis than those in the minor salivary glands.

TABLE 115.14 RELATIVE SURVIVAL RATES FOR CANCER OF THE SUBMANDIBULAR GLAND

Tumor Type	5-y Survival (95% CI)	10-y Survival (95% CI)
Carcinoma ex-pleomorphic	71 (54–86)	62 (43–82)
Adenoid cystic carcinoma	84 (76–90)	73 (63–82)
Acinic cell carcinoma	83 (50–100)	86 (46–100)
Mucoepidermoid carcinoma	55 (42–69)	53 (37–71)
Adenocarcinoma	43 (29–61)	42 (25–65)
Undifferentiated carcinoma	50 (32–70)	53 (32–81)

Adapted from Wahlberg P, Anderson H, Bjorklund A, et al. Carcinoma of the parotid and submandibular glands: a study of survival in 2465 patients. *Oral Oncol* 2002;38:706–713.

TABLE 115.15 RISK STRATIFICATION OF SALIVARY GLAND CANCERS

Low Risk	High Risk
Acinic cell carcinoma	Sebaceous carcinoma and lymphadeno carcinoma
Low-grade mucoepidermoid carcinoma	High-grade mucoepidermoid carcinoma
Epithelial–myoepithelial carcinoma	Adenoid cystic carcinoma
Polymorphous low-grade adenocarcinoma	Mucinous adenocarcinoma
Clear cell carcinoma	Squamous cell carcinoma
Basal cell adenocarcinoma	Small cell carcinoma
Low-grade salivary duct carcinoma (low-grade cribriform cystadenocarcinoma)	Large cell carcinoma
Myoepithelial carcinoma	LEC
Oncocytic carcinoma	Metastasizing pleomorphic adenoma
Carcinoma ex pleomorphic adenoma (intracapsular/minimally invasive or with low-grade histology)	Carcinoma ex pleomorphic adenoma (widely invasive or high-grade histology)
Sialoblastoma	Carcinosarcoma
Adenocarcinoma NOS and cystadenocarcinoma, low grade	Adenocarcinoma and cystadenocarcinoma, NOS, high grade

HIGHLIGHTS

- Salivary gland neoplasms represent a diverse group of benign and malignant tumors.
- In the parotid gland, 75% to 80% of tumors are benign and 25% malignant.
- In the submandibular gland, a higher proportion of neoplasms are malignant compared to the parotid gland.
- In the minor salivary glands, most neoplasms are malignant.
- An accurate diagnosis is important for guiding proper therapy.
- Most salivary gland tumors develop in the parotid gland.
- Low-dose radiation exposure has been implicated as an etiologic factor for salivary gland neoplasms.
- A mass in the region of the parotid gland should be considered a salivary gland neoplasm until proven otherwise.
- FNA biopsy is an accurate method to confirm the diagnosis of a salivary gland neoplasm.
- Parotidectomy with identification and preservation of the facial nerve is diagnostic and curative for most parotid gland neoplasms.
- In select cases, extracapsular dissection of pleomorphic adenoma of the parotid gland yields low rates of recurrence and complications.
- Combined surgery and radiation therapy has improved locoregional control and survival in patients with carcinoma of the major salivary glands.
- Tumor grade, stage, and histologic type are important prognostic variables for salivary gland malignancies.

116 Lip Cancer

Liana Puscas *Michael A. Fritz* *Ramon M. Esclamado*

Lip cancer is one of the most common malignant tumors of the head and neck. The typical patient is a white male smoker with a fair complexion in his sixth to seventh decade of life who presents with a squamous cell carcinoma (SCCA) involving the lower lip. As the lips are in a prominent position on the face, appropriate management of this malignancy should have as its goals maximizing survival while minimizing the functional and cosmetic morbidity associated with treatment. This requires a thorough understanding of the functional anatomy of the lips, the biologic behavior of the disease, treatment options, and reconstructive considerations.

FUNCTIONAL ANATOMY

The lips form the anterior boundary of the oral cavity and function as a mobile oral sphincter that prevents dribbling of fluids and assists in mastication, deglutition, and articulation. The lips are also important aesthetically, contributing to appearance and facial expression. The anatomic extent of the lips includes only the vermilion, or that portion of the lip mucosa that contacts the opposing lip. Anteriorly, the lip ends at the vermilion border, which is the junction of the vermilion with the skin. The lower lip vermilion in repose is more everted than the upper lip. The transverse length of the upper lip is slightly longer: about 8.0 cm compared with 7.5 cm for the lower lip.

The orbicularis oris muscle is the sphincter that lies within the lip and encircles the oral aperture. Superiorly, it extends almost to the columella and attaches to the anterior nasal spine. Inferiorly, it interdigitates with the mentalis muscles to form the mental crease. Numerous paired muscles of facial expression insert on its lateral deep surface and contribute to oral competence and the diversity of lip movement (Fig. 116.1). The deep surface of the orbicularis oris is covered by loosely attached mucous membranes containing numerous minor salivary glands. Superficially, it is loosely attached to overlying skin.

The sensory and motor innervations of the lips are separate. The infraorbital branch of the maxillary division of the trigeminal nerve (V2) provides the major sensory supply to the skin and mucous membrane of the upper lip. The oral commissure area is supplied by the buccal branch of the mandibular division of the trigeminal nerve (V3), whereas sensation of the lower lip skin and mucosa is derived from the mental branch of the mandibular division. The seventh cranial nerve (facial nerve) provides the motor innervation of the lip. The upper lip musculature is supplied by the buccal branch of the facial nerve, whereas the marginal mandibular branch innervates the lower lip musculature.

The main blood supply to the lips consists of the superior and inferior labial arteries, which travel between the submucosa of the lip and the orbicularis at the level of the vermilion cutaneous junction. The vessels branch from the facial artery just lateral to the oral commissure. These paired vessels create a circumoral vascular arcade that provides the anatomic basis for the classic lip-switch procedures and other local myocutaneous flaps. Efforts should therefore be made to preserve the facial vessels when performing concomitant neck dissections. The arteries have accompanying veins that drain to the anterior facial veins.

The lymphatics of the lips (Fig. 116.2) begin as a fine capillary network in the vermilion border and combine to form collecting trunks. The trunks from the upper lip and commissure drain first to the ipsilateral preauricular, infraparotid, submandibular, and submental lymph nodes. No contralateral drainage occurs because the embryonic fusion plane of the central frontonasal process separates the lateral maxillary processes and their associated neurovascular and lymphatic connections. The lower lip lymphatics drain first to the submental and submandibular nodes. Because the mandibular processes fuse in

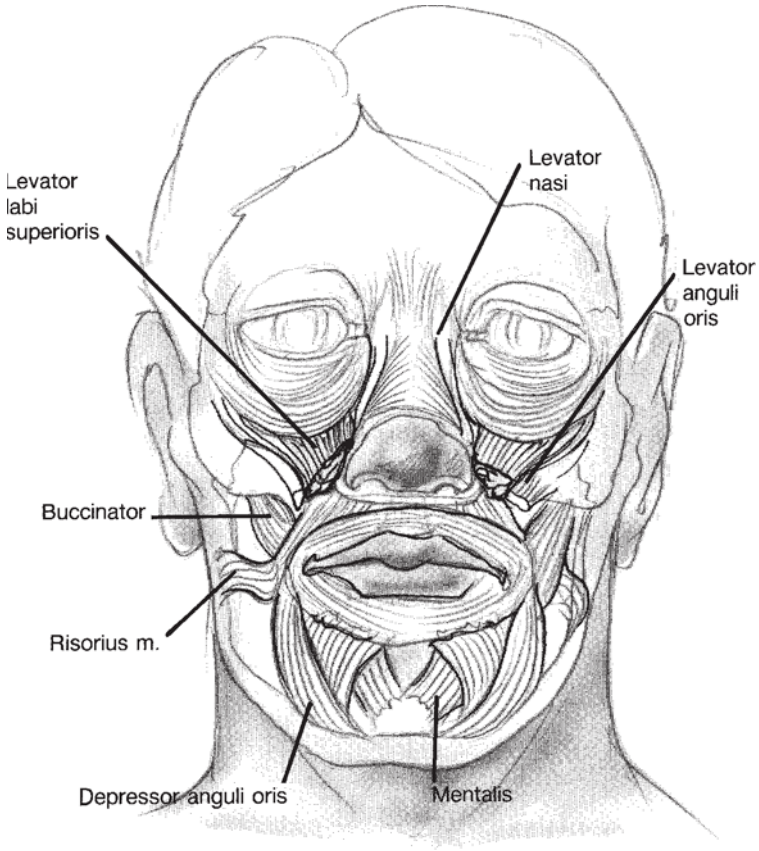

Figure 116.1 Musculature of the lips. The orbicularis oris muscle is the sphincter lying within the lip and encircles the oral aperture. Numerous paired muscles of facial expression insert on its lateral deep surface to contribute to oral competence and the diversity of lip movement.

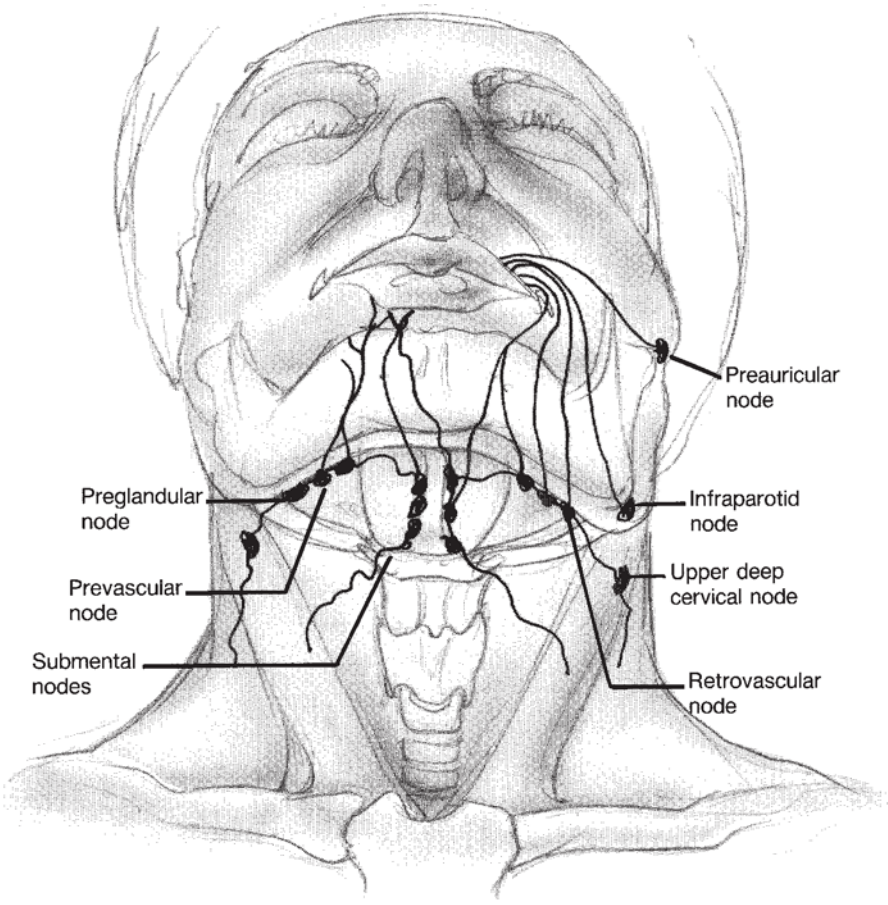

Figure 116.2 Lymphatic drainage of the lips. Lymphatic channels of the upper lip and commissure drain to the ipsilateral preauricular, infraparotid, submandibular, and submental lymph nodes. The lower lip lymphatics drain to both ipsilateral and contralateral submental and submandibular lymph nodes. The second nodal station for both lips is the upper deep jugular nodes and occasionally the middle deep jugular nodes.

the midline, numerous anastomoses cross the midline to drain bilaterally. Lower lip lymphatics also enter the mental foramen in 22% of patients. The second nodal station for both upper and lower lips is the upper deep jugular nodes (level II) or occasionally the middle deep jugular nodes (level III).

BIOLOGIC BEHAVIOR

The age-standardized rate (ASR) of lip cancer varies according to gender, race, and geography. Around the world, lip cancer rates are highest in white males (1). In the United States, the ASR for white males is 2.5/100,000 per year compared to 0.3/100,000 per year for white females (2). South Australia has the highest ASR of lip cancer in the world: over 15/100,000 per year in men and 4/100,000 per year in women (3). Lip cancer is rare in Asia and in blacks (1,4,5). In the United States, for example, the ASR for both black males and females is 0.1/100,000 per year (2). The most common type of lip cancer is SCCA that is usually found on the lower lip in men. Basal cell carcinoma (BCCA) is the second most common malignancy and is found most frequently on the upper lip in women (6,7). Most cancers are found in individuals in their sixth to seventh decade of life (6–8).

The etiology is multifactorial and includes prolonged exposure to ultraviolet radiation, use of tobacco, consumption of alcohol, poor dental hygiene, and low socioeconomic status (6–9). Actinic cheilitis, or actinic keratosis of the lip, is considered to be a premalignant condition that doubles the risk of lip SCCA (10,11). Immunosuppression also significantly increases the risk of lip cancer as evidenced by higher rates in organ transplant patients. Unfortunately, both SCCA and BCCA arising in this setting are more aggressive in their behavior. Interestingly, failure of a transplanted kidney with its attendant cessation of immunosuppression decreases the risk of lip cancer to baseline (12).

Lip cancer is one of the most readily curable malignancies of the head and neck. When diagnosed at an early stage, 10-year cause-specific survival is as high as 98%, with a recurrence-free survival of 92.5% (13). The prominent location of the lips typically allows for early detection and treatment of this lesion. Characteristically, a history of crusting that bleeds on removal and a nonhealing blister for several months to years has been noted. When left untreated, the tumor progresses to involve skin of the mentum and alveolar mucosa. In advanced cases, mandibular bone, floor of the mouth, and tongue can be involved, which renders the patient an oral cripple. Metastasis to cervical nodes develops with advanced lesions, and ultimately distant metastasis occurs. In a retrospective study of 1,036 patients with lip cancer (14), multivariate analysis yielded several prognostic factors predictive for significantly decreased determinate survival: patients with primary tumors larger than 3 cm, presence of cervical metastasis, poorly differentiated or undifferentiated histology, and involved surgical margins. The risk of cervical metastases is increased in large primary tumors (greater than 3 cm), particularly if the oral commissure is involved; locally recurrent tumors; tumors thicker than 5 mm; poorly differentiated histology; or if perineural invasion is present (15–18).

CLINICAL EVALUATION

Lip carcinoma should be readily recognized and diagnosed (see Table 116.2). Its early stages can be indolent and protracted. As previously mentioned, the patient may present with a history of lower lip crusting that bleeds on removal or a nonhealing blister present for several months to years. Physical examination typically reveals an area of crusting with surrounding induration in an area of leukoplakia of the lower lip. In more advanced stages, a large bleeding mass may be present that can involve chin skin, the oral commissure, the upper lip, or the mandible. The integrity of the mental nerve must be evaluated even in early lesions, because tumor may track along the mental nerve and involve the mandible by direct extension, perineural invasion, or lymphatic spread into the mental foramen.

The diagnosis is established by incisional biopsy, which should include part of the deep or lateral tumor margin. This allows the pathologist to determine the pattern of invasion and the presence of perineural invasion. Prophylactic antibiotics are not necessary for simple biopsies (19). Ancillary radiographic studies such as a Panorex, computerized tomography (CT), and magnetic resonance imaging (MRI) are indicated when tumor is attached to the mandible or extends over the gingiva into a tooth root, when dentition is loose, or when hypesthesia of the mental nerve is present. Positron emission tomography (PET) resolution is too imprecise to correctly define the extent of the tumor compared to CT or MRI. Ipsilateral enlargement of the mental nerve foramen is a sign of mandibular invasion via the mental nerve, and obliteration of fat in the masticator space, in the pterygopalatine fossa, or along the mandibular canal must be regarded as suspicious for tumor spread, even in the absence of gross osteolytic changes (20). An aggressive metastatic workup is not indicated in previously untreated lip carcinomas, because fewer than 2% of patients have distant metastases at the time of initial evaluation (21). The staging of SCCA of the lip, as defined by the American Joint Committee on Cancer, is outlined in Table 116.1.

Although 90% of lower lip malignancies are SCCA (22), it is important to keep in mind the differential diagnosis of other nonhealing or ulcerative lesions of the lips, particularly when the clinical presentation is atypical for squamous cell cancer. BCCA is the second most common malignancy of the perioral region. Cancers of the upper lip are nearly always BCCA (6,14). It rarely arises on lip mucosa; rather, it involves the lip by direct extension of

TABLE 116.1 STAGING OF SCCA OF THE LIP: PRIMARY TUMOR (T)

TX	Primary tumor cannot be assessed.
T0	No evidence of primary tumor
Tis	Carcinoma *in situ*
T1	Tumor ≤2 cm in greatest dimension
T2	Tumor >2 cm but ≤4 cm in greatest dimension
T3	Tumor >4 cm in greatest dimension
T4a	Moderately advanced local disease: Tumor invades through cortical bone, inferior alveolar nerve, floor of mouth, or skin of face (e.g., chin or nose).
T4b	Very advanced local disease: Tumor invades masticator space, pterygoid plates, or skull base and/or encases internal carotid artery.

a perioral skin lesion. This is most commonly seen with sclerosing BCCAs. These tumors usually have a distinct clinical appearance of a pearly white nodule with central dimpling, although larger tumors may appear similar to squamous cell tumors. They grow very slowly, rarely metastasize to cervical lymph nodes, and when located near embryonic fusion planes tend to track deeply into the soft tissues along these planes.

Overall, minor salivary gland tumors (MSGT) comprise less than 3% of all head and neck neoplasms, but the lips are the second most common site after the hard palate for the occurrence of MSGT (23). A neoplasm arising from the minor salivary glands typically presents as a smooth, firm, nonulcerated mass, very often involving the upper lip. However, when a MSGT presents on the lower lip, it is far more likely to be malignant. Overall, MSGT have about a 25/75 distribution between benign and malignant, but on the lip, they are more likely to be benign due to the great preponderance of pleomorphic adenomas. The most common malignant MSGT are mucoepidermoid and adenoid cystic carcinoma (23,24). Other rare malignant lesions of the lips include melanoma, microcystic adnexal carcinoma, Merkel cell carcinoma, malignant fibrous histiocytoma, and malignant granular cell tumors. Keratoacanthoma is a benign self-limiting epithelial neoplasm that can mimic SCCA. It is commonly seen in patients aged 60 to 80 years. It has an initial rapid growth phase (over several weeks) to 1 to 2 cm in diameter and then stabilizes and spontaneously regresses after several weeks to months. It occurs on the lips in 8.1% of cases, appearing as an ulcerated circumscribed lesion with elevated or rolled margins, a keratinized central region, and an indurated base. It is firm in consistency, and the central keratin core can desquamate, leaving an ulcer. Diagnosis is established by incisional biopsy, which is reported to accelerate its involution (25) (Table 116.2). Excisional biopsy, sparing as much normal tissue as possible, is indicated for persistent or enlarging lesions over several months, when SCCA cannot be excluded after previous incisional biopsies.

Again, a high index of suspicion for tumor should prompt a biopsy in the face of an abnormal physical exam of the lip. Common signs and symptoms of actinic cheilitis include dryness, atrophy, scaliness, swelling, erythema, ulceration, loss of distinction of the vermilion border, and the formation of transverse fissures (11). When any of these changes or leukoplakia or hyperkeratosis is seen, either as an isolated lesion or if the lesion progresses in size, biopsy is indicated. Other ulcerative inflammatory lesions involving the lips, including viral stomatitis and the primary chancre of syphilis, can mimic lip carcinoma but are acute in onset, and the lip lesion heals spontaneously.

MANAGEMENT

The most efficacious treatment modality for lip carcinoma is one that allows adequate treatment of the primary tumor, appropriate management of cervical lymph nodes,

TABLE 116.2 DIAGNOSIS LIP CANCER

Diagnosis	Symptoms and Signs	Tests
Squamous cell cancer	Nonhealing blister or recurrent crusting, lip induration, ulcer or mass for months to years, mental nerve numbness	Panorex CT/MRI Biopsy
BCCA	Pearly nodule with central dimpling, upper lip, or perioral skin	Biopsy
Minor salivary gland tumor	Submucosal mass, usually upper lip	Biopsy
Keratoacanthoma	Rapid growth then spontaneous regression, may mimic SCCA in appearance	Incisional biopsy

CT, computed tomography; MRI, magnetic resonance imaging.

and successful reconstruction. The treatment plan should have the following goals:

1. Extirpate all tissue involved with cancer, both at the primary site and regional lymph nodes
2. Maintain oral competence in terms of speech, mastication, and retention of saliva
3. Maintain satisfactory lip cosmesis
4. Permit early rehabilitation and return to daily activities

Surgery and radiation therapy are equally effective in controlling T1, T2, and T3 lesions, while T4 lesions require combined modality treatment (26–28). In a series of 323 patients, of which 91% were T1 or T*cis* treated primarily by surgery, cause-specific survival at 10 years was 98% (29). In a series of 158 stage I and II patients, 108 (68%) of whom were treated with surgery, and 50 (32%) of whom were treated with XRT; determinate survival rates were 95% for stage I and 90% for stage II without any difference between the treatment received (30). Another group reported on their 228 patients of whom 197 (86%) were treated only with surgery and 205 (90%) of whom were stage I and II. Their actuarial disease-specific survival for all stages was 92% at 5 years (22). A study of 256 stage I patients treated either with surgery (n = 90) or XRT (n = 166) found no difference between the two groups in local control or overall survival rates; however, disease-free survival rates were higher for those treated with surgery (31). A very large European study of 1,870 patients looking at the effectiveness of brachytherapy showed 5-year local control rates of 98% for T1, 97% for T2, and 90% for T3 lesions (27). In another set of 85 N0 patients treated primarily with XRT, the actuarial 5-year survival rate was 97% with a locoregional control rate of 93% in patients who had T1–T3 disease (26).

Patients with higher overall stages, and especially those with higher nodal stages, have a worse prognosis. In the series mentioned earlier with 5-year determinate survival rates of 95% for stage I and 90% for stage II, patients with stage III and IV lip cancers had a 37% 5-year determinate survival rate (30). In one series of 118 patients treated with surgery and post-op XRT as indicated, determinate 5-year survival rates were 100% for stage I, 94% for stage II, 67% for stage III, and 49% for stage IV. Not surprisingly, patients in stage IV also had the highest rate of recurrence (32).

Radiation therapy is a low-risk noninvasive technique that avoids the potential complications associated with general anesthesia and surgical morbidity (Table 116.3). However, the treatment time is prolonged (as much as 5 to 6 weeks for external beam XRT, 1 week for brachytherapy), a whistle deformity may result from tissue loss and wound contracture with very large tumors, osteoradionecrosis of the mandible may develop, and future reconstructive options may be limited. It is contraindicated as primary therapy in patients with definite bony involvement. Studies looking at the sequelae of XRT have found that the majority of patients have good aesthetic and functional outcomes, especially with smaller or intermediate tumors (26,27), but the great difficulty with XRT as primary therapy (especially for larger tumors) is that when complications occur, surgical reconstruction becomes more difficult. Primary radiation therapy may be most useful in the treatment of commissure lesions due to aesthetic and reconstructive considerations in this setting (27).

TABLE 116.3 COMPLICATIONS LIP CANCER

Surgical
Wound infection and dehiscence
Incompetent oral sphincter
Microstomia
Poor cosmetic result
Radiation
Whistle deformity
Osteoradionecrosis

In the United States, surgical management is recommended for most patients. The oncologic, functional, and cosmetic outcome is usually excellent in early T stage disease, and the oncologic outcome is poor with primary radiation of advanced tumors, particularly when it is close to or involves the mandible. We prefer a combination of surgery and postoperative radiotherapy for stage III disease with high-risk features, stage IV disease, and for recurrent disease after primary surgical treatment.

Vermilionectomy is indicated in T*cis*, superficial carcinoma limited to mucosa, or multicentric or premalignant lesions such as actinic cheilitis (10). The standard approach to surgical resection of the primary lip lesion is full-thickness excision and careful intraoperative frozen-section evaluation of the surgical margins. The appropriate margin around a T1 primary lip tumor is controversial. A study of 72 stage I and II patients reported a 2.8% local recurrence rate when a 3-mm margin of normal tissue was obtained and frozen-section margins were negative (33). When tumor margins were 2 mm or less, local recurrence was seen in 13% of patients, half of whom had received postoperative radiation therapy (34). Even with 5 to 10 mm of seemingly normal tissue as a margin, 17 of 131 (13%) T1–T3 patients had positive margins on frozen sections, and 9 of 131 (7%) had a "close" margin in which the tumor was within 5 mm on permanent histologic examination. Sixteen of the seventeen patients had T1 tumors (35). In T2 tumors, we advocate a 5- to 8-mm margin of normal tissue because tendency to underestimate margins is more common and reported local recurrence rates have been higher than anticipated.

The primary goal of therapy is eradication of all tumor tissue, without limitation of extirpation for reconstructive

considerations. More advanced tumors may require resection of chin skin, mandibular bone, or oral cavity soft tissues to allow a 1- to 2-cm margin. Skin incisions should be planned so as to minimize the secondary deformity and to facilitate reconstruction but not at the expense of compromising tumor margins. BCCA should also be treated with margins of at least 4 mm to improve control rates (36). The importance of frozen section margin control and the achievement of negative margins in the treatment of cancer cannot be overemphasized as it is well known that positive margins decrease locoregional control rates and may require the addition of another treatment modality (e.g., XRT).

Mohs micrographic surgery is an accepted treatment for cutaneous carcinomas and is recommended as first-line therapy in the following settings due to superior cure rates: BCCA greater than 2 cm, SCCA greater than 1 cm, tumors at high risk for recurrence (tumors in the H-zone or embryonic fusion planes, tumors in immunocompromised patients, tumors with aggressive histologic features), tumors with indistinct clinical margins (e.g., morpheaform BCCA), and especially recurrent tumors (37). Looking specifically at the performance of Mohs in the setting of lip carcinoma, two different studies with 5 years of follow-up have shown a recurrence rate of 3% for BCCA and 8% for SCCA (38,39). A metaanalysis of cutaneous, lip, and ear SCCA showed a 5-year local recurrence rate of 10.5% in 7,022 patients treated with non-Mohs modalities versus 2.3% in 952 patients undergoing Mohs micrographic surgery (40). However, in this study, electrodesiccation and curettage were also included in the non-Mohs modalities, and not every series included in the metaanalysis may have used frozen section control of the margins. In a study of 599 facial BCCA lesions (lips $n = 29$) with 5-year follow-up comparing surgical excision with 3-mm margins and frozen section control against Mohs, there was not a significant difference between the two regarding recurrence of primary BCCA, but Mohs did show a statistically significant lower rate of recurrence in the treatment of recurrent BCCA (41).

The management of regional lymph nodes in patients with lip carcinoma is controversial and requires a thorough understanding of the risk of nodal metastasis and the patterns of nodal spread. In contrast to other SCCAs of the oral cavity, lip carcinoma uncommonly metastasizes to regional lymph nodes. However, when nodal metastasis occurs, 5-year determinate survival is significantly decreased as discussed earlier. In fact, nodal disease is the single most important prognostic factor of survival in lip cancer (15). Regional nodal metastasis is present at the time of initial diagnosis in up to 15% of patients, and up to another 15% of patients will develop delayed nodal metastasis (15,30). Therefore, appropriate management of the neck in lip cancer requires separate decision making for clinically palpable disease versus occult metastatic nodal disease in the newly diagnosed, untreated patient. For patients with recurrent disease, the cervical lymph nodes must be addressed.

In patients with clinically palpable, suspicious lymph nodes, the rate of pathologically positive nodes ranges from 44% to 97% (15,17,42). If the primary tumor was on the lateral one-third of the lip, the ipsilateral nodes were involved 84% of the time and were limited to levels I to III (42). Bilateral or contralateral metastasis was seen 3% to 14% of patients and was usually associated with larger tumors that crossed the midline of the lower lip (15,17,42). Neck dissection of the ipsilateral side alone is recommended if radiation therapy is planned postoperatively and includes the contralateral, undissected, clinically N0 neck. Indications for postoperative radiation therapy include a T3 or T4 primary tumor, a recurrent tumor, extracapsular spread, metastasis in multiple levels or more than two nodes, or perineural invasion. A modified radical or radical neck dissection is performed for bulky (greater than 3 cm) nodal disease in levels II/III, but a selective neck dissection of levels I to III is oncologically sound if the nodes are freely mobile, and postoperative radiation therapy is used for extracapsular spread, more than two pathologically positive nodes, or multiple levels are involved (15,30,43,44).

Decision making for treating clinically N0 necks is more complex. Sentinel node biopsy for lip cancer is slowly growing in usage, and it holds promise as in other oral cavity sites (45,46). Current studies will help to determine its place in the treatment algorithm. T1 lesions rarely need the neck addressed, because the risk of nodal metastasis is approximately 3% (29). The risk for occult metastases increases with increased primary tumor size as evidenced in a large study of 617 patients: only 4% of T1/T2 patients had occult metastasis versus 23% of T3/T4 patients ($P < 0.001$) (17). The likely location of possible occult metastases is determined by the lymph node drainage basin of the primary lesion as described earlier.

Our treatment philosophy is to perform ipsilateral selective neck dissection, levels I to III and contralateral level I in N0 necks when a significant risk (20%) of occult metastasis is present and radiation therapy is not planned. As previously mentioned, there is a higher risk of cervical metastasis in primary tumors greater than 3 cm, particularly if the oral commissure is involved; locally recurrent tumors; tumors thicker than 5 mm; poorly differentiated histology; or if perineural invasion is present (15–17,30). We also perform ipsilateral selective neck dissection, levels I to III and contralateral level I when ipsilateral N1 disease is present, the contralateral neck is N0, and postoperative radiation therapy is not planned, or when reconstruction requires revascularized tissue transfer. Bilateral I to III SND can be performed for primary lesions greater than 3 cm crossing the midline, but neck dissection is unnecessary if postoperative radiation will be used to treat the primary site, because the neck can be included in the treatment fields.

LIP RECONSTRUCTION

Lip reconstruction must be carefully considered when managing lip carcinomas and requires meticulous planning to achieve optimal functional and cosmetic results. The ideal reconstructive procedure should result in a lip that is sensate; has sphincter or muscle function that maintains a watertight continent seal; allows sufficient opening for food, dentures, and oral hygiene; and is aesthetically acceptable. It is not possible to satisfy all these criteria in every instance; therefore, reconstructive goals must be prioritized. The most critical component of successful reconstruction is oral continence, which is a function of sensation and two sphincteric mechanisms oriented at right angles. The deep orbicularis and buccinator muscle interplay to create an axial force that seals the lips against the teeth, and the superficial orbicularis functions as a coronal sphincter, pursing and sealing the opposing lips (47). This complex relationship is best preserved when circumferential continuity of the orbicularis is maintained; however, larger defects often mandate alternative solutions to avoid compromising oral aperture size.

Multiple preoperative factors will influence reconstructive plans including defect size, tissue laxity, and patient factors such as dentures. In addition, planned adjunctive surgery, which may affect vascular supply (e.g., neck dissection), previous radiation therapy, or surgery, may compromise vascularity and affect design or preclude pedicled flaps. To optimize reconstructive and oncologic results, it is best to employ a flexible game plan of lip repair, with multiple options in mind, choosing the technique that best fits the final oncologic defect and the patient's specific tissue characteristics. It is important to keep in mind priorities of structure, function, and form (in that order), realizing that satisfaction of all goals often requires more than one stage, particularly with regard to large or complex defects. If possible, incisions should be placed within the circumoral relaxed skin tension lines (oriented radially), at borders of lip subunits or at boundaries such as the melolabial crease and labiomental sulcus. Tattooing the white scroll at the vermilion border with a fine needle and methylene blue dye ensures accurate postoperative realignment of this aesthetically critical boundary.

Partial-Thickness Defects

Partial-thickness or mucosal loss at the vermilion only is most commonly encountered when vermilionectomy or lip shave is performed for diffuse premalignant or superficial malignant disease or preventatively in conjunction with primary tumor resection when actinic cheilitis is present in remaining lip tissue. The most commonly used method of reconstitution of lining involves submucosal dissection and advancement of labial buccal mucosa. Undermining is performed deep to minor salivary glands and superficial to the orbicularis oris muscle and labial artery, and it can be extended to the apex of the buccal sulcus to ensure tension-free redraping. Problems with this technique include thinning of lip, persistent deep red color of advanced mucosa (more of a problem for males), and potential inversion of hairs at the vermillion border with irritation. These drawbacks can be avoided with carbon dioxide laser lip shaves and mucosalization by secondary intention, although healing time requires 2 to 3 weeks. Other less commonly used two-stage techniques for vermillion mucosa replacement include bipedicle visor-type flaps from the undersurface of the opposing lip, ventral tongue flaps, and cross-lip mucosal flaps (48). Small vermilion deficiencies can be managed with V-Y advancement flaps.

Small partial-thickness defects involving the lips are managed following basic principles of cutaneous surgery. Optimal reconstructive results are often achieved when the defect can be converted to a wedge or pentagonal defect oriented within relaxed skin tension lines. M-plasty is used when possible to avoid scars that cross the boundaries of the lip subunits. Extending resections through uninvolved vermilion and orbicularis often achieves better cosmetic results than A-to-T methods that create horizontal scars parallel to the mucocutaneous junction (48,49).

Larger partial-thickness defects mandate consideration of lip subunits. Upper lip subunits include a central segment composed of the philtrum and philtral ridges and two trapezoid-shaped lateral segments (50). The lower lip consists of a single subunit. Similar to principles of nasal reconstruction, absence of the majority of a subunit is often best repaired after excision of the remaining portion. Medial advancement of lateral upper lip skin is aided greatly by the excision of perialar crescents of skin and anchoring dermis to pyriform periosteum deep to the ala. Partial-thickness defects of the central segment are amenable to full-thickness skin grafting or healing by secondary intention—with the intention of narrowing the philtrum as little as possible. Patients with flat, less distinct philtral columns may be an exception to this rule (47). Large cutaneous lateral defects are optimally resurfaced with V to Y island flaps or with inferiorly or superiorly based melolabial transposition flaps (Fig. 116.3).

Full-Thickness Defects

Isolated full-thickness defects of vermilion only (mucosa and orbicularis) are uncommon, but full-thickness deficiencies along the length of the vermilion are almost always present after extensive reconstructions with local or distant flaps. Several techniques have therefore been designed to address this issue. Small complete vermilion defects can be addressed with a full-thickness horizontal releasing incision at the vermilion–cutaneous junction of the longer portion of the remaining lip (48). Vermilion is then advanced laterally into the defect. Another option is to convert the defect to a full-thickness wedge through the cutaneous lip.

When extensive vermilion substance has been lost, a muscle-mucosal flap from the ventral surface of the tongue may be used. This flap is based posteriorly with the free

edge of the flap attached to the mucocutaneous border. Two to three weeks later, the pedicle is transected at the junction of the lateral and ventral tongue, retaining muscle for bulk and mucosa for vermilion reconstruction. This technique does not limit tongue mobility; however, the newly created vermillion has a pebbled surface (51). A better alternative for more extensive defects may be the facial artery musculomucosal (FAMM) flap (52). This axial flap containing buccal mucosa, submucosa, and a small amount of buccinator muscle is based on the facial artery as it courses through the cheek lateral to the buccinator muscle and medial to other muscles of facial expression. Inferiorly based FAMM flaps incorporate the facial artery as it enters the face at the anterior edge of the masseter muscle, whereas superiorly based FAMM flaps are perfused retrograde through the angular artery. Both designs allow for a long thin flap to be harvested without compromise of viability—this both minimizes donor site morbidity and enables single-stage reconstructions of the entire vermillion. Bilateral and unilateral FAMM flaps have been used with particular success as adjuncts in total lip reconstruction for color and contour-appropriate replacement of vermilion deficiencies.

The algorithms in Figures 116.4 and 116.5 outline an excellent general approach to upper and lower lip reconstruction (51). The relative proportion of total lip length that can be excised and closed directly without distortion

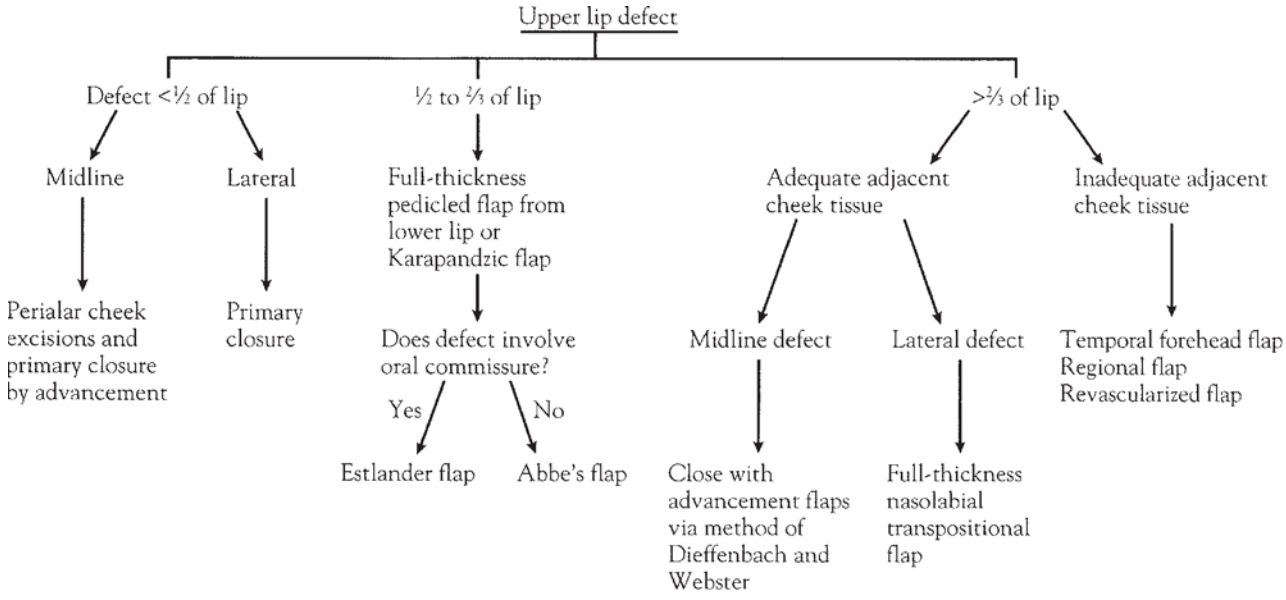

Figure 116.5 Upper lip reconstruction. From Baker SR, Krause CJ. Pedicled flaps in reconstruction of the lip. *Facial Plast Surg* 1983;1:68–69, with permission.

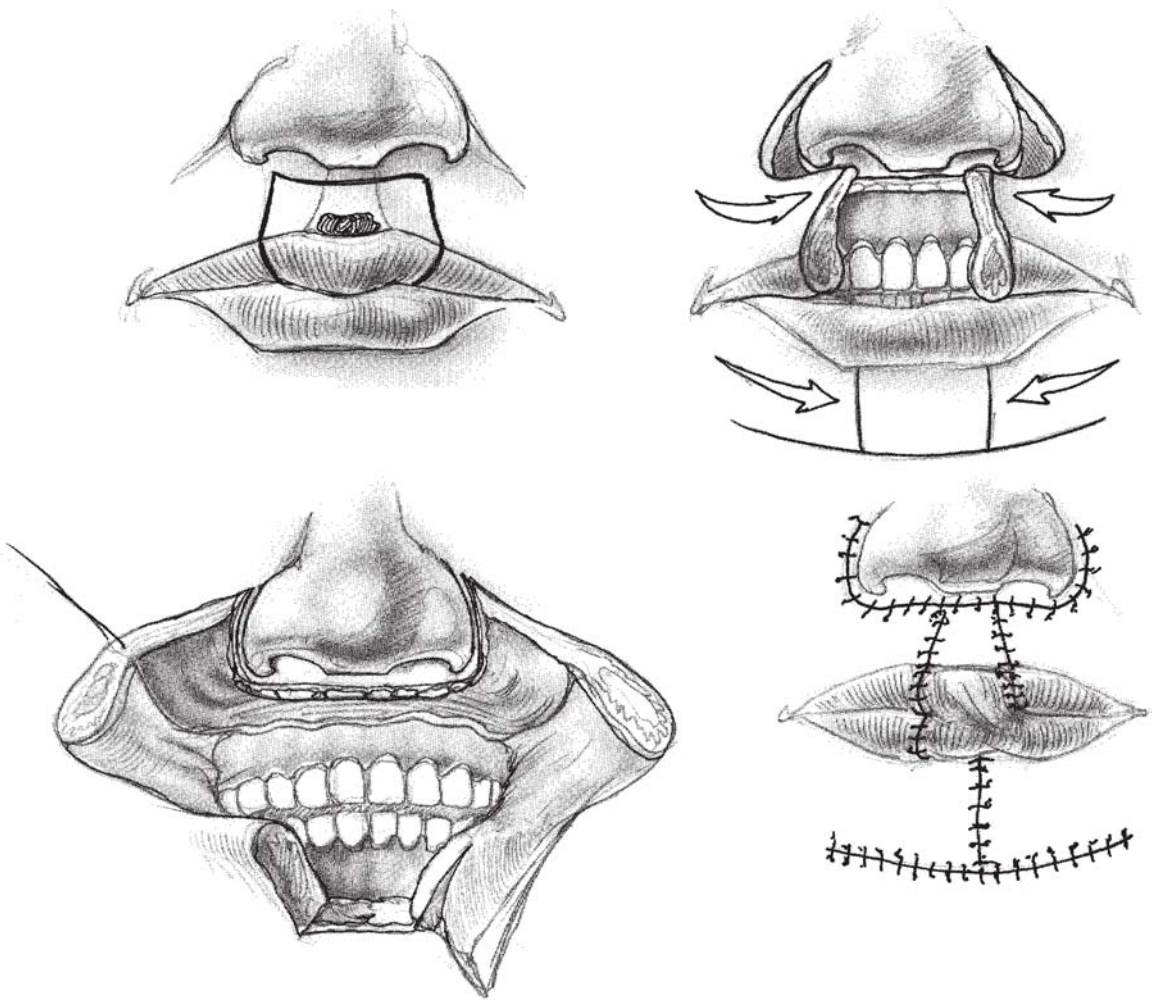

Figure 116.6 Primary closure of defects in the midline of the upper lip can be facilitated by excising crescents of cheek skin in the perialar regions. An Abbe flap can be added in the midline if the wound closure is under excessive tension.

varies between individuals and depends on overall lip length and tissue laxity. In general, one-fourth to one-third of the upper lip may be closed directly with larger lateral resections sometimes amenable to direct closure. Lower lip defects of one-third to one-half lip length may be closed primarily. Shield or V excision is usually adequate with closure in three layers (mucosa, muscle, skin) and meticulous reapproximation of the orbicularis and white scroll at the vermilion border on either side of the defect.

In the lower lips, lateral advancement with incisions placed in the mental crease may be required when the defect base is broad. Every attempt should be made not to extend incisions beyond the mental crease to avoid a pointed chin deformity. Just as in partial-thickness defects, full-thickness advancement in the mesial upper lip is facilitated by excising a crescent of cheek skin in the perialar region and anchoring the lateral flap to periosteum (53) (Fig. 116.6). This method is similar to that described by Diffenbach and Webster and lessens tension on remaining lip segments after primary closure (48). An Abbe flap may be used in the midline to replace the central subunit and prevent excessive tension on the wound closure.

Defects of One-Third to Two-Thirds of the Lip

The majority of these defects are amenable to closure using rotated or pedicled tissue from the opposing lip. Three procedures constitute the majority of reconstructions in this group: the Karapandzic labioplasty, the Abbe cross-lip flap, and the Estlander cross-lip flap. Each method has advantages and disadvantages and individual surgeons favor different techniques (48,54).

The Karapandzic labioplasty, described in 1974, modified older circumoral advancement techniques to preserve vascularity, sensation, and motor innervation to the lips. This single-stage reconstructive procedure has gained popularity to become the favored reconstructive method of many surgeons for moderate-sized defects (48). This technique (Fig. 116.7) is more commonly used for lower lip defects but can be applied to upper defects as well. Circumoral

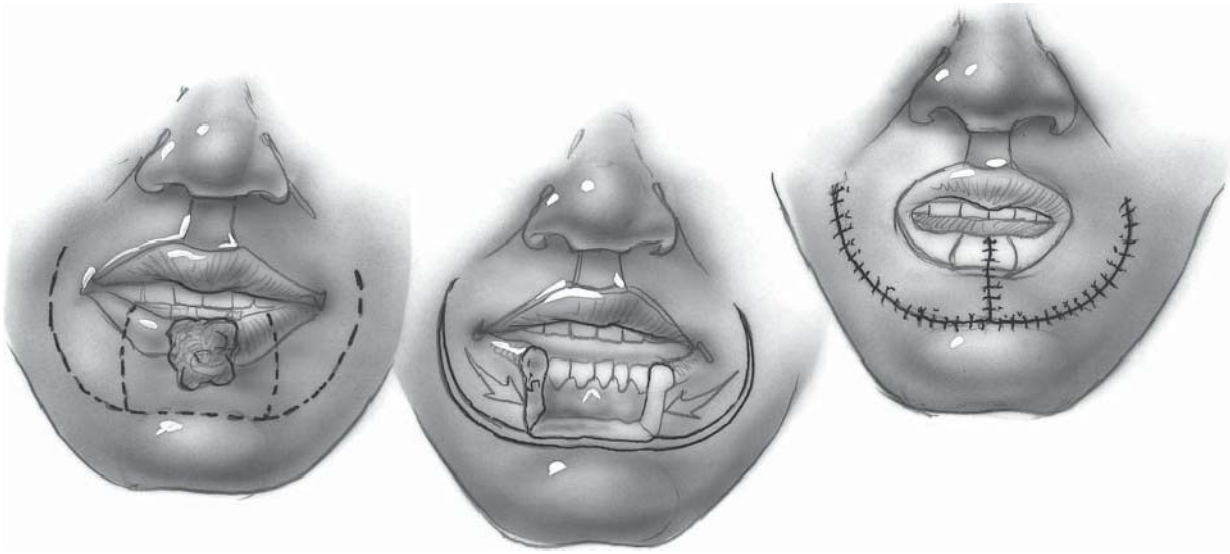

Figure 116.7 The Karapandzic labioplasty. Circumoral skin incisions are made within the nasolabial and mental creases. The orbicularis oris muscle is bluntly dissected from supporting perioral muscles, taking care to preserve the neuromuscular pedicles, which enter from the periphery. The oral mucosa usually does not require transection.

incisions are begun in the mental crease and carried around the oral commissures into the melolabial sulci. An important technical point is to maintain appropriate flap width in the area of the oral commissure. Flap width in this area must approximate the height of the lip portion, which it will replace after rotation. Incisions, therefore, cannot remain within the melolabial sulcus where it runs very close to the commissures. After incisions are carried through skin and subcutaneous tissue, the lateral border of the orbicularis oris muscle is mobilized from the other supporting perioral muscles to allow rotation of segments and tension-free closure. Blunt dissection of the muscle allows identification and preservation of the superior and inferior labial arteries and the neurovascular pedicles that enter the orbicularis muscle from its periphery. The underlying oral mucosa usually does not require transection for mobilization. Flaps are rotated and advanced into their new positions and divided perioral muscles and reattached at appropriate positions along the repositioned lip.

The advantages of the Karapandzic flap are its ease of design and the preservation of oral competence. Disadvantages include blunting of the commissures; circumoral scars, which can be unsightly; and the potential for microstomia, which may preclude the use of dentures. One potential solution to microstomia is to initially reconstruct with this technique, accept temporary microstomia, and allow tissues to stretch with time and use, then perform a cross-lip procedure to improve oral opening (54,55).

Abbe and Estlander flaps transfer full-thickness tissue between opposing lips pedicled on the labial artery. These techniques allow precise flap design, typically result in less microstomia than rotation flap reconstruction, and avoid circumoral incisions (54). Abbe flaps preserve the aesthetically important oral commissure but require a second stage for flap division. Additional disadvantages include denervation of tissue with variable reinnervation over time and the potential for pincushioning or trapdoor deformity in a lip segment surrounded by scars on three sides (56). The Abbe flap was originally designed to close medial defects, and it can be based either medially or laterally, depending on the location of the defect and blood supply. There are several important points for consideration in Abbe flap design (Fig. 116.8). Flap height should equal the height of the defect. Flap width is classically designed to be one-half the width of the defect, but more modern approaches advocate reconstruction of upper lip subunit defects with like-size flaps from the lower lip when possible (50,56). Creation of the flap involves full-thickness incisions through all portions except the region of the pedicle, which consistently is found at the level of the vermilion border on the posterior surface of the orbicularis muscle just deep to the labial submucosa (57). The pedicle should be narrow to facilitate rotation, and extension of anterior incisions into the vermilion allows for more accurate alignment of vermilion borders. Because the pedicle does not contain an associated major venous structure, it is important to leave a fairly wide mucosal bridge posteriorly to allow venous return. The donor site defect and flap reconstruction should be closed in three layers, with careful alignment of both orbicularis muscle and vermilion. When an Abbe flap is designed from the upper lip, lateral lip tissue should be used with medial incisions placed on the philtral ridges to camouflage donor site closure (54). This closure is facilitated by advancement of the lateral upper lip segment and excision of perialar crescents as described earlier. In general, cross-lip pedicles may be divided in 3 weeks.

The Estlander flap uses the same techniques as the Abbe flap to create a flap based a narrow labial artery pedicle

Figure 116.8 **A:** Large recurrent upper lip arteriovenous malformation following previous lip wedge resections. Anticipated resection with planned Abbe flap design. **B:** Defect involving two-third of upper lip following lesion removal. **C:** Closure with Abbe flap and cheek advancement with peri-alar crescent removal. **D:** Appearance following Abbe flap division.

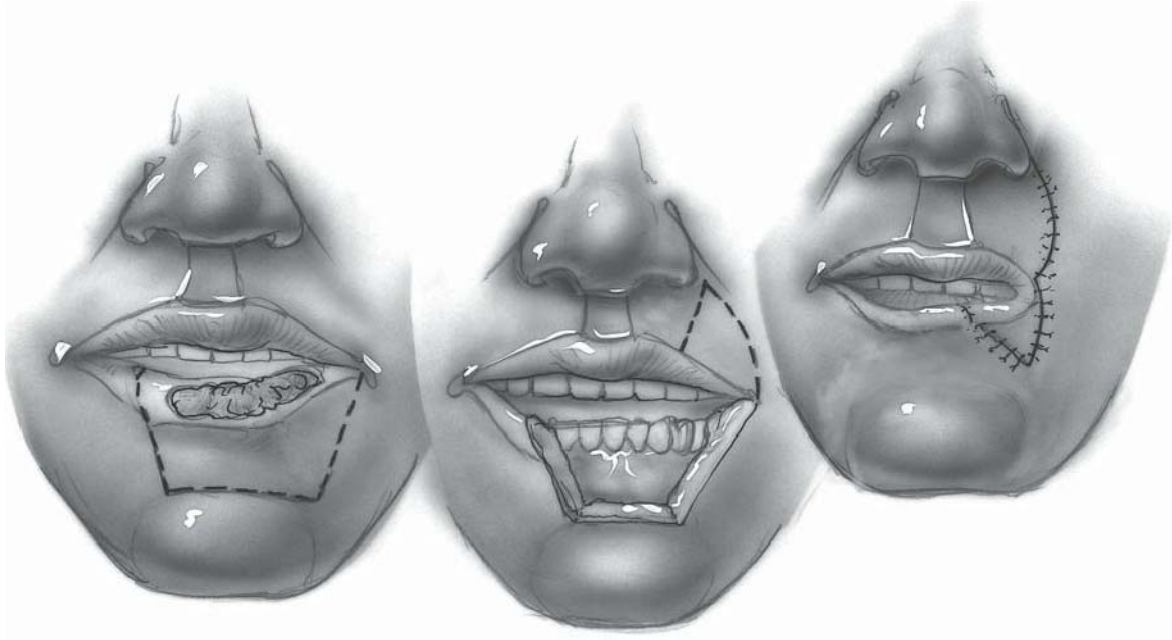

Figure 116.9 The superiorly based Estlander flap may be modified from its original description by designing the flap so that it lies within the nasolabial fold.

approximately one-half of the defect size. One exception is that the anterior incision on the pedicle side is not carried into the vermilion. Superiorly based Estlander flaps should be modified to incorporate scars within the nasolabial fold (Fig. 116.9). Donor tissue is rotated around the oral commissure to the opposing lip, and therefore, this single-stage procedure is only applied to defects involving the commissure. This technique results in blunting of the oral commissure that, unlike the symmetric blunting of circumoral advancement, is starkly contrasted by the unviolated opposing commissure. As a result, secondary commissuroplasty is often performed to minimize this disparity.

Defects Greater Than Two-Thirds of the Lip

Lip reconstruction with locoregional tissue is favored if possible, particularly techniques that allow for salvage of dynamic muscle function and color-matched skin. Cross-lip flaps may be combined with lateral advancement flaps for larger central upper lip defects (Fig. 116.6), but this technique is not sufficient for total upper lip reconstruction. Modified cheek flaps that preserve neurovascular structures and the original position of the oral commissures have been used with success in reconstruction of near total and total upper lip defects (58). The main disadvantage of this technique is large transverse scars that cross the cheeks. Bilateral superiorly based composite nasolabial flaps have also provided reasonable aesthetic and functional results (59). Free temporal scalp flaps based on the superficial temporal vessels have been used with some success to import hair-bearing tissue to restore male beard patterns and provide camouflage (60). A major disadvantage of this technique is the lack of innervated tissue.

Relatively large lower lip defects can be managed with Karapandzic circumoral rotation flaps followed by cross-lip flaps as previously described. Extended Karapandzic flaps and bilateral Karapandzic flaps have also been used with success for total and subtotal lower lip defects, provided tissue inferior and lateral to the oral commissures has been spared (61). Buccal advancement flaps allow for mucosal restoration.

Midline lower lip defects may be corrected by using any of several modifications of the Bernard repair, which essentially uses full-thickness advancement flaps of adjacent cheek tissue. These techniques have the advantage of single-stage reconstruction with innervated flaps but frequently result in a tight lower lip with poor function (48,54,62). The Webster modification of the Bernard cheiloplasty employs Burow triangles whose medial vertical limbs lie within the melolabial fold (Fig. 116.10). The width of the base of the triangles is calculated so that the distance from the oral commissure to the lateral portion of the base equals one-half the width of lip tissue excised. Skin and subcutaneous tissue only are excised from the triangles, and incisions are deepened along its base, identifying and preserving the neurovascular supply to the orbicularis oris and buccinator muscles. A mucosal flap based on the superior margin of the cheek flap is elevated to create a new vermilion or a tongue flap may be employed. Usually, incisions through skin and muscle are required around the mental crease, with Burow triangles strategically placed in the submental area to allow sufficient advancement of the cheek flaps.

Full-thickness inferiorly based nasolabial flaps have been used to reconstruct subtotal lower lip defects (54). The disadvantage of this technique is that the flaps are not innervated, and in raising the flaps, the upper lip is

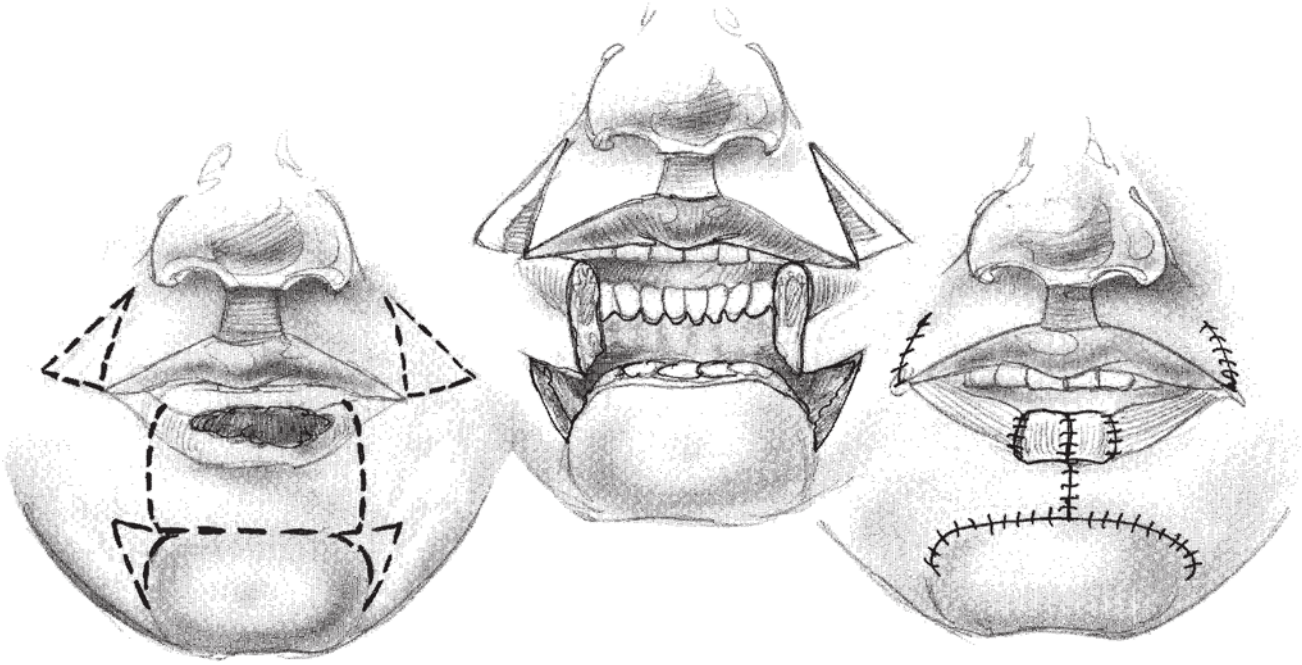

Figure 116.10 Webster modification of Bernard cheiloplasty. *Cross-hatched area* denotes mucosal flap used to create new vermilion (see text).

usually denervated. To avoid this complication, total lower lip reconstruction with skin only nasolabial flaps has been described with good aesthetic results and preservation of oral competence (63). Consistent functional reconstruction of total and subtotal defects has also been described using musculocutaneous island flaps based on the facial artery and innervated depressor anguli oris (DAO) muscle (62). Similarly, an unequal double Z-plasty transferring the DAO and platysma has been utilized with success, achieving sensation, sphincter function, and acceptable cosmesis (64).

Defects involving the entire lower lip and adjacent soft tissue of the cheek or chin require reconstruction with distant flaps. A variety of axial or myocutaneous flaps, particularly the pectoralis myocutaneous flap, have been utilized for extensive reconstructions, but variable flap bulk, inferior tension, and the lack of sensory reinnervation resulted in less consistent outcomes than those provided by free tissue transfer.

The composite radial forearm free flap with palmaris longus tendon has yielded reliable reconstructive results and remains the most commonly employed method (65–67). The skin paddle is folded over the palmaris longus tendon (or harvested fascia lata when palmaris is absent) to provide internal and external lip lining. The tendon ends are suspended superiorly to attain lip support and function. Various tendon inset methods described include fixation to orbicularis muscle at the modiolus, circumferential tunneling within the remaining lip, and attachment into medial upper lip orbicularis or tendon suspension to zygomatic arch periosteum (68). Although all described methods reportedly yield competence, long-term dynamic function is difficult to achieve and often elusive in the face of postoperative radiation (which is often required) (67). One promising alternative is to attach palmaris longus or fascia lata suspensions to bilateral orthodromic temporalis tendon transfers (TTTs), providing long-term support and dynamic voluntary closure. Experience using TTT in facial reanimation including bilateral facial paralysis has demonstrated long-term support and dynamic control of the lower lip (Fig. 116.11).

To facilitate sensory recovery, the lateral antebrachial cutaneous nerve can be neurotized to the stump of the mental or inferior alveolar nerve (69). The vermilion can be established on a deepithelialized segment of the forearm flap using a facial artery myomucosal flap as described earlier or with mucosal flaps from the tongue, upper lip, or cheek (52,65,66). Medical tattooing has also been used with acceptable results.

Anterolateral thigh flaps and free innervated gracilis flaps have also been utilized with success in lower lip reconstruction. While the former has become a dominant reconstructive flap at many centers due to its minimal harvest site morbidity and abundant available tissue, variable thickness, less favorable color match, and perforators less tolerant of aggressive suspension have maintained radial forearm dominance in this subsite. Innervated gracilis flaps have shown significant promise with advantages of true dynamic function mediated by facial nerve branches and better color match when external full-thickness skin grafts are employed (70,71). Despite reported successes, experience with this technique has been limited, and performance in the face of extensive mucosal defects and postoperative radiation has not been established.

When the anterior mandibular arch has been resected along with the lower lip, vascularized osteomyocutaneous flaps allow for immediate single-stage reconstruction with cosmetically and functionally acceptable results. The flap selected is dependent on bone and soft tissue requirements. For anterior mandible and lip alone, an osteocutaneous radial forearm or fibular flap is an option, whereas larger defects may require use of scapular flap or more commonly two separate free flaps (e.g., fibula and radial forearm). In the latter case, the fibula flap provides internal lining (e.g., buccal, floor of mouth, tongue), while the forearm is utilized for lip and additional external coverage (Fig. 116.11). Anterolateral thigh flaps have the advantage of providing greater coverage and may be superior for massive external defects.

COMPLICATIONS

Complications of radiation therapy, as discussed previously, include a prolonged treatment time, with delayed rehabilitation; a whistle deformity from tissue loss and scar contracture with large tumors, which may require secondary reconstruction; osteoradionecrosis of the mandible; and limitation of future reconstructive options. Surgical complications include those associated with general anesthesia, neck dissection, and wound infection and dehiscence. In regard to lip reconstruction, complications include fistula, an incompetent oral sphincter, microstomia, or poor cosmetic result. To avoid these complications, the surgeon must thoroughly understand the biologic behavior of lip carcinoma and its management principles and must carefully plan and meticulously execute the reconstructive option chosen.

EMERGENCIES

There are very few situations in which patients with lip carcinoma require emergent intervention (Table 116.4). As previously mentioned, lip carcinoma is usually a slow-growing lesion and is usually diagnosed relatively early. Large tumors involving the tongue and the floor of the mouth may cause airway problems when general anesthesia is required; this is readily managed by initial tracheotomy under local anesthesia. Patients with large tumors may be malnourished, in part due to oral incompetence; adequate preoperative nutritional assessment is important when major resection and reconstructive procedures are contemplated.

TABLE 116.4 EMERGENCIES LIP CANCER

Airway compromise with large tumors

HIGHLIGHTS

- The lips are important functionally in maintaining oral competence and aesthetically by contributing to appearance and facial expression. The lips are characterized by the vermilion, or that lip mucosa that contacts the opposite lip mucosa.
- The orbicularis oris muscle serves as the oral sphincter and is innervated by branches of the facial nerve. The blood supply is from the labial branches of the facial artery. Sensation is provided by the paired mental nerves.
- Lymphatic drainage from the lower lip is to the submental and submandibular nodes bilaterally; the upper lip drains to the ipsilateral parotid and submandibular nodes.
- Lip carcinoma is the most common malignancy of the oral cavity. As a rule of thumb, 90% are SCCA, 90% occur on the lower lip, and the overall 5-year determinate survival rate is 90%. Sunlight is thought to be the principal etiologic factor in its development.
- The diagnosis is established by biopsy but is suggested by a history of recurrent crusting or a nonhealing area of lip induration noted over several months. With a high index of suspicion, lip carcinoma is easily diagnosed and successfully managed if treated in its early stages.
- Surgery and radiation therapy are equally efficacious for lesions less than 3 cm. Surgery is preferred, because it offers the advantages of tumor margin assessment, rapid rehabilitation through immediate reconstruction, and avoidance of radiation complications. For advanced lesions, surgery combined with postoperative radiation therapy is indicated.
- Indicators predictive of poor outcome are large primary tumors, mandibular involvement, mental nerve involvement, cervical node metastases, recurrent disease, and undifferentiated histology.
- The goal of lip reconstruction is to provide the patient with a sensate innervated lip that functions as a competent oral sphincter of adequate size while remaining aesthetically acceptable. Successful reconstruction requires careful preoperative planning and meticulous execution of the appropriate technique.
- Defects of less than one-third of the upper lip and one-half of the lower lip can be closed primarily. Defects of one-third to two-thirds of the lip can be closed with an Abbe-Estlander flap or Karapandzic labioplasty. Both techniques require an intact labial artery.
- When the entire lip or surrounding soft tissue or mandibular bone is resected, reconstruction requires a distant flap. The ideal technique uses revascularized fasciocutaneous or osteomyocutaneous composite flaps, which can be done in a single stage for immediate reconstruction.

Neck Dissection

117

Jesus E. Medina *Nilesh R. Vasan*

ANATOMY

Any student of neck dissection must understand the vascular supply of the skin of the neck and the anatomic characteristics and relationships of certain structures that are encountered within the course of performing a neck dissection.

Vascular Supply to the Skin of the Neck

To avoid complications such as wound breakdown, skin flap necrosis, and exposure of the carotid artery after neck dissection, the incisions must be placed correctly.

The skin of the anterior lateral aspect of the neck is supplied by descending branches of the facial, submental, and occipital arteries and by ascending branches of the transverse cervical and suprascapular artery (Fig. 117.1). These arterial branches anastomose, forming a superficial network of vessels that runs predominantly in a vertical direction. Although some or all the main arteries or their perforating branches may be ligated or divided during a neck dissection, the superficial, predominantly vertical, vascular plexus must remain intact to ensure adequate blood supply to the skin flaps. Thus, the incisions in the neck that are more likely to safeguard the blood supply to the skin flaps are the single transverse incision in the mid portion of the neck, the superiorly based apron-like incision from mastoid to mentum for combined neck dissection with intraoral procedures (Fig. 117.2A), and the apron-like incision used when a neck dissection is performed in conjunction with a laryngectomy (Fig. 117.2B).

The Y incision and the double-Y incision jeopardize the blood supply to the inferior and middle skin flaps, respectively, and suffer from placing a trifurcate incision over the carotid artery (Fig. 117.2C and D). The modification of the Schobinger incision creates a long anterior medial flap, the tip of which may necrose as a result of the limited ascending blood supply (Fig. 117.2E). The MacFee double transverse incision transects the ascending and descending blood supply to the central portion of the flap (Fig. 117.2F). This flap, however, usually fares well even in the previously irradiated patient.

Platysma Muscle

Located in the anterolateral aspect of the neck, the platysma is a wide, quadrangular, sheet-like muscle that extends obliquely from the upper chest to the lower face. This muscle, a remnant of the *panniculus carnosus*, is located immediately deep to the subcutaneous tissue and thus provides an easily identifiable plane to raise skin flaps during neck surgery. In most neck dissections, flaps are elevated by dissecting in a plane immediately deep to the platysma; however, when the extent of the disease is such that the platysma must be left attached to the specimen, flaps can be elevated easily in a plane immediately superficial to this muscle. The beginning head and neck surgeon must remember that, because of its oblique direction, the platysma does not cover an inferiorly based triangle in the anterior aspect of the neck and most of the posterolateral aspect of the neck. Here, flaps must be elevated in a subcutaneous plane created by the surgeon. While making the incisions for a neck dissection and elevating the skin flaps, it is helpful to remember that the posterior border of the platysma is either over or slightly anterior to the external jugular vein and the greater auricular nerve.

Marginal Mandibular Branch of the Facial Nerve

Identifying the marginal mandibular branch is essential to perform an adequate excision of the lymph nodes in the submandibular triangle. The practice of ligating the anterior facial vein low in the submandibular triangle and

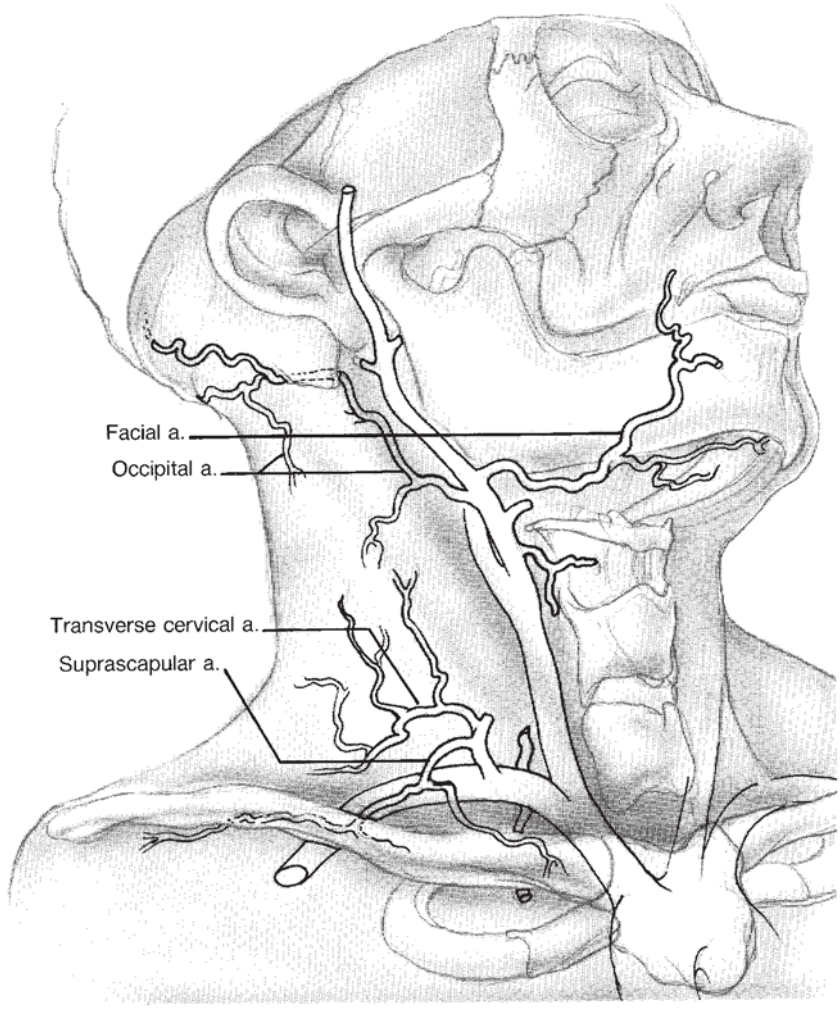

Figure 117.1 Vascular supply of the neck skin. (Adapted from Freelend AP, Rogers JH. The vascular supply of the cervical skin with reference to incision planning. *Laryngoscope* 1975;85:714, with permission.)

retracting it superiorly to "protect the marginal branch" can also result in elevation of the prevascular and retrovascular lymph nodes, thus precluding their appropriate removal. When indicated, it is preferable to identify the nerve and thoroughly remove these lymph nodes.

The nerve can be identified about 1 cm in front of and below the angle of the mandible by incising the superficial layer of the deep cervical fascia that envelops the submandibular gland, immediately above the gland, in a direction parallel to the direction of the nerve. The incised fascia then is gently pushed superiorly, exposing the nerve that lies deep to it but superficial to the adventitia of the anterior facial vein. The submandibular retrovascular lymph nodes are usually near the nerve and must be carefully dissected away from it. As this is done, the facial vessels are exposed and can be divided.

Spinal Accessory Nerve

Below the jugular foramen, the external branch of the spinal accessory nerve is located medial to the digastric and stylohyoid muscles and lateral or immediately posterior to the internal jugular vein (IJV). Occasionally, the uppermost portion of the nerve is posteriomedial to the vein. From here, the nerve runs obliquely downward and backward to reach the medial surface of the sternocleidomastoid muscle (SCM) near the junction of its superior and middle thirds (two to three finger breadths below the tip of the mastoid). Although the nerve can continue its downward course entirely medial to the muscle (18%), more commonly, it traverses and appears in the posterior border of it (82%) (1). Here, the nerve is always located above the point where the greater auricular nerve turns around the posterior border of the SCM, also known as Erb point (2). The mean distance between Erb point and the spinal accessory nerve is 10.7 mm, SD ± 6.3. It then runs through the posterior triangle of the neck and crosses the anterior border of the trapezius muscle. The mean distance between this point and the clavicle is 51.3 mm, SD ± 17 (2). Two anatomic characteristics of this portion of the nerve are relevant to avoid injuring it in the course of a neck dissection. First, the spinal accessory nerve is located rather superficially as it courses through the middle and low posterior triangle of the neck, and it can be easily injured while elevating the

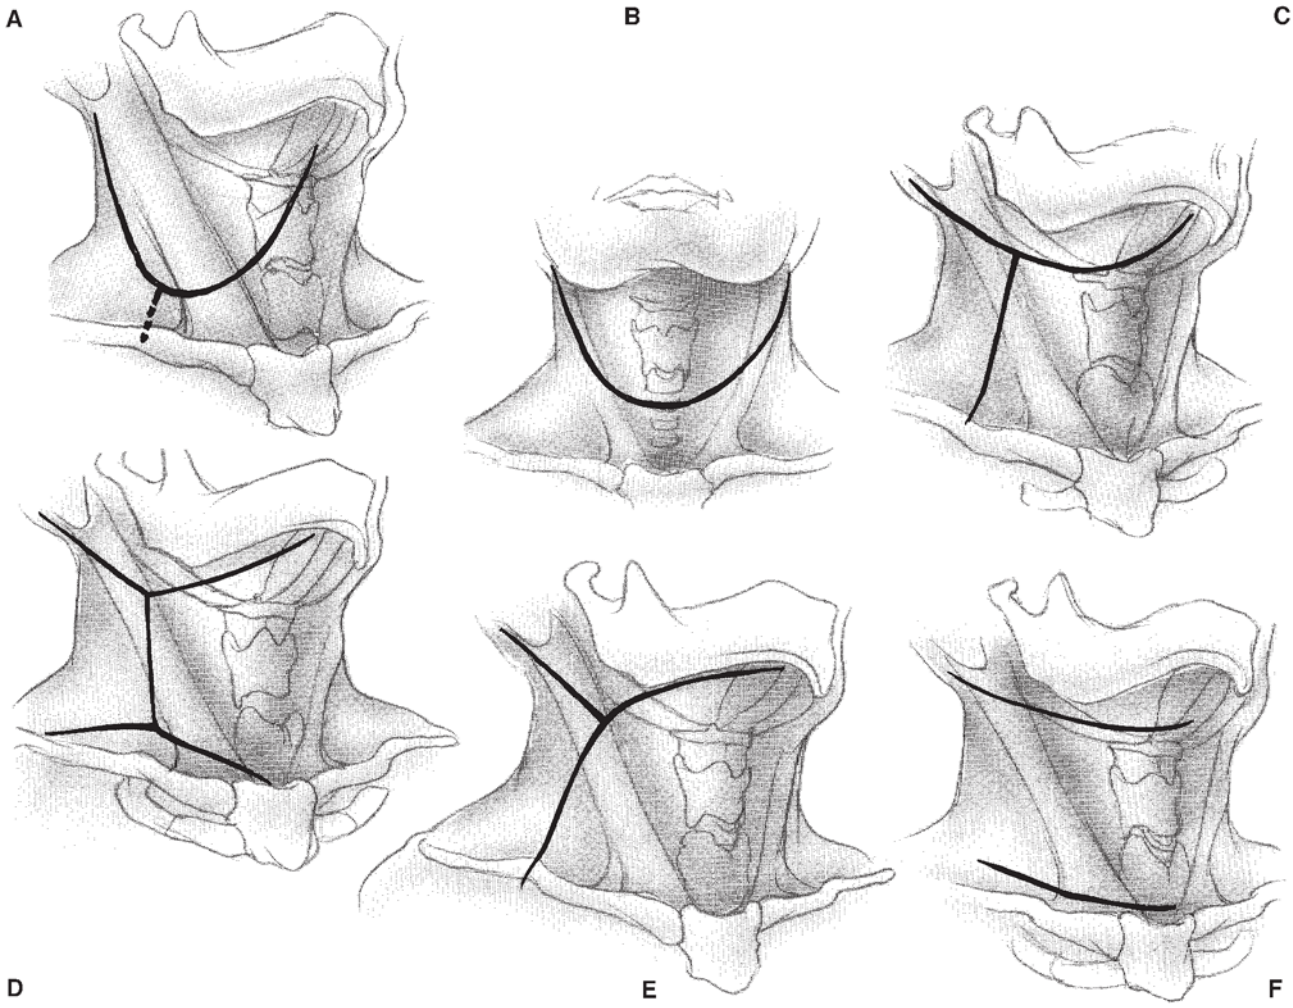

Figure 117.2 Neck dissection incisions. **A:** Latyschevsky and Freund. **B:** Freund. **C:** Crile. **D:** Martin. **E:** Babcock and Conley. **F:** MacFee.

posterior skin flaps. Second, the nerve does not enter the trapezius muscle at the anterior border of it but courses along the deep surface of the muscle in close relationship with the transverse cervical vessels. Therefore, isolating the nerve to the level of the anterior border of the trapezius does not ensure its preservation during surgical dissection below this point, particularly in a bloody operative field.

Nerve to the Levator Scapulae Muscle

The levator scapulae is a triangular muscle located deep in the lateral aspect of the neck, anterior and medial to the splenius capitis muscle. It extends from the transverse process of the atlas and the next three cervical vertebrae to the superior angle and the spine of the scapula. The action of levator scapulae is to raise the medial angle of the scapula and incline the neck to the corresponding side with rotation of the neck in the same direction. With the trapezius muscle, the levator scapulae makes a shrug possible.

The nerves to the levator scapulae, which vary in number from 1 to 3, branch off the fourth and fifth cervical nerves and travel posteriorly and inferiorly. They cross the anterior border of the levator scapulae and remain on the surface of the muscle for a short distance. The nerves to levator scapulae are under the fascia of this muscle; thus, in the course of any neck dissection, but especially in a radical neck dissection (RND) or a modified radical neck dissection (MRND), it is crucial to keep the plane of dissection superficial to the fascia of the levator in order to preserve these nerves. The dorsal scapular nerve is inconsistent in its anatomic relations in the posterior triangle of the neck and contributes to the innervation of the levator scapulae in a minority of cases (3).

Because one of the functions of the levator is to draw the scapula and the shoulder upward and medially, inadvertent or unnecessary resection of the nerves to it during an RND may add to the resulting deformity and functional disability of the shoulder.

Thoracic Duct

At the base of the neck, the thoracic duct is located medial to and behind the left common carotid artery and the

vagus nerve. From here, it arches upward, forward, and laterally, passing behind the IJV and in front of the anterior scalene muscle and the phrenic nerve. It then opens into the IJV, the subclavian vein, or the angle formed by the junction of these two vessels. The duct is anterior and medial to the thyrocervical trunk and the transverse cervical artery. Precise knowledge of these anatomic relationships is important to avoid injuring the duct during a neck dissection. It is even more important when the surgeon is called on to search for and repair a chyle leak during or after a neck dissection. To prevent a chyle leak, the surgeon also must remember that the thoracic duct may be multiple in its upper end and that at the base of the neck it usually receives a jugular, a subclavian, and usually other minor lymphatic trunks, which must be ligated or clipped individually.

Fascial Compartments of the Neck

The deep cervical fascia of the neck is divided into three layers: superficial, middle, and deep (Fig. 117.3). The superficial or investing layer surrounds the entire neck. It arises from the vertebral spinous processes and the ligamentum nuchae and encircles the entire neck to attach itself again to the spinous processes on the opposite side. This fascia divides to enclose the trapezius muscle. At the anterior border of this muscle, the two layers fuse into a single layer that crosses the posterior triangle of the neck. It divides again to surround the inferior belly of the omohyoid muscle and the sternomastoid muscle. At the lateral border of the strap muscles, it sends fibers between them before fusing in front of them as it extends onto the other side of the neck. This fascia also envelops the submandibular and parotid glands.

The middle layer of the deep cervical fascia, also called the visceral fascia, surrounds the visceral structures of the anterior portion of the neck. The deep layer of the deep cervical fascia or prevertebral fascia surrounds the deep muscles of the neck. Among them, it covers the splenius capitis, the levator scapulae, and the scalene muscles. It extends onto the other side of the neck, covering the prevertebral muscles.

The carotid sheath encircling the jugular vein, common carotid artery, and vagus nerve is formed by all layers of the deep cervical fascia. The carotid sheath originates superiorly at the jugular foramen, where it attaches to the skull base. It then follows the course of the vessels, traversing the anterior cervical triangle and extending inferiorly into the thoracic inlet.

Lymphatics of the Neck

The lymph node regions of the neck are shown in Figure 117.4. The six levels currently used encompass the complete topographic anatomy of the neck. The concept of sublevels has been introduced into the classification since certain zones have been identified within the six levels, which may have clinical significance.

Level I is divided in two sublevels: sublevel IA (submental), which includes the lymph nodes within the triangle bound by the anterior bellies of the digastric muscles and the mylohoid muscle, and sublevel IIB (submandibular), which includes the lymph nodes with the boundaries of the triangle formed by the anterior and posterior bellies of the digastrics and body of the mandible.

Level II (upper jugular) includes the lymph nodes located around the upper third of the IJV and adjacent spinal accessory nerve extending from the level of the

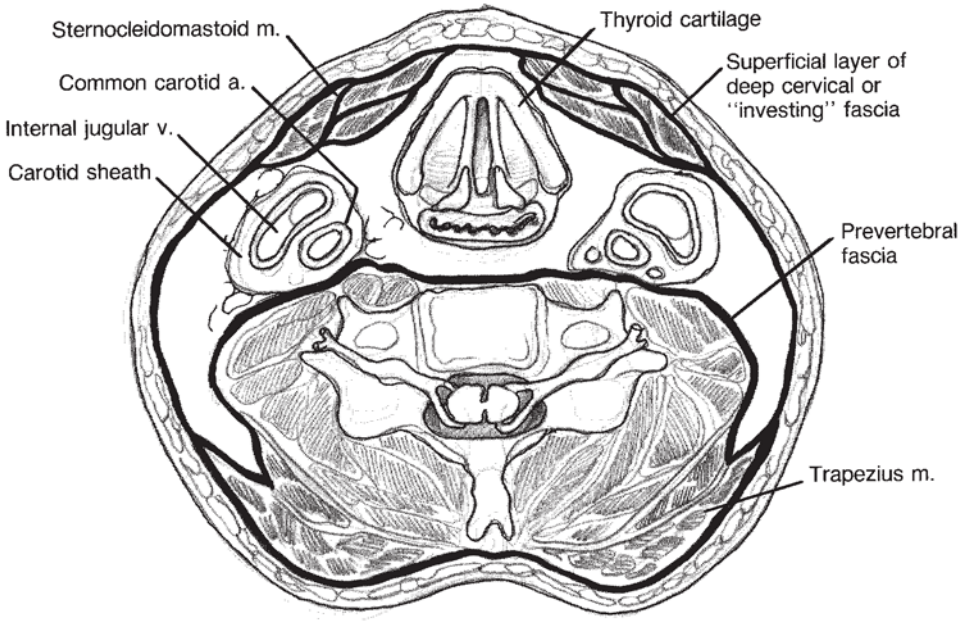

Figure 117.3 Layers of the cervical fascia.

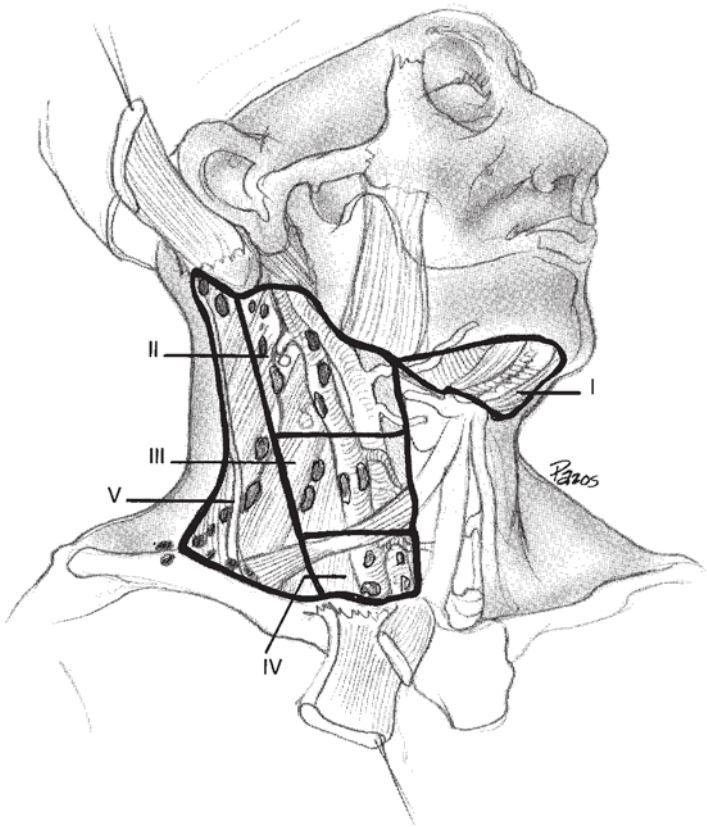

Figure 117.4 Lymph node regions of the neck.

skull base to the level of the inferior border of the hyoid. The anterior/medial boundary is the stylohyoid muscle (the radiologic correlate is the vertical plane defined by the posterior surface of the submandibular gland), and the posterior (lateral) boundary is the posterior border of the SCM. Two sublevels are recognized in level II: sublevel IIA contains nodes in the region anterior to the spinal accessory nerve (SAN) and sublevel IIB contains nodes posterior to the SAN.

Level III (midjugular) includes the lymph nodes located around the middle third of the IJV extending from the inferior border of the hyoid bone to the inferior border of the cricoid cartilage. The anterior/medial boundary is the lateral border of the sternohyoid muscle, and the posterior/lateral boundary is the posterior border of the SCM.

Level IV (lower jugular) encompasses the lymph nodes located around the lower third of the IJV extending from the inferior border of the cricoid cartilage to the clavicle.

The anatomic boundary that separates the medial border of levels III and IV from the lateral border of level VI has traditionally been the lateral border of the sternohyoid muscle, a landmark that cannot be easily discerned on imaging studies. Therefore, the medial aspect of the common carotid artery has been suggested as an alternate boundary to separate these levels in an axial plane in imaging studies (4).

Level V (posterior triangle) comprises predominantly of the lymph nodes located along the lower half of the spinal accessory nerve and the transverse cervical artery. The supraclavicular nodes are also included in posterior triangle group. The superior boundary is the apex formed by convergence of the sternocleidomastoid and trapezius muscles, the inferior boundary is the clavicle, the anterior boundary is the posterior border of the SCM, and the posterior boundary is the anterior border of the trapezius muscle. A horizontal plane marking the inferior border of the anterior cricoid arch separates two sublevels. Sublevel VA, above this plane, includes the spinal accessory nodes. Sublevel VB, below this plane, includes the nodes that follow the transverse cervical vessels and the supraclavicular nodes with the exception of Virchow node, which is located in level IV.

Level VI (anterior compartment): Lymph nodes in this compartment include the pre- and paratracheal nodes, precricoid (delphian) node, and the perithyroidal nodes including the lymph nodes along the recurrent laryngeal nerves. The superior boundary is the hyoid bone, the inferior boundary is the suprasternal notch, and the lateral boundaries are the common carotid arteries.

Other lymph node groups: Lymph nodes involving regions not located within these levels should be referred to by the name of their specific nodal group; examples of these are the superior mediastinum, the retropharyngeal, the periparotid, the buccinator, the postauricular, and the suboccipital lymph nodes.

TABLE 117.1 PERCENTAGE OF METASTATIC LYMPH NODES INVOLVED IN ELECTIVE AND THERAPEUTIC RNDs

Modified from Shah JP. Patterns of cervical lymph node metastasis from squamous carcinomas of the upper aerodigestive tract. *Am J Surg* 1990;160(4):405–409.

Patterns of Lymph Node Metastases

Lindberg first described the clinical pattern of cervical metastases for various primary sites in 1972 (5). Shah (6), in 1990, examined the distribution of nodal metastases in 1,119 RNDs performed both electively and therapeutically for squamous cell carcinoma (SCCA) of the oral cavity, oropharynx, hypopharynx, and larynx. He found a consistent distribution of cervical metastases (Table 117.1). The majority of metastases from cancer of the oral cavity were found in lymph nodes in levels I, II, and III. On the other hand, most metastases from carcinomas of the oropharynx, hypopharynx, and larynx were found in levels II, III, and IV. The lymph nodes in level V were not involved in the absence of metastases at other levels.

The significance of other lymphatic groups, such as the retropharyngeal lymph nodes (RPLNs) and paratracheal nodes, has also been characterized (7). Metastases to the RPLNs can occur with SCCA of the hypopharynx, tonsil, soft palate, posterior and lateral oropharynx, nasopharynx, and supraglottis.

Metastases from cancers of the larynx can occur to the paratracheal lymph nodes (PTLNs). In a study of 91 selected patients with carcinoma of the larynx who underwent PTLN dissection, Weber et al. (8) found that metastases to these lymph nodes occurred primarily in patients with subglottic and transglottic tumors, but they also occurred in patients with glottic tumors. In a prospective study of 45 patients with advanced glottic cancers, who underwent bilateral paratracheal node dissection as part of their treatment, Shenoy et al. (9) found metastases in the ipsilateral paratracheal nodes in 4% of the cases and contralateral metastases in 2%. Failure to address the paratracheal nodes for laryngeal cancer is a known cause of stomal recurrence.

PHYSIOLOGY

The trapezius is a fan-shaped muscle composed of upper, middle, and lower segments, each of which functions in a different but complementary manner. The trapezius and the other muscles that insert on the scapula stabilize and control the shoulder girdle during arm movement. The levator scapulae acts synergistically with the upper division of the trapezius to elevate the scapula; the rhomboid assists the middle part of the trapezius in retracting and stabilizing the scapula against the posterior thoracic cage. The simultaneous action of the upper and lower divisions of the trapezius muscle results in a unique rotatory action of the scapula. The upward rotation of the scapula, in combination with abduction of the arm at the glenohumeral joint, permits elevation of the arm beyond 90 degrees at the shoulder level.

As is discussed in detail later in this chapter, paralysis of the trapezius muscle causes a syndrome characterized by weakness and deformity of the shoulder girdle, usually accompanied by pain.

DIAGNOSTIC EVALUATION

Clinical Examination

Clinical examination of the neck by palpation is not uniformly reliable in the detection of cervical lymph node metastases, particularly of lymph nodes minimally involved by the tumor. The reported error rate in assessing the presence or absence of cervical lymph node metastases by palpation ranges from 20% to 50%. The factors responsible for this variation are not only the ability and experience of the examiner but also the patient's habitus and previous treatment to the neck with surgery or radiation therapy. With the advent of modern imaging techniques, it was hoped that the clinician would not have to rely solely on clinical examination to make decisions in the treatment of the neck.

Imaging Studies

Using the histologic demonstration of metastasis in a lymph node as the gold standard, several studies have shown that ultrasonography (US), computed tomography (CT), and magnetic resonance imaging (MRI) have a

higher sensitivity and specificity than clinical examination in the detection of metastases in lymph nodes. In a prospective study of 48 patients who were to undergo neck dissection, Haberal et al. (10) found that the sensitivity and specificity of palpation for the detection of metastases in the lymph nodes were 64% and 85%, respectively, while the corresponding values were 72% and 96% for US and 81% and 96% for CT. Adams et al. (11) reported similar results for US and CT; in addition, they reported a sensitivity of 80% and a specificity of 79% for MRI. What these observations indicate is that a "negative" US, CT, or MRI of the neck cannot be relied to withhold elective treatment of the cervical lymph nodes, since they cannot detect metastases in 19% to 28% of the patients staged clinically N0. Obviously the imaging criteria used to diagnose metastasis in a lymph node are not absolutely reliable. The imaging criterion used most often to consider a cervical node suspicious for metastasis is size larger than 1.5 cm in maximum diameter for nodes located in levels I and II and larger than 1 cm for nodes in other regions of the neck (12). Although a correlation exists between the size of a lymph node and the presence of histologic metastasis (Table 117.2), it is clear that not all enlarged lymph nodes contain metastatic deposits and that nodes smaller than 1 or 1.5 cm can indeed contain metastases. Thirty-three percent of all metastases from SCCAs of the head and neck are found in lymph nodes smaller than 1 cm, 10% of tumor-positive neck dissection specimens contain only metastases less than 3 mm in diameter, and, more importantly, 25% of all clinically occult lymph node metastases are too small to be detected by any of the currently available imaging techniques (13). DiNardo (14) demonstrated that 88% of metastases from the carcinomas of the floor of the mouth were found in nodes that were 1 cm or less in diameter.

The presence of a central area of lucency within a node shown on CT was at one time considered equivalent to the presence of necrotic tumor within a node; however, such a finding can be caused by an artery with plaque formation or a fatty inclusion in a lymph node. Another imaging criterion used to "diagnose" metastasis in a lymph node is the shape of the node, as determined by the ratio of its long (l) and short (s) axis diameters. In a study by Steinkamp et al. (15), 730 enlarged cervical lymph nodes in 285 patients were examined using ultrasound, and the l/s ratio was calculated. Histologic examination after neck dissection revealed that 95% of the enlarged cervical nodes, shown on ultrasound to have a l/s ratio of more than 2, were correctly diagnosed as benign. Nodes presenting with a more circular shape and a l/s ratio of less than 2 were diagnosed correctly as metastases with 95% accuracy.

Ultrasound Guided Fine-Needle Aspiration Biopsy

In an attempt to overcome the lack of sensitivity of morphologic imaging criteria, US was combined with fine needle aspiration biopsy (US-FNAB). This technique appeared more promising for the preoperative evaluation of the N0 neck as it enables sampling of lymph nodes as small as 3 mm in diameter and adds the advantages of cytologic evaluation (16). However, the usefulness of this technique is strongly dependent on the skill and time of the ultrasonographer and on the experience of the cytopathologist. Furthermore, the outcomes of a wait-and-see policy after negative US-FNAB have been disappointing. In a study of 92 patients with tumors of the oral cavity, staged T1 and T2, who were observed after a negative US-fine-needle aspiration (US-FNA), metastases in neck nodes became apparent subsequently in 19 (21%) (17). In a more recent study, Wensing et al. (18) found that palpation and US with or without US-FNAB missed occult lymph node metastases in 22% of the patients with oral cavity SCCA. These figures are troubling because the incidence of lymph node metastases in patients with such tumors, who are observed without any intervention to the neck, is about 25%.

TABLE 117.2 NODAL SIZE AND PRESENCE OF HISTOLOGIC METASTASES

	Histologic Status (%)		
Node Size (cm)	Negative	Positive	Positive with Extranodal Extension
1	67	33	14
2	38	62	26
3	19	81	49
4	12	88	71

From Hamakawa H, Fukizumi M, Bao Y, et al. Genetic diagnosis of micrometastasis based on SCCA antigen mRNA in cervical lymph nodes of head and neck cancer. *Clin Exp Metastasis* 1999;17(7):593–599, with permission.

Positron Emission Tomography

Prospective studies using 18-fluorodeoxyglucose (FDG) positron emission tomography (PET) to assess lymph node metastases from SCCAs of the oral cavity have shown a sensitivity and specificity higher than MRI, CT, and US. However, current FDG-PET techniques are also limited in the detection of tumor foci smaller than 1 cm (19,20). Kyzas et al. (21) performed a meta-analysis of 32 studies that assessed the diagnostic performance of PET scans in patients with SCCA of the head and neck. In patients staged clinically N0, the sensitivity of 18 PET scan was only 50% (95% CI: 37% to 63%), whereas specificity was 87% (95% CI: 76% to 93%). These authors also compared the performance of PET scan with that of "conventional diagnostic methods," that is, CT, MRI, and ultrasound with fine-needle aspiration (FNA) by analyzing studies that had also used these diagnostic methods on the same patients. The sensitivity and specificity of PET scans were 80% and 86%, respectively, and of "conventional diagnostic tests" were 75% and 79%. Thus, at the present time, the role for PET scan in the evaluation of the N0 neck is limited as it will not detect metastases in 20% to 50% of the cases.

In another effort to overcome the limitations of current imaging techniques, particularly their inability to differentiate a tumor-infiltrated lymph node from a normal or a reactive one, de Bree et al. (22) have experimented with radioimmunoscintigraphy (RIS). With this technique, SCCA specific monoclonal antibodies labeled with ^{99}mTc were given intravenously to patients with SCCA who underwent neck dissection. Unfortunately, RIS was not superior to CT and MRI for the detection of lymph node metastases.

CT and MRI are valuable in the evaluation of lymph nodes that are not easily accessible to the hands of the examiner, such as the retropharyngeal, upper mediastinal, and, in some patients, the PTLNs. They are also valuable in the assessment of resectability of large metastatic deposits in the neck, because in most instances they can define the relationship of a metastatic tumor with critical structures, such as the common and the internal carotid artery, the cervical spine, the vertebral artery, and the brachial plexus. If tumor involvement of the common or the internal carotid artery is suspected, a systematic preoperative evaluation should include four-vessel cerebral angiography to determine the status of the contralateral carotid and to assess collateral intracerebral circulation. In addition, an attempt should be made during the angiography to measure carotid back pressure and to assess dynamically the collateral circulation by using balloon occlusion techniques while monitoring the patient for evidence of neurologic deficits under normotensive and hypotensive conditions.

Fine-Needle Aspiration

FNA has become a valuable diagnostic tool in patients with a mass in the neck in whom metastatic carcinoma is suspected. According to numerous recent reports, the specificity of FNA ranges from 94% to 100% and the sensitivity ranges from 92% to 98%. The interobserver variability between cytopathologists in one series has been reported as 8%. FNA has been found to be most accurate in the diagnosis of epithelial malignancies, achieving nearly 100% accuracy.

FNA is indicated in the patient with a solid mass in the neck after a thorough examination of the mucosal surfaces and skin of the head and neck region fails to reveal a primary tumor. If the mass is located in the supraclavicular area, FNA is essential in the initial evaluation of the patient. The cytopathology findings then can guide the clinician's search for a primary tumor below the clavicles.

Sentinel Node Biopsy

Sentinel lymph node biopsy (SLNB) is feasible and useful as a staging procedure in patients with early carcinomas of the oral cavity and in particular for patients with cancers of the oral tongue. Proponents of this technique point out that it allows accurate histopathologic staging of the neck by examining the sentinel lymph node (SLN) with serial sectioning and immunohistochemistry, and it avoids unnecessary neck dissection and its possible complications.

The SLNB is based on the belief that cancers metastasize via lymphatics to regional lymph nodes in an orderly fashion, that this process is embolic in nature, and that the lymph node that first receives lymphatic drainage from the primary site can be identified and excised for histologic analysis (23).

Early studies in patients with SCCAs of the mucosal surfaces of the head and neck investigated the methodology and feasibility of SLNB (23–26). In general, the primary cancer should be accessible to infiltration with a radioisotope-labeled colloid to perform a lymphoscintigraphy and a blue dye to aid in intraoperative localization of the sentinel node. These localizing methods have been shown to be complementary. Ross et al. (26) in a multicenter study investigated SLNB in 134 patients with SCCA of the oral cavity and oropharynx, staged T1/T2 N0. Lymphoscintigraphy was performed preoperatively; blue dye and a gamma probe were used intraoperatively to aid in the identification of sentinel nodes. Sentinel nodes were identified in 93% of the cases. The number of sentinel nodes varies, but in a series of 48 patients studied by Ross et al. (24), the mean number of sentinel nodes harvested was 2.4.

Subsequent studies have examined the utility of SLNB in patients with oral cavity or oropharyngeal cancers staged T1/T2 N0. The sensitivity of the procedure is 90% when the histopathology of the sentinel node is compared with that of the neck dissection specimen (27). It results in histopathologic upstaging of the clinically N0 neck in 36% of the patients when the nodes are examined with routine hematoxylin–eosin staining; serial sectioning and immunohistochemistry upstage an additional 8% of the cases (24). The detection of micrometastases can be further enhanced by using highly specific tumor markers and molecular methods (28,29).

Recently, Civantos et al. (30) reported the results of a North American Multi-Institutional Prospective Study that evaluated the utility of SLNB in T1/T2 oral SCCAs. The study included 140 patients (68% oral tongue, 19% the floor of the mouth) from 25 institutions who underwent SLNB and selective neck dissection (SND) (levels I–IV). The negative predictive value (NPV) was 94% when the SLNs were examined with hematoxylin–eosin stains and 96% when they were examined with serial sectioning and immunocytochemistry (30). The NPV among experienced surgeons was 100% versus 95% for less experienced ones. The SLN was the only positive node in 51% of the cases with a positive SLN. The false-negative rate was 9.8% overall. Interestingly, however, the false-negative rate was 10% in patients with cancers of the oral tongue but was 25% in patients with cancers of the floor of the mouth. In the experience of the University of Miami (31), the NPV of SLNB was 88.5% in patients with cancers of the floor of mouth (FOM) and 95.8% when these patients were excluded. Similarly, Ross et al. (26) have reported that the identification of SLNB in patients with FOM cancers was lower (86%) than in patients with tumors in other locations (97%); the sensitivity of SLNB in FOM cancers was also lower (80%), compared with other tumor locations (100%). It appears that lymphoscintigraphy in cancers of the FOM is not as helpful in identifying the SLN due to the shine-through effect of the radioactivity at the primary site; it obscures the lymph nodes in level I, which are one of the primary echelons of lymphatic drainage for the FOM and lower gum. Obviously, this limits the utility of SLNB in patients with tumors in these locations.

STAGING

At completion of the clinical evaluation of a patient with SCCA of the head and neck region, the disease should be classified according to stage. The staging for the lymph nodes proposed by the American Joint Committee on Cancer in 2009 (32) is outlined below:

NX: Regional lymph nodes cannot be assessed.
N0: No regional lymph node metastasis.
N1: Metastasis in a single ipsilateral lymph node, 3 cm or less in greatest dimension.
N2: Metastasis in a single ipsilateral lymph node, more than 3 cm but not more than 6 cm in greatest dimension; or in multiple ipsilateral lymph nodes, none more than 6 cm in greatest dimension; or in bilateral or contralateral lymph nodes, none more than 6 cm in greatest dimension.
N2a: Metastasis in a single ipsilateral lymph node more than 3 cm but not more than 6 cm in greatest dimension.
N2b: Metastasis in multiple ipsilateral lymph nodes, none more than 6 cm in greatest dimension.
N2c: Metastasis in bilateral or contralateral nodes no more than 6 cm in greatest dimension.
N3: Metastasis in a lymph node more than 6 cm in greatest dimension.

Staging of the neck in nasopharyngeal carcinoma patients is different because the distribution and the prognostic impact of regional lymph node spread from nasopharynx cancer, particularly of the undifferentiated type, are different from those of other head and neck mucosal cancers and justify the use of the following scheme:

NX: Regional lymph nodes cannot be assessed.
N0: No regional lymph node metastasis.
N1: Unilateral metastasis in lymph node(s), 6 cm or less in greatest dimension, above the supraclavicular fossa.
N2: Bilateral metastasis in lymph node(s), 6 cm or less in greatest dimension, above the supraclavicular fossa.
N3: Metastasis in a lymph node(s) greater than 6 cm and/or to supraclavicular fossa.
N3a: Greater than 6 cm in dimension.
N3b: Extension to the supraclavicular fossa.

CLASSIFICATION OF NECK DISSECTIONS

Several cervical lymph node dissections are currently used for the surgical treatment of the neck in patients with cancer of the head and neck region. To standardize the nomenclature used to refer to these operations, it is essential to adopt a common nomenclature for the lymph node groups of the neck, such as the one outlined earlier in this chapter. The current classification of neck dissections recommended by the American Academy of Otolaryngology-Head and Neck Surgery (Table 117.3) takes into account the lymph node groups of the neck that are removed and secondarily the anatomic structures that may be preserved, such as the spinal accessory nerve and the IJV. Analyzing neck dissections from these two points of view, there are essentially four anatomic types of neck dissections: radical, modified radical, selective, and extended. Recently, clinicians from around the world have proposed a nomenclature for neck dissection that, if recognized internationally, would be "logical, unambiguous, precise, and easy to remember" (33).

In this classification, the following three descriptors are used to label a neck dissection:

1. "ND" to represent neck dissection that is prefaced by either "L" or "R" for side. If bilateral, both sides must be classified independently.
2. The levels and sublevels of lymph nodes removed designated by Roman numerals I through VII in ascending order. For levels that contain sublevels (I, II, and V), listing of the level without a sublevel indicates that the entire level (both A and B) was excised.
3. The nonlymphatic structures removed designated by their internationally recognized initials, that is, SCM for sternocleidomastoid muscle, IJV for internal jugular vein.

It is hoped that this new classification system will convey precisely the extent of lymphatic and nonlymphatic structures removed in a neck dissection that will then allow better comparison of results between studies.

TABLE 117.3 CLASSIFICATION OF NECK DISSECTIONS

2001 Classification	2010 Proposed Classification
1. Radical neck dissection	1. ND (I–V, SCM, IJV, CNXI)
2. Modified radical neck dissection	2. ND (I–V, SCM, IJV), ND (I–V, IJV, CNXI), ND (I–V)
3. Selective neck dissection (SND):	3.
SND (I–III/IV)	ND (I, II, II/IV)
SND (II–IV)	ND (II–IV)
SND (II–V, postauricular, suboccipital)	ND (II–V, postauricular, suboccipital)
SND (level VI)	ND (VI)
4. Extended neck dissection	4. ND (levels removed, nodes or structures removed)

Lastly, the surgeon must orient the surgical specimen for the pathologist and identify the different lymph node groups it contains. Only then can the pathologist be expected to generate a clinically and prognostically meaningful report that describes the location and number of lymph nodes examined, the number of nodes that contain the tumor, and the presence or absence of extranodal extension of the tumor.

ND (I–V, SCM, IJV, CN XI)

Radical Neck Dissection

This operation is defined as the en bloc removal of the lymph node–bearing tissues of one side of the neck, from the inferior border of the mandible to the clavicle and from the lateral border of the strap muscles to the anterior border of the trapezius. Included in the resected specimen are the spinal accessory nerve, the IJV, and the SCM (Fig. 117.5). A comprehensive description of the surgical technique of this operation was recently provided by McCammon and Shah (34).

Rationale

The first description of the systematic en bloc removal of the lymphatics of the neck was published by Crile in 1906. The operation he described came to be known as the RND. Although Crile believed that removing the IJV was essential because of the intimate relation of this structure with the lymph nodes of the neck, it is interesting to note that the drawings that illustrate his publication indicate that the spinal accessory nerve and the ansa hypoglossi were preserved. It was Martin et al. in the 1950s who championed the concept that a cervical lymphadenectomy for cancer was inadequate unless all the lymph node–bearing tissues of one side of the neck were removed and that this was impossible unless the spinal accessory nerve, the IJV, and the SCM were included in the resection. In fact, they categorically stated, "any technique that is designed to preserve the spinal accessory nerve should be condemned unequivocally."

In describing the RND, Crile contended that an en bloc removal of the primary tumor and the lymphatic system of the neck should be carried out in a manner similar to the Halstead operation for breast cancer. He believed that normal lymph flow is interrupted by metastasis in a lymph node, causing further tumor dissemination to occur in any direction, and that a less radical "incomplete" operation would disseminate and stimulate the growth of the tumor. Like Crile, Martin et al. believed that it was impossible to remove the lymphatics of the neck completely without resecting the SCM and IJV because of the close association of the lymphatics in this area with the vein walls.

Removing the SCM unquestionably facilitates access to the jugular vein and the removal of the lymph node–bearing tissues of the neck. In some instances, the muscle must be removed because it is involved by the tumor. However, removal of this muscle is no longer justified for ease or exposure alone.

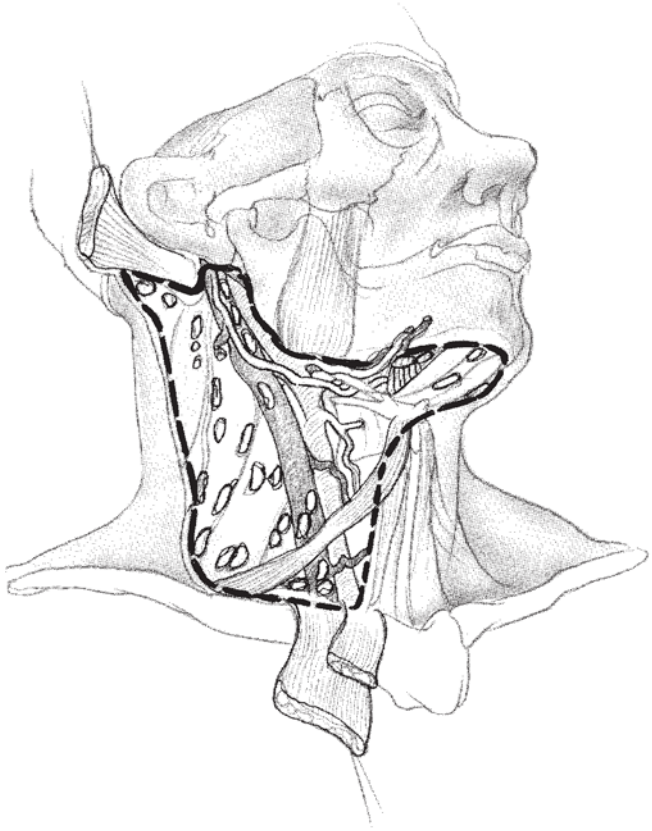

Figure 117.5 Radical neck dissection.

An RND is not indicated in the absence of palpable cervical metastases (i.e., in the treatment of the N0 neck). Currently, RNDs represent less than 20% of all neck dissection done at many institutions (35), as familiarity with the other types of neck dissection has increased.

Indications

An RND is indicated when there are multiple clinically obvious cervical lymph node metastases, particularly when they involve the lymph nodes of the posterior triangle of the neck and are found to involve or to be tightly related to the spinal accessory nerve. An RND is also indicated when there is a large metastatic tumor mass or when multiple matted nodes are present in the upper part of the neck. In such instances, it is unwise to preserve the sternocleidomastoid or the internal jugular or to dissect the spinal accessory nerve and risk entering the tumor. A similar situation can be created by the inflammation, hematoma, or ecchymosis that follows ill-advised excisional biopsies of neck metastases. An RND may be the safest option in such patients.

ND (I–V, SCM, IJV, CN XI)

Modified Radical Neck Dissection (MRND)

This category includes modifications of the RNDs developed with the intention of reducing the morbidity of the operation by preserving one or more of these structures: the spinal accessory nerve, the IJV, or the SCM.

The three neck dissections that can be included in this category are outlined in Table 117.3. They differ from each other only in the number of neural, vascular, and muscular structures that are preserved. Therefore, they can be subclassified as follows:

- ND (I–V, SCM, IJV) (MRND type I) with preservation of the spinal accessory nerve
- ND (I–V, SCM) (MRND type II) with preservation of the spinal accessory nerve and the IJV
- ND (I–V) (MRND type III) with preservation of the spinal accessory nerve, the IJV, and the SCM. This corresponds to the operation often called "functional neck dissection."

ND (I–V, SCM, IJV)

Modified Radical Neck Dissection with Preservation of the Spinal Accessory Nerve

This operation is defined as the en bloc removal of the lymph node–bearing tissues of one side of the neck, from the inferior border of the mandible to the clavicle and from the lateral border of the strap muscles to the anterior border of the trapezius, preserving the spinal accessory nerve. The IJV and the SCM are included in the resected specimen (Fig. 117.6). The surgical technique is essentially the same as that of the RND.

Rationale

The following observations have compelled surgeons, for several decades, to explore and develop alternatives to the RND:

- The morbidity associated with the RND, especially the shoulder disability that results from the resection of the spinal accessory nerve and, to a lesser extent, the cosmetic deformity that results from this operation, particularly when it is done on both sides of the neck

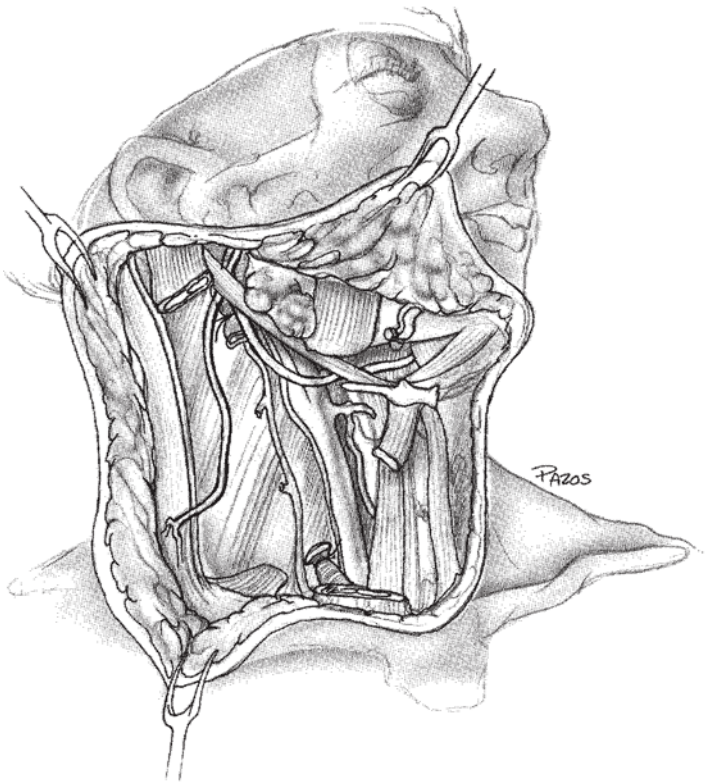

Figure 117.6 MRND (type I) with preservation of the spinal accessory nerve.

- The realization that in many instances the spinal accessory nerve is not in close proximity to the nodes grossly involved by the tumor and that its preservation does not compromise the oncologic soundness of the operation

Indications

This type of neck dissection is used in the surgical treatment of the neck of patients with clinically obvious lymph node metastases when the spinal accessory nerve is not directly involved by the tumor, regardless of the number, size, and location of the involved lymph nodes. The decision to preserve the spinal accessory nerve is, therefore, a delicate intraoperative judgment call. Much like the philosophy about preservation of the facial nerve during surgery for parotid tumors, the spinal accessory nerve can be preserved whenever there is a clearly identifiable, not an artificially created, plane of dissection between the tumor and the nerve. The reported rate of recurrence in the neck when used for the treatment of the N+ neck in combination with postoperative radiation is 8.1% (36).

ND (I–V, SCM)

Modified Radical Neck Dissection with Preservation of the Spinal Accessory Nerve and the Internal Jugular Vein

In this type of dissection, the lymph node–bearing tissues of one side of the neck are removed en bloc, preserving the spinal accessory nerve and the IJV. This operation is seldom planned. It is done occasionally when in the course of a neck dissection the metastatic tumor in the neck is noted to be adherent to the SCM but away from the accessory nerve and the jugular vein. This situation occurs occasionally in patients with hypopharyngeal or laryngeal tumors with metastases under the middle third of the SCM.

ND (I–V, SCM, IJV, CN XI)

Modified Radical Neck Dissection with Preservation of the Spinal Accessory Nerve, the Internal Jugular Vein, and the Sternocleidomastoid Muscle

This operation consists of the en bloc removal of the lymph node–bearing tissues of one side of the neck, including lymph nodes in levels I through V, preserving the spinal accessory nerve, the IJV, and the SCM. The submandibular gland may or may not be removed (Fig. 117.7). A description of the operative technique of this operation, as it is currently advocated by most European surgeons, can be found in a publication by Gavilan et al. (37).

Rationale

The muscular and vascular aponeurosis of the neck demarcate compartments filled with fibroadipose tissue that contains lymph nodes. In the early 1960s, Suárez observed that the lymph nodes of the neck are not located within the muscular aponeurosis of the SCM and do not form part of the adventitia of nearby blood vessels, particularly veins. He then showed that it was technically feasible and

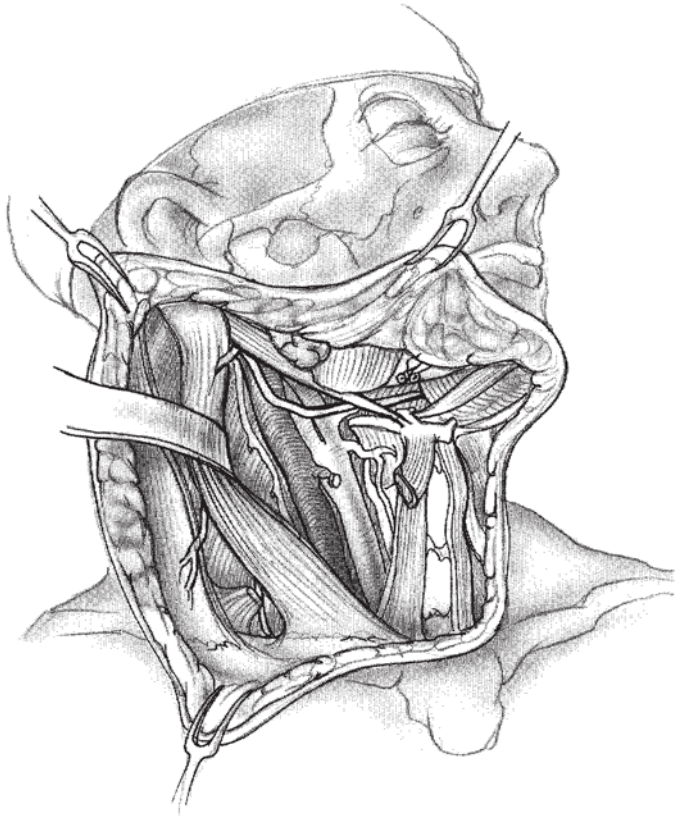

Figure 117.7 MRND (type III) with preservation of the spinal accessory nerve, the internal jugular vein, and the SCM.

oncologically sound to perform a comprehensive removal of the lymph node–bearing tissues of one or both sides of the neck without removing the SCM, the submandibular gland, and the IJV (38). It should be pointed out that the nerves of the neck do not follow the aponeurotic compartment distribution, except for the vagus nerve that is contained within the carotid sheath. The phrenic nerve and the brachial plexus are partially within a compartment; the hypoglossal and the spinal accessory nerves run across several compartments. Unless these nerves are directly involved by the tumor, they can be dissected free and preserved.

Indications

This operation was widely used, particularly in Europe, as the neck dissection of choice for the treatment of the N0 neck in patients with SCCA of the upper aerodigestive tract, especially when the primary tumor was in the larynx or hypopharynx. It is now considered an unnecessarily extensive procedure for the treatment of the clinically negative neck in patients with head and neck cancers. A multi-institutional prospective randomized study comparing MRND to ND (levels II–IV)) in patients with laryngeal cancer was performed by the Brazilian Head and Neck Cancer Study Group (39). All patients had previously untreated T2–T4 N0M0 supraglottic and transglottic squamous carcinoma. Pathologically positive nodes were found in 26% of the patients, and most positive nodes were located at levels II and III. There were six ipsilateral neck recurrences (four in the MRND group and two in the lateral neck dissection ND II–IV group). Five-year actuarial survival calculated by the Kaplan-Meier method was 72.3% in the MRND group and 62.4% in the ND (II–III) (log-rank test $P = 0.312$). Another prospective study and a recent retrospective study also support the practice of not dissecting level V in patients with clinically N0 laryngeal and hypopharyngeal cancers (40,41).

According to some surgeons, this operation is indicated for the treatment of the N1 neck, when the metastatic nodes are mobile and no greater than 2.5 to 3 cm. The reported rates of recurrence in the neck with this type of neck dissection range between 0% and 16.6% for the clinically N0 neck and between 3.7% and 25% for the N+ neck (42–47).

This type of MRND remains the operation of choice for most patients with differentiated carcinoma of the thyroid who have palpable lymph node metastases in the lateral compartment of the neck.

Selective Neck Dissections

The SNDs consist of the removal of only the lymph node groups at highest risk of containing metastases according to the location of the primary tumor, preserving the spinal accessory nerve, the IJV, and the SCM. There are four main types of SNDs:

- SND of levels I–III or ND (I–III) (commonly referred to as "supraomohyoid" neck dissection) (Fig. 117.8) and SND of levels I–IV or ND (I–IV) (also referred to as "extended supraomohyoid" neck dissection). These are the neck dissections commonly used in the treatment of patients with SCCA of the oral cavity. The lymph nodes removed are those contained in the submental and submandibular triangles (level I), the upper jugular region (level II), and the midjugular region (level III). The posterior limit of the dissection is marked by the cutaneous branches of the cervical plexus and the posterior border of the SCM. The inferior limit is the omohyoid muscle as it crosses the IJV. Some surgeons prefer to perform an SND of level I–IV in cases with cancer of the oral tongue (48). For cancers of the oral cavity that are close to or involve the midline, either type of SND is done bilaterally, since the lymph nodes in both sides of the neck are at risk. These operations have been described in detail by Medina and Byers (49).
- SND of levels II–IV or ND (II–IV) (Fig. 117.9). This neck dissection, commonly referred to as the "lateral" neck dissection, is used in the treatment of patients with SCCA of the larynx, oropharynx, and hypopharynx. It consists of the removal of the upper (level II), middle (level III), and lower (level IV) jugular lymph nodes. The superior limit of the dissection is the digastric muscle and the mastoid tip. The inferior limit is the clavicle. The anteriomedial limit is the lateral border of the sternohyoid muscle. The posterior limit of the dissection is marked by the cutaneous branches of the cervical plexus and the posterior border of the SCM. For tumors of the supraglottic

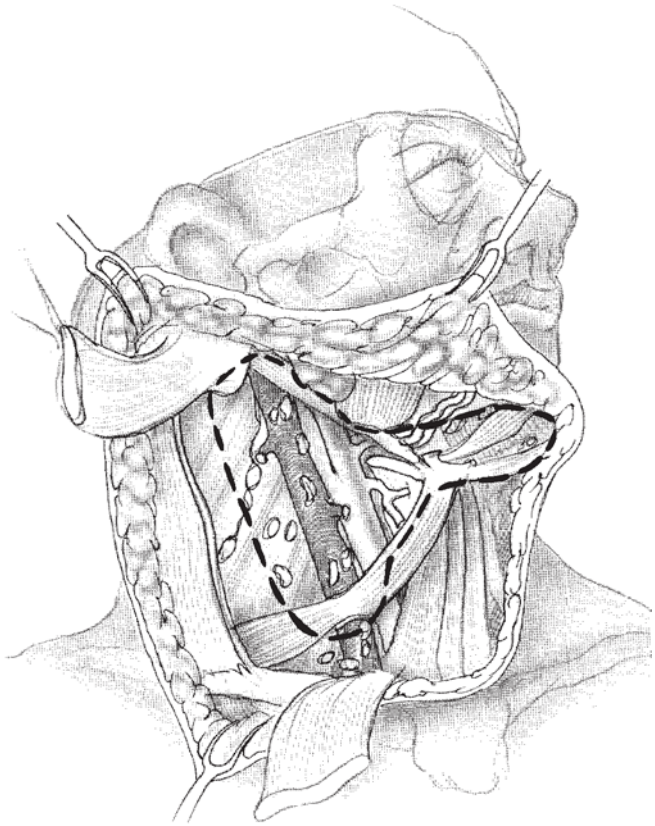

Figure 117.8 Supraomohyoid neck dissection.

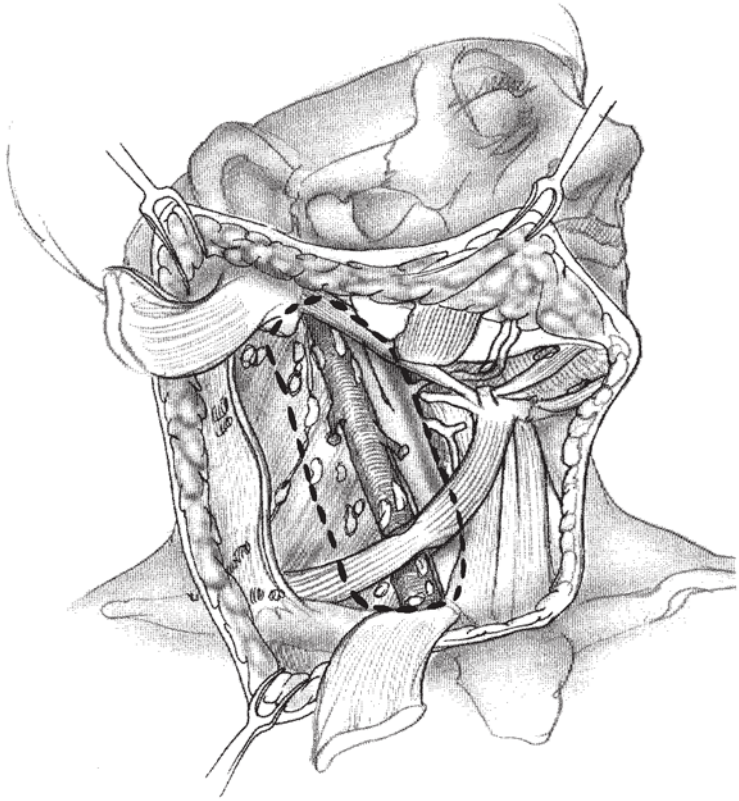

Figure 117.9 Lateral neck dissection.

larynx and posterior pharyngeal walls, the dissection is often bilateral. A recent description of the technique of this operation has been provided by Khafif (50).

- SND of level VI or ND (VI). This operation is also called "anterior" neck dissection or "central compartment" dissection. It is used in the treatment of patients with cancer of the midline structures of the anterior inferior aspect of the neck and thoracic inlet, such as the thyroid, the glottic and subglottic regions of the larynx, the pyriform sinus, and the cervical esophagus and trachea. It consists of the removal of the prelaryngeal, pretracheal lymph nodes, as well as the PTLNs on both sides. However, using a single denomination (i.e., SND of level VI) to refer to any dissection of the lymph nodes in this region is confusing. For instance, if the surgeon elects to remove the prelaryngeal, pretracheal, and the right PTLNs, the operation would have the same designation as one in which only the left paratracheal nodes are removed. Therefore, until consensus is reached about grouping of the lymph nodes in this area (i.e., level VIA and VIB), it is best to describe the operation in terms of the specific lymph nodes removed (e.g., left thyroid lobectomy with dissection of level VI that included the pretracheal and left paratracheal nodes) (51). These operations have been described recently by Weber and Holsinger (52).
- SND for cutaneous malignancies of the head and neck. The extent of the regional node dissection in patients with cutaneous malignancies depends on the location of the primary lesion and the lymph node groups that are likely to harbor metastases. For skin cancers originating from the posterior scalp and the upper-lateral aspect of the neck, the operation most commonly done is an ND (levels II–V, retroauricular, suboccipital), which is also known as the "posterolateral" neck dissection (Fig. 117.10). The superior limit of this dissection is the posterior belly of the digastric muscle and the mastoid tip anterior laterally and the nuchal line/ridge posteriorly. The inferior limit is the clavicle. The anteriomedial limit is the lateral border of the sternohyoid muscle. The posteriolateral limit of the dissection is marked by the anterior border of the trapezius muscle inferiorly and the posterior midline of the neck superiorly (53). The regional node dissection often performed for cutaneous malignancies originating from the periauricular skin, anterior scalp, and temporal region is an SND (parotid, facial and external jugular nodes, levels II, III, VA).

Rationale

In the 1960s, surgeons at The University of Texas MD Anderson Cancer Center modified the concept of the RND by selectively removing only those lymph node groups that, based on the location of the primary tumor, were at highest risk of containing metastases" (54). These operations were eventually called "SNDs" (55) and their current use is based on the following observations:

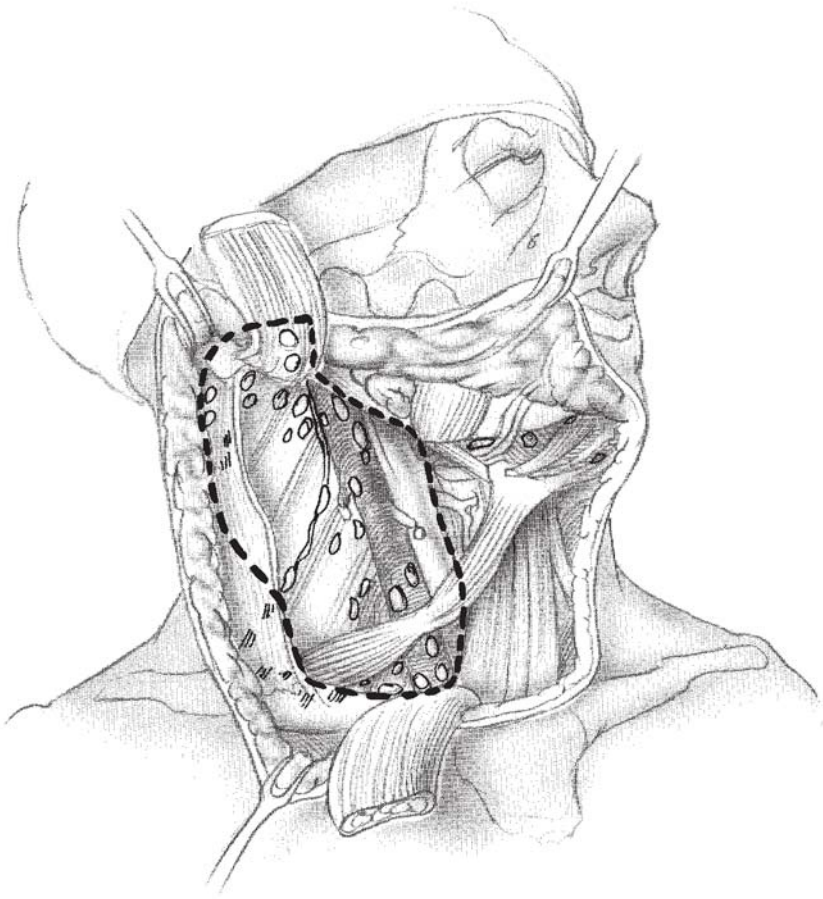

Figure 117.10 Posterolateral neck dissection.

1. Anatomic, pathologic, and clinical investigations (5,6,48,56–64) and recent prospective studies (39,40) have demonstrated that cervical lymph node metastases occur in predictable patterns in patients with SCCA of the head and neck.

The lymph node groups most frequently involved in patients with carcinomas of the oral cavity are the nodes in levels II and III. In addition, the nodes in level I are frequently involved in patients with carcinoma of the floor of the mouth, anterior oral tongue, and buccal mucosa. These tumors frequently metastasize to both sides of the neck, and they can skip levels I and II, metastasizing first to the nodes in level III. In a retrospective study of 1,119 RNDs, Shah (6) found that tumors of the oral cavity metastasized most frequently to the neck nodes in levels I, II, and III, whereas carcinomas of the oropharynx, hypopharynx, and larynx involved mainly the nodes in levels II, III, and IV.

It has been demonstrated that in the absence of metastases to the first-echelon nodes, tumors of the oral cavity and oropharynx rarely involve the nodes in level IV and level V. The nodes in level V are not commonly involved, regardless of the site of the primary tumor and the presence or absence of metastases in the jugular nodes (41), conceivably because there is no retrograde flow from the jugular nodes into the spinal accessory nodes.

The predictability of lymphatic spread applies to both occult (N0 neck) and clinically evident (N+ neck) lymph node metastases. In an analysis of the distribution of lymph node metastasis in a cohort of 164 patients with oral cancer, who had a single clinically positive node (N1 or N2a), Kowalski and Carvalho (60) found that there were no isolated lymph node metastases in levels IV or V. These findings suggest that an SND of levels I–III could encompass the tumor in the neck in these patients. In other reports, the prevalence of metastases in level IV in clinically N+ cases is 17%, suggesting that it is a safer practice to include level IV whenever an SND is done for an N+ neck in patients with cancer of the oral cavity. The prevalence of nodal metastases in level V, on the other hand, is so low (0.5% in cN0 and 3% in cN+) that dissection of this region of the neck is rarely necessary (6). Similarly, in a prospective analysis of the prevalence and distribution of histologic lymph node metastases in 100 consecutive neck dissections done as part of the initial treatment of laryngeal and hypopharyngeal cancer, Buckley and MacLennan (40) found that all metastases in N0 and N1 cases were confined to levels II, III, IV, and VI. Metastases to levels I

and V were infrequent, even in N+ disease, and occurred only in cases with N2c and N3 disease. These results support the use of dissection of nodes in levels II–IV for N0 and selected N+ cases with laryngeal and hypopharyngeal cancer.

2. SNDs provide the surgeon with the same staging information as the more extensive radical and MRNDs. There is substantial evidence that, at this time, micrometastases cannot be detected consistently by noninvasive methods (6). To detect such metastatic deposits, it is necessary to remove the regional lymph nodes, guided either by lymphoscintigraphy or by the anticipated pattern of metastases, and scrutinize them histopathologically. Thus, an SND serves as a staging procedure and can be used for decision making regarding the need for adjuvant postoperative radiation therapy. The concept of disease staging in the neck is important in patients whose primary tumors are amenable to treatment with surgery alone but who are highly likely to produce metastases to the cervical lymph nodes. Patients who have T2N0 and T3N0 SCCAs of the oral cavity and faucial arch region are excellent examples of this situation. Because the probability of lymph node metastasis is high in most of these patients, the neck dissection may only have the value of a staging procedure, the results of which determine whether or not postoperative radiation therapy is necessary. If the lymph nodes are histologically negative, no further therapy is indicated and the patient is treated with surgery alone. However, to make this decision with confidence, all the lymph nodes at risk of containing metastases must be evaluated. This evaluation requires dissecting both sides of the neck in patients with lesions of the anterior tongue and floor of the mouth, with the attendant morbidity of a bilateral RND. On the other hand, if the nodal metastases are multiple or the tumor extends beyond the capsule of a lymph node, the neck dissection alone is associated with a high incidence of recurrence in the neck (6,65,66). In these situations, the addition of postoperative radiation therapy results in better regional control of the disease (67).
3. When SND is utilized for the elective treatment of the regional lymphatics, regional control and survival rates are similar to those of more extensive neck dissections (39,40,68–78).
4. SNDs result in less postoperative morbidity. The dysfunction of the trapezius muscle produced by SNDs is minimal and, unlike that produced by the RND, is usually temporary and reversible (79–84).

Indications

Elective SND: N0 Neck

ND I–III/IV (Supraomohyoid Neck Dissection and Extended Supraomohyoid Neck Dissection). This SND is indicated in the surgical management of patients with SCCA of the oral cavity staged T2–T4 N0. The procedure is performed on both sides of the neck in patients with cancers of the anterior tongue and floor of the mouth. This type of dissection is performed when an elective neck dissection is indicated in the management of patients who have SCCA of the lip or skin of the midportion of the face and when these lesions are associated with clinically discrete, single metastases to the submental or submandibular nodes. A bilateral dissection is performed when the lesion is located at or near the midline.

The need to remove routinely the nodes in level IV in patients with cancer of the oral tongue is controversial. Byers et al. (48) reported finding "skip metastases" in 15.8% of patients with oral tongue cancer. In these cases, metastases to either level IV or level III were the only manifestation of the disease in the neck. In a similar more recent review of 119 neck dissections in patients with cancer of the oral cavity, De Zinis et al. (85) found metastases in level IV nodes in 15% of the patients and 28% of them were skip metastases. In another study of 49 patients with cancer of the oral cavity, staged N0, undergoing "extended supraomohyoid" neck dissection, occult metastases in level IV were found in 10% of the cases (86). These and other authors contend that the supraomohyoid neck dissection is inadequate for a complete pathologic evaluation of all the nodes at risk, and they recommend dissecting the nodes in level IV when performing an elective neck dissection in patients with cancer of the oral tongue.

The opposing point of view has been advanced by Khafif et al. (87) whose practice has been to dissect level IV only when a suspicious node is found at level III or there are multiple obviously involved lymph nodes. They reported their findings in a cohort of 58 patients with SCCA of the oral tongue (stage T1–T2 N0). The node dissections performed included levels I through III in 42 patients (69%), levels I through IV in 16 patients (26%), and levels I through V in 1 patient (5%). A positive node was found in level IV in only one instance (1/54, 1.8%), and no recurrences were observed in level IV. Ambrosch et al. (68) reported similar observations in a study of 167 patients with cancer of the oral cavity and oropharynx of whom 82 had a clinically staged N0 neck. They dissected level IV only when multiple metastases were suspected during the neck dissection. At a median follow-up of 34 months, the rate of regional recurrence in that series was 5.4%. Shah et al. (62) studied RND specimens performed as elective treatment for oral cavity tumors and found metastatic involvement of level IV in 3% of the patients. Li et al. (88) studied 153 patients who had an RND for oral cavity cancer (60 therapeutic and 93 elective) and found metastases to level IV in 3.2% of the patients. Wang et al. (89) studied 116 patients with oral tongue cancer, staged N0, who underwent comprehensive neck dissections and 5 patients who had SND. Metastases in level IV or level V were found in only one patient each. Interestingly, there were five cases with level III involvement as a first echelon of metastasis.

These studies and others (90) have shown that the risk of metastases to level IV in patients with cancer of the oral tongue with clinically negative neck is low, thus the controversy about the routine inclusion of this level in such patients.

ND II–IV (Lateral Neck Dissection). This type of SND is indicated in patients with tumors of the larynx, oropharynx, and hypopharynx staged T2–T4 N0. Because the lymphatic drainage of these regions is such that metastases are frequently bilateral, the operation is often done on both sides of the neck.

The need to dissect the lymph nodes of sublevel IIB and level IV in every patient undergoing elective SND for laryngeal cancer has recently been questioned. In 2006, Rinaldo et al. (91) collected data from five prospective, multi-institutional studies of neck dissection specimens using pathologic and molecular analysis. These studies included 211 patients with laryngeal cancer and clinically N0 neck. Only three patients (1.4%) were found to have positive lymph nodes at sublevel IIB (one patient had also lymph node metastases to sublevel IIA and level III; the other two patients had also a positive lymph node at sublevel IIA). In a more recent prospective multi-institutional study, metastases in sublevel IIB nodes were found in only 2% of 92 neck dissections done for laryngeal cancer (92). This and other recent studies have shown that the incidence of sublevel IIB metastases in patients undergoing elective neck dissection for hypopharyngeal and oropharyngeal cancers is also low, ranging between 5% and 9% for hypopharyngeal cancer and between 0% and 6% for oropharyngeal cancer (92–94). These observations strongly suggest that dissection of sublevel IIB is not necessary in patients with larynx, oropharynx, and hypopharynx cancer and clinically N0 neck. Since dissection of this region requires, in most patients, a more extensive manipulation of the spinal accessory nerve, avoiding it can decrease operative time and the risk of postoperative dysfunction of this nerve, as it has been suggested by a recent study using electromyography (95). The need to electively dissect level IV in patients with laryngeal cancer has also been questioned recently. In a review of 43 patients with laryngeal SCCA who underwent elective ND of levels II–IV, Khafif et al. (96) found that only one patient (2.3%) had metastases in level IV nodes and that patient also had metastases in level II nodes. Others have reported similar observations indicating that the prevalence of positive nodes found in level IV in the absence of palpable metastases elsewhere in the neck varies from 0% to 2.3% (73,97). Furthermore, a recent analysis of the data from three prospective multi-institutional studies of neck dissection specimens, including 175 patients with laryngeal cancer and clinically N0 necks, revealed only 6 patients (3.4%) with positive lymph nodes at level IV (98,99). Based on a thorough review of prospective multi-institutional studies published to date, Ferlito et al. (100) concluded that dissection of sublevel IIa and level III appears to be adequate for the elective surgical treatment of the neck in supraglottic and glottic carcinomas. Appropriate outcome studies are now needed to ascertain that not dissecting these areas of the neck will not have a negative effect on regional control of the disease.

There appears to be a role for elective SND in patients previously treated with primary radiation therapy or chemoradiation for SCCA of the head and neck, who had recurrence or persistent disease at the primary site or develop a second primary tumor. In a retrospective study of 69 such patients who underwent SND as part of their treatment, Solares et al. (101) found metastases evident histologically in 23% of the SND specimens. There were no cases of recurrence in the neck when the primary site remained controlled. All patients who had more than two positive nodes had recurrence either at the primary site or distant metastasis. The authors concluded that SND is oncologically safe in the management of the N0 previously irradiated neck and that the finding of more than two positive nodes is associated with a poor outcome.

SND of Level VI. The role of elective dissection of the lymph nodes in level VI, also referred to as the central compartment dissection, is the main controversy in the surgical management of differentiated carcinoma of the thyroid today (102). The most recent guidelines published by the American Thyroid Association state that "prophylactic central-compartment neck dissection (ipsilateral or bilateral) may be performed in patients with papillary thyroid carcinoma with clinically uninvolved central neck lymph nodes, especially for advanced primary tumors (T3 or T4)" (103).

SND is now the preferred type of neck dissection for the elective surgical management of the cervical lymph nodes in patients with malignant tumors of the head and neck. The effectiveness of the ND (I–III/"supraomohyoid") and the ND (II–IV/"lateral") in the treatment of the N0 and N1 neck in patients with SCCA of the upper aerodigestive tract has been evaluated in a prospective analysis of our practice in which the indications for the operations, the surgical technique, and the indications for postoperative radiation were standardized. The overall recurrence rates observed in the dissected side of the neck at 2 years, with the primary tumor under control, was 3.4% when the lymph nodes removed were histologically negative and 12.5% when multiple positive nodes or extracapsular invasion were found. These results are typical of what has been reported in the literature during the past two decades regarding the effectiveness of SND in the management of the N0 neck (39,40,68–78,104).

Therapeutic SND: N+ Neck. SND is being used with increasing frequency in the management of selected patients with clinically obvious lymph node metastases (N+). In order to determine the feasibility of doing a supraomohyoid neck dissection in patients with oral cavity carcinoma who

have a single clinically metastatic lymph node smaller than 6 cm (N1 and N2a), Kowalski and Carvalho (60) studied 164 oral cavity cancer patients with clinically N1 or N2a stage cancer submitted to RND. Interestingly, metastases were found in level IV lymph nodes in only one patient (0.6%), and metastases were not found in level V nodes. The authors concluded that in patients with clinical N1 stage in whom the metastasis is at level I, a supraomohyoid neck dissection (extended or not to level IV) is feasible instead of an RND. Andersen et al. (105) recently reported a 10-year multi-institutional retrospective review of pooled data from 106 previously untreated clinically and pathologically node-positive patients undergoing 129 SNDs and followed for a minimum of 2 years or until death. The neck was clinically staged N1 in 58 patients (57.7%), N2a in 5 (4.7%), N2b in 28 (26.4%), N2c in 14 (13.2%), and N3 in 1 (0.9%). Extracapsular extension of the tumor was present pathologically in 36 patients (34.0%), and postoperative radiation therapy was administered to 76 patients (71.7%). Overall, nine patients had recurrence in the neck. Six of these recurrences were in the areas of the neck that had been dissected during the SND, for a regional recurrence rate of 5.7%. The recurrence rates reported by others using SND in the N+ neck range from 5.5% to 11.1% (mean recurrence rate of 8.3%) (106,107). These rates are comparable to those reported after MRND or RND (36,42,43,54, 108–110) although absolute comparison is difficult because the SND patients represented a more selected sample (67). Nonetheless, these observations support the use of SND in selected patients with clinically positive nodal metastasis from SCCA of the upper aerodigestive tract.

Extended Neck Dissections

Any of the neck dissections described herein can be "extended" to include either lymph node groups that are not routinely removed (i.e., retropharyngeal, paratracheal, upper mediastinal) or other structures that are not routinely removed (i.e., skin of the neck, carotid artery, levator scapulae, vagus or hypoglossal nerve).

Skin, Muscles, Nerves

In a review of 106 cases of extended neck dissections, the largest review on record in the literature, involvement of the skin occurred in 18% of cases (111). Involvement of the skin did not have a significant prognostic implication.

Involvement of muscles requiring extension of the neck dissection may affect superficial, prevertebral, and paraspinal muscles. The superficial group is composed of the strap muscles (sternohyoid, sternothyroid, and omohyoid), the mylohyoid, and the digastric/stylohyoid muscle complex. Removal of one or more of these muscles was the reason for extending neck dissections in as many as 62% of the cases studied by Carew and Spiro (111), the digastric muscle being among the structures sacrificed in 51% of cases. The functional deficit resulting from removal of these muscles is of little consequence and their removal usually does not require reconstruction. The dissection was extended to include the prevertebral muscles in only 3% of the cases. The muscles deep to the sternocleidomastoid that may be involved by a tumor are the splenius capitis, the levator scapulae, and the semispinalis capitis muscles. Involvement of these muscles occurs most commonly just lateral to the carotid artery. It was the reason to extend a neck dissection in 14% to 18% of cases.

Tumors may be adherent to or involve several important nerves in the neck. Since the lymph nodes in level II are the most common site of metastases, it stands to reason that the nerve most commonly involved is the hypoglossal nerve (41%). This is followed distantly by the sympathetic chain (8%), the lingual nerve (7%), the vagus nerve (4%), the superior laryngeal nerve (3%), the phrenic nerve (3%), and the glossopharyngeal nerve (2%) (111). When a nerve is resected, it is advisable to obtain an intraoperative frozen section of the margin of resection even if the appearance of the nerve is normal; perineural tumor spread is initially axial and may not result in thickening of the nerve until late (112).

Retropharyngeal Lymph Node Dissection

The RPLNs lie within a fat pad located behind the posterior wall of the pharynx and anterior to the prevertebral fascia and the cervical sympathetic trunk and ganglion. This fat pad extends from about the level of the carotid bifurcation to just below the skull base. The RPLNs are divided into medial and lateral groups; the medial group of nodes lies behind the pharyngeal midline at a level between the first and fourth cervical vertebrae. The lateral group of nodes, better known as the nodes of Rouviere, are the nodes removed in an RPLN dissection. They are contained within a sliver of fatty tissue located immediately medial to the internal carotid artery. The RPLNs receive lymphatic drainage from the nasopharynx, tonsillar fossa, oropharyngeal and hypopharyngeal walls, and the posterior ethmoidal sinuses.

Clinically, involvement of the retropharyngeal nodes by the tumor may be signaled by pain and stiffness in the neck. More ominous and characteristic is an ipsilateral occipitoparietal headache described by the patient as pain located behind the eye. Also ominous is the presence of a Horner syndrome that results from tumor involvement of the cervical sympathetic trunk.

The highest incidence of RPLN metastases is associated with advanced cancers of the oropharynx and hypopharynx in patients who present with neck metastases. Therefore, elective RPLN dissection is indicated when these patients are treated surgically. An RPLN dissection should also be performed in patients in whom imaging studies suggest the presence of metastases in the RPLN. An RPLN dissection should also be considered in patients with advanced cancer of the oropharynx and hypopharynx who are treated with organ preservation protocols, have an

incomplete response of the tumor in the neck, and require a neck dissection. An RPLN dissection in these situations is likely to afford the patient perhaps a last opportunity to prevent recurrence in the RPLN.

Dissection of the retropharyngeal nodes can be performed separately or in continuity with the resection of the primary tumor. When it is done electively, this operation is relatively simple and it takes only a few minutes. On the other hand, when the RPLNs are grossly involved by the tumor, the operation may be difficult and sometimes not feasible. The proximity of the nodes to the internal carotid artery and prevertebral structures is such that these structures may be involved as soon as tumor extends beyond the capsule of the lymph nodes. The technique of retropharyngeal node dissection has been described in detail by Vasan and Medina (7).

In a retrospective study designed to assess the frequency of RPLN metastases in 774 patients with SCCA of the nasopharynx, oropharynx, hypopharynx, and supraglottis, using enlargement of the RPLN on CT scans as an indicator of the presence of metastases, McLaughlin et al. (113) found an overall incidence of radiologically "positive" RPLN of 9% in the patients. The highest incidence was seen in patients with cancer of the nasopharynx (74%) and the pharyngeal walls (19%). They also noted that in patients with advanced cancer of the oropharyngeal walls and hypopharynx, the incidence of radiologically positive RPLN was higher in patients with cervical metastases (N+ necks) than in those with an N0 neck (pharyngeal wall: N+ 21%, N0 16%; hypopharynx: N+ 9%, N0 0%) (113).

Amatsu et al. (114) studied 82 patients who had RPLN dissection for SCCA of the hypopharynx and cervical esophagus. They reported finding metastases in the RPLN in 16 patients (20%) (114). Fourteen of these patients had hypopharyngeal cancer, and the posterior pharyngeal wall was involved in 57% of them. In keeping with the studies mentioned previously, the majority of patients with RPLN metastases also had metastases in other neck nodes. However, in 15% of the patients with RPLN metastases, the neck was staged N0 (114).

In these studies, the presence of RPLN metastases did not appear to influence survival (115,116). Recently, Gross et al. (117) found no statistically significant difference in the rate of local/regional recurrence, survival, or distant metastases between patients with RPLN metastases and those without them. These authors attribute this finding to more aggressive, multimodality treatment of these patients, and they advocate performing RPLN in patients with advanced tumors of the oropharynx, hypopharynx, and supraglottic larynx (117).

Paratracheal and Upper Mediastinal Lymph Node Dissection

The paratracheal nodes are a common site of metastases for laryngeal carcinomas that involve the subglottic region and for carcinomas of the cervical esophagus. In a study that included 91 patients with carcinoma of the larynx who underwent PTLN dissection, Weber et al. found that metastases to these lymph nodes occurred more often in patients with subglottic tumors (40%) and transglottic tumors (21.4%), but they also occurred in patients with glottic (13%) and supraglottic tumors (15.7%). The presence of PTLN metastases had a significant negative impact on survival. While the survival at 48 months for the entire group of 141 patients was 60%, none of the 29 patients with PTLN metastases survived beyond 42 months ($P > 0.001$) (8). In 2005, Plaat et al. performed a retrospective study of 85 patients who underwent total laryngectomy and PTLN dissection for laryngeal and hypopharyngeal carcinomas. The prevalence of PTLN metastases was 30%, 12%, and 67% in patients with supraglottic, glottic, and subglottic carcinomas, respectively. Among all laryngeal carcinomas with subglottic extension, PTLN metastases were found in 27% of the cases (118).

Based on the anatomy of the lymphatic drainage of the different laryngeal sites and on the pertinent clinical observations described in the literature, dissection or treatment with radiation of the lymph nodes in level VI is indicated in the following situations (51):

1. Primary subglottic carcinomas. Treatment/dissection in these cases should include the pretracheal and the paratracheal nodes on both sides.
2. Advanced (T3–T4) glottic carcinomas particularly those with involvement of the anterior commissure and with subglottic extension. In tumors confined to one side of the larynx, treatment/dissection should include the prelaryngeal, pretracheal, and the ipsilateral paratracheal nodes. In tumors involving both sides of the larynx, treatment should include the paratracheal nodes on both sides.
3. Advanced (T3–T4) supraglottic carcinomas, particularly those with involvement of the ventricle/ paraglottic space, those with the anterior commissure, and those with clinically apparent lymph node metastases in the lateral compartment of the neck. In tumors confined to one side of the larynx, treatment/dissection should include the prelaryngeal, pretracheal, and the ipsilateral paratracheal nodes. In tumors involving both sides of the larynx, treatment should include the paratracheal nodes on both sides.

In these situations, a neck dissection may need to be extended to include the paratracheal and pretracheal lymph nodes; failure to do so may predispose to the development of peristomal recurrence. It should also be emphasized that the presence of metastases in PTLN has been found to be associated with increased tumor recurrence (51).

In addition, lymph node metastases from thyroid carcinomas tend to occur first in the paratracheal nodes regardless of the location of the primary within the thyroid gland (119).

Resection of the Carotid Artery

Controversy still exists about the advisability of extending a neck dissection to resect the common or the internal carotid artery. Initial reports on carotid artery resection showed very poor results, with approximately 50% of patients suffering either a severe stroke or death. Recent reports have shown a decrease in these events to approximately 25%, with modest improvement in survival compared to those who did not undergo resection. This is epitomized by the recent report by Freeman et al. (120) of their experience with 58 patients with neck metastasis adherent to the internal or common carotid artery. Angiography was used in patients who demonstrated fixation of the tumor to the carotid artery on examination or imaging, followed by balloon test occlusion and single photon emission computer tomography (SPECT) brain scanning. In most patients (70%), the carotid was reconstructed with a vein graft, especially if there was insufficient collateral cerebral circulation. In addition, these patients were given 15 to 20 Gy of intraoperative radiation. In their more recent cases, the carotid was permanently occluded preoperatively when possible. Unfortunately, in spite of such aggressive treatment preceded by a systematic, "state of the art" preoperative assessment, the median disease-specific survival was 12 months and 11 patients (19%) suffered a stroke (120). The mean 1-year disease-free survival rates reported in the literature after resection and reconstruction of the carotid vary between 0% and 44% (121).

When considering resection of the carotid the surgeon must make critical preoperative, intraoperative, and postoperative decisions. Preoperative evaluation of these patients requires a clear understanding of the methods available for assessment of the cerebral circulation. Several tests are available that involve occlusion of the carotid artery with either digital pressure (Matas test) or using a balloon during arteriography. The objective of each method is to determine a "critical point" that indicates when reconstruction of the artery is necessary. With the transcranial color Doppler method, the "critical point" is reverse flow from the external carotid artery to the internal carotid. Technetium-99m hexamethylpropyleneamine oxime brain SPECT measures cerebral perfusion. A 19% to 29% reduction in radioactivity is considered the "critical point." Unlike some of the other methods, this is not a real-time measurement but requires delayed imaging. Another method uses Xenon in an aerosolized mixture that is inhaled by the patient, and then cerebral perfusion is measured by CT scan. Xenon is concentrated in areas of the brain that are well perfused, correlating with blood flow. Two CT scans are obtained to assess cerebral blood flow: the first one during balloon occlusion and the second after the balloon is released. The "critical point" is a 25% reduction in the degree of enhancement on the first occlusion scan compared to the open study. Electroencephalography has a distinct disadvantage compared to other methods. It does not evaluate blood flow volume to the brain directly. However, it has the advantage that it can be used intraoperatively. The "critical point" is a 50% attenuation of the somatosensory-evoked cortical potential in relation to the preoperative exam. Finally, stump pressure measurements can be taken during angiography to determine the pressure on the distal side of the balloon when it is occluded. The critical point is a measurement of less than 50 mm Hg. There is significant individual variability with this measurement, as it is affected by systemic blood pressure.

Intraoperatively, patients with frank involvement of the carotid wall whose preoperative evaluation indicates intolerance to carotid ligation should have the carotid reconstructed. Saphenous vein grafts are preferred over prosthetic grafts for reconstruction, and if the skin has been heavily radiated or a portion of skin over the carotid is resected, an appropriate flap should be used to cover the graft. There is still considerable debate regarding the routine use of intraoperative shunts, and to date, there has not been a prospective study to prove their usefulness. However, shunting is clearly indicated when there is angiographic evidence of inadequate flow through the circle of Willis.

Postoperatively, delayed strokes can occur in as many as 25% of patients who have undergone carotid artery resection without reconstruction, even if they "passed" the balloon occlusion test (122). Flow from the contralateral side through the circle of Willis prevents a stroke initially. However, the resection creates an arterial stump that begins at the takeoff of the middle cerebral artery and continues down to the level of the resection. This can be a site for thrombus formation, which can then propagate up into the circle of Willis. Alternatively, the thrombus may produce emboli that can travel into the distribution of the middle cerebral artery. While these mechanisms have not been conclusively proven, many surgeons advocate the use of heparin postoperatively to prevent delayed strokes following resection of the internal carotid artery. Recommended doses range from 5,000 units subcutaneously twice a day to full therapeutic anticoagulation (123). The benefit of anticoagulation has not been shown in a prospective controlled study.

"CONTRAINDICATIONS" TO NECK DISSECTION

It is not advisable to attempt a neck dissection when the diagnostic evaluation of the patient reveals any of the following circumstances: (a) frank involvement of the carotid wall in patients whose preoperative evaluation indicates intolerance to carotid ligation, and the location and extent of the tumor in the neck is near the skull base, precluding reconstruction of the carotid artery and (b) involvement of the base of the skull, paraspinal muscles, and transverse processes of the cervical vertebrae and the brachial plexus.

ADJUVANT THERAPY FOLLOWING NECK DISSECTION

Numerous studies in the 1980s showed that the rate of tumor recurrence in the neck is decreased by the addition of postoperative radiation, when multiple nodes are involved at multiple levels of the neck, and when extracapsular spread (ECS) of the tumor is found (124–126). Since then, it has also been accepted that timing of the initiation of radiotherapy is important; delays beyond 6 weeks may compromise tumor control (125). The seminal study of Peters et al. in the early 1990s established the dose of postoperative radiation therapy that is essential to achieve optimal results. Daily fractions of 1.8 Gy to a total dose of 57.6 Gy to the entire operative bed is currently recommended. Sites of increased risk for recurrence, such as areas of the neck where ECS of the tumor was found, should be boosted to 63 Gy (127). A prospective, randomized clinical study published in 2004 showed that the concurrent postoperative administration of chemotherapy (cisplatin 100 mg/m^2 on days 1, 22, and 43) and radiotherapy (60 to 66 Gy in 30 to 33 fractions over 6 to 6.6 weeks) significantly improved the rates of local and regional control and disease-free survival in patients with high-risk resected head and neck cancers (128). The high-risk criteria included any or all of the following: histologic evidence of metastases in two or more lymph nodes, ECS, and microscopically involved margins of resection. Although the study subjects were stratified according to the presence or absence of microscopically positive margins, the published results did not include an analysis of outcomes with and without concomitant chemotherapy in the cohort of patients with microscopically negative margins, which would have elucidated whether or not the addition of chemotherapy was beneficial to patients with high-risk neck disease. A similar study by the European Organization for Research and Treatment of Cancer (EORTC), published at the same time, included patients with various clinical (primary tumor and nodal volume and nodal site) and pathologic (involved margins of resection, ECS, perineural involvement, and vascular embolism) high-risk factors related to neck metastases (129). It also showed that concomitant postoperative chemoradiation was significantly more efficacious than radiation alone in these high-risk patients. However, resection margins were positive in 30% of the patients included in the study and the design did not include an analysis focused on the neck disease factors. Nonetheless, both of these studies suggest that the addition of chemotherapy may be beneficial to patients with resectable head and neck cancers who have advanced neck metastases, N2–N3, and to patients with N0 or N1 disease who are found to have multiple histologically positive nodes or ECS of the tumor.

In a subsequent analysis of both the EORTC and Radiation Therapy Oncology Group (RTOG) studies, Bernier et al. (130) found that chemoradiation improved overall survival in patients with ECS and/or positive margins in both studies (EORTC P = 0.0019; RTOG P = 0.0.63). Thus, in regard to adjuvant treatment of neck metastases following neck dissection, the presence of ECS of the tumor is currently considered an indication for postoperative concurrent chemoradiation.

CURRENT CONTROVERSIES

Pertinent controversies regarding neck dissection concern the need for postoperative radiation in patients with pathologically proven metastasis in a single cervical lymph node (pN1) and the need for and the extent of "planned" neck dissection in patients with SCCA of the upper aerodigestive tract who have clinically obvious neck node metastases (N+ neck) and are treated with radiation alone or in combinations with chemotherapy.

IS Postoperative Radiation Beneficial in the Pathologically N_1 (pN_1) Neck?

When a single metastasis is found (pN_1) in a neck dissection specimen, surgery alone has been considered adequate treatment. Recently, however, regional recurrence rates from 16% to 25% have been reported with surgery alone, and it has been suggested that postoperative radiation may be beneficial (73,131).

In a retrospective analysis of 517 SNDs performed in 363 patients, Byers et al. found 51 (17.6%) patients who had metastases in only one lymph node (pathologically N1) with or without ECS. A regional failure occurred in 2 of 36 (5.6%) of these patients who received postoperative radiation and in 5 of 14 patients (35.7%) who did not. All recurrences were within the dissected area of the neck (73). More recently, Chen et al. (132) analyzed 59 patients with T1–T2/N0–N1 SCCA of the oral cavity to determine the effect of postoperative radiation. Of the patients staged pathologically N1, 28 received postoperative radiation and 31 did not. With a mean follow-up period of 46 months (12–109), locoregional recurrences occurred in 14% of the patients who received postoperative radiation and in 39% of the patients who did not. As in the Byers' study, all regional recurrences occurred within the dissected neck. To characterize further the impact of the N1 status and radiation, the authors excluded from the analysis patients with ECS, positive margins, lymphovascular invasion, and perineural invasion and compared those who had received post-op XRT with those who did not. The 5-year disease-free survival rate and overall survival were 95% and 92.3%, respectively, for the group that received postoperative radiation and 54.7% and 54.9%, respectively, for the group that did not. On the other hand, radiation was not found to be beneficial in an unpublished retrospective review we conducted of 58 patients with T1/T2 SCCA of the oral tongue treated with surgery, which included an ipsilateral SND, who were found to have metastasis in a single lymph node. These patients were treated

at seven institutions and were followed for a minimum of 2 years. Twenty-two (38%) patients were treated with surgery alone, while 36 (62%) received postoperative radiation. In the group treated with surgery alone, two patients had recurrence at the primary site and in the neck. Of the remaining 20 patients, 6 patients (30%) had recurrences in the neck (5 contralateral and 1 simultaneous ipsilateral and contralateral). In the surgery plus radiation group, four (11%) tumors recurred in the neck, all within the operative field. The difference in the rate of recurrence in the neck for the two groups was not statistically significant.

Thus, it appears that a prospective randomized study is necessary to determine in a controlled manner whether or not postoperative radiation is beneficial in patients whose neck is pathologically staged N1.

"Planned" Neck Dissection After "Organ Preservation" for Squamous Cell Carcinoma of the Head and Neck

The treatment of advanced carcinomas of the larynx and pharynx has evolved from surgery and postoperative radiation to "organ preservation" strategies with hyperfractionated radiation and more recently with various combinations of radiation and chemotherapy. This has brought up several dilemmas in the management of patients with clinically obvious lymph node metastases, particularly those with advanced neck disease (N2–N3).

The first dilemma is whether or not a planned neck dissection should be performed, irrespective of the response of the tumor in the neck to the treatment with radiation or chemoradiation. Some clinicians argue that a neck dissection should be carried out as part of the treatment plan, irrespective of the response of the tumor in the neck, because the clinical and pathologic responses of the tumor in the neck correlate poorly with each other. In a study by Brizel et al. (133), a planned neck appeared to confer a disease-free survival and overall-survival advantage in patients with N2–N3 disease undergoing chemoradiation, with acceptably low morbidity. This was a retrospective study of a cohort of 108 patients with advanced squamous carcinoma of the head and neck, who presented with nodal disease and were treated with hyperfractionated radiotherapy and concurrent cisplatinum and 5-fluorouracil. A "modified neck dissection" was performed in 65 patients, while 29 patients did not undergo neck dissection because of "the physician and/or patient preference." The 4-year disease-free survival was 70% for patients with N1 disease, irrespective of the clinical response or whether a neck dissection was performed. For patients with N2–N3 disease who had a complete clinical response to chemoradiation, the 4-year disease-free survival rate was 75% for those who had a neck dissection and 53% for those who did not. This difference was not statistically significant ($P = 0.08$). However, the 4-year overall survival rate was significantly better (77% vs. 50%) for the group treated with neck dissection ($P = 0.04$). These authors and others have suggested that a planned neck dissection be considered for all patients with N2 and N3 disease (133,134).

On the other hand, some clinicians argue that it is not necessary to perform a "planned" neck dissection when the tumor in the neck undergoes a complete response to the treatment (135,136). This position is based on the observation that less than a third of patients with clinically positive nodes before therapy have histologic evidence of metastases at neck dissection (137), even when there is residual clinical or radiologic "adenopathy" in the neck after completion of (chemo)radiation (138,139). Furthermore, when the tumor in the neck undergoes a complete response to the treatment, the probability of an isolated recurrence in the neck is low (0% to 11%) if the patients are simply observed (135–141).

The controversy over whether or not a planned neck dissection (PND) is needed is in good part due to the inability to determine, preoperatively, when a complete clinical response is associated with the presence or absence of viable tumor cells. PET scanning may be useful in identifying the subset of patients who need a neck dissection, since this imaging modality has been shown to be more accurate than others in the evaluation of patients following treatment (142). However, the timing of posttreatment PET imaging appears to be important. In a series of 12 patients studied prospectively by Rogers et al. (143) a positive PET 1 month after radiation therapy accurately indicated the presence of residual disease in all cases; however, a negative PET indicated absence of disease in only 14% of the cases. Other studies have also shown that PET scan obtained 1 month after completion of treatment with radiation was inaccurate in predicting the presence of residual cancer (144). In contrast, a PET scan done 12 weeks after completion of treatment with radiation or chemoradiation may be more useful (145). Porceddu et al. (146) evaluated the utility of PET imaging in 39 N+ patients who achieved a complete response at the primary site but had a residual mass in the neck, 8 weeks or more after definitive (chemo)radiotherapy. The PET scan was performed at a median of 12 weeks (range, 8 to 32 weeks) after treatment. Interestingly, the PET scan showed no metabolic activity in the residual mass in 32 patients. Five of these patients had a neck dissection and the neck dissections were all pathologically negative. The remaining 27 patients were observed for a median of 34 months (range 16 to 86 months), and only one of them had a locoregional recurrence. Thus, the NPV of PET for viable disease in a residual anatomic abnormality in the neck was 97%. These authors concluded that a neck dissection is not necessary in patients who have achieved a complete response at the primary site but have a residual abnormality in the neck that is PET negative approximately 12 weeks after treatment and that these patients can be observed safely. Others have reported similar results. Rabalais et al. (147) in a retrospective analysis of 52 patients treated with chemoradiation therapy (CRT) found that 10 (19.2%) had

a positive PET scan on an average 11.8 weeks after completion of treatment. Three of the ten underwent neck dissection of which two partial responders had residual disease and the one complete responder did not. The remaining 7 (70%) patients were observed only. One of these patients was shown to have residual tumor on FNA but was not a surgical candidate for neck dissection and another had disease in the neck in addition to persistent disease at the primary site. Of the five remaining patients with positive PET-CT results who did not undergo PND, all five showed gradual resolution of the disease on serial PET-CT scans with no failures in the neck. Of the 42 (81%) who had a negative posttreatment PET finding, 2 underwent neck dissection for palpable lymphadenopathy and 3 had neck dissections as a component of salvage surgery for the primary tumor. None of the five neck dissection specimens revealed residual tumor. There were no isolated neck recurrences in the remaining 37 patients (average follow-up of 60.4 weeks). Recently, Corry et al. (148) reviewed their experience with N2/N3 disease following CRT in 102 patients. Of the 28 patients in whom there was a complete response within the primary and a partial response in the neck, 11 patients demonstrated resolution of their adenopathy with continued observation, 1 was diagnosed with metastatic disease prior to any further therapy, and 16 patients had a neck dissection of which 9/16 (65%) were pathologically negative. In another study, patients with a clinically complete response to chemoradiation who were observed rather than having a neck dissection demonstrated a regional failure rate of 3% to 8%, and if negative PET imaging was included as part of the definition of a complete response, the regional failure rate decreased to 0% to 3% (149). Thus, it appears from this information that observation with a PET-CT obtained at least 12 weeks after completion of chemoradiation is a reasonable alternative to a "routine" planned neck dissection (149).

The second dilemma regarding "planned" neck dissections is the extent of the operation. Traditionally, surgeons performed comprehensive neck dissections (levels I–V) with or without preservation of nonlymphatic structures (150). Recently, however, surgeons have reported performing SNDs with reasonable results (151). Robbins et al. (140,151) performed 33 SNDs in patients treated with targeted intra-arterial high-dose cisplatin infusions combined with radiation therapy (RADPLAT). There was only one recurrence in the neck. Stenson et al. (152) reported the results in 69 patients who had planned neck dissections after various concomitant chemoradiation protocols. The majority of them (56/69) underwent an SND and only one patient had a recurrence in the neck. These studies suggest that SND may be an appropriate option for some patients with an N+ neck who are treated with organ preservation regimens.

Robbins et al. (153) in 2005 reported the results of 106 neck dissections performed in 84 patients with advanced N stage disease (N2–N3) that were treated with the RADPLAT protocol. Fourteen neck dissections were radical or modified radical, eighty-one were selective, and eleven were dissections of levels II and III and were labeled as "super selective neck dissections" (SSNDs). Interestingly, there were no recurrences in the neck in the group that underwent SSND. The authors outlined the indications for the different types of neck dissection as follows: In general, an RND or MRND was performed in patients in whom the residual lymphadenopathy involved multiple levels, an SND was performed when the residual disease was confined to two levels involving the lymph node groups at greatest risk, and an SSND was performed when the residual lymphadenopathy was confined to one level.

Vasan et al., at our institution, investigated the feasibility of performing a "single-level dissection." To that end, they studied a cohort of 51 patients, treated between January 1999 and March 2005, who underwent a total of 55 "planned" neck dissections for clinically or radiologically apparent residual disease in the neck, after definitive treatment of the primary tumor and neck with radiation therapy alone or with chemotherapy (138). The primary tumor was in the tonsil in 20 (39%) patients, base of the tongue in 12 (23%), supraglottic larynx in 10 (20%), hypopharynx in 4 (8%), faucial arch in 3 (6%), and "unknown" in 2 (4%). The neck was staged N1 in 19 (38%) patients, N2A in 8 (16%), N2B in 10 (20%), N2C in 6 (12%), and N3 in 7 (14%). All patients were treated with radiation therapy with curative intent. The mean radiation dose was 7,077 cGy and 5,814 cGy to the primary and neck, respectively. Twelve patients also received chemotherapy. The neck dissections performed included lymph node levels II–IV in 32 (58%) of the cases, II–III in 16 (29%), I–IV in 4 (7.1%), and one each of I–IV, II–V, and II only. In 19 dissections (34%), nonlymphatic structures were removed, including the IJV (19/34%), a portion or all of the SCM (14/25%), the digastric (5/9%), and the cranial nerve XI (4/7%). Interestingly, Robbins et al. (140,151) also reported the need to remove one or more of these nonlymphatic structures in 24% of "planned" SNDs. The pathologists found histologically "viable looking" tumor in one or more lymph nodes in 15 of the 55 neck dissection specimens; thus, the yield of histologically positive nodes was 27.2%. In the analysis of the distribution of the positive nodes, five patients had clinical or radiologic evidence of metastases of one or more nodes in level II only; in all of them (5/5), histologically positive nodes were found only in level II. Eight patients had clinical/radiologic evidence of metastases in one or more nodes in levels II and III (one patient also had a node in level V); histologically positive nodes were found in level II in one instance, in level III in four, and in levels II, III, and IV in three. Two patients had clinically/radiologically positive nodes in levels I and II; histologically positive nodes were found in levels I and II in one of them and in levels I and III in the other. Over a mean follow-up time of 25.9 months, there were only two recurrences in the neck (4%).

These findings confirm the effectiveness of SND in the management of residual disease in the neck. In addition, they suggest that it may be feasible to perform a single-level dissection in patients whose disease is confined to level II nodes, before, during, and after treatment with radiation with or without chemotherapy. Boyd et al. (154) noted a predictable pattern of residual metastases following irradiation and suggested that a lateral (II–IV) neck dissection may be appropriate in the majority of patients. In this study, of nine positive specimens, six revealed malignant cells in a single nodal echelon. Obviously such an approach must be investigated further in prospective studies.

More recently, investigators have used CT scans of the neck following chemoradiation to determine the extent of neck dissection. Goguen et al. (155) and Yeung et al. (156) noted that the NPV for CT for the posttreatment neck was 95%. They noted that an SND or SSND guided by posttreatment CT would have captured all disease in 95% and 93% of the cases, respectively.

SEQUELAE OF NECK DISSECTION

The most notable sequelae observed in patients who have undergone an RND are related to removal of the spinal accessory nerve. The resulting denervation of the trapezius muscle, one of the most important shoulder abductors, causes destabilization of the scapula with progressive flaring at the vertebral border, drooping, and lateral and anterior rotation. The loss of trapezius function decreases the patient's ability to abduct the shoulder above 90 degrees. These physical changes result in the recognized shoulder syndrome of pain, weakness, and deformity of the shoulder girdle commonly associated with the RND. It should also be noted that preserving the cervical plexus contributions to the spinal accessory nerve may not decrease shoulder morbidity significantly (157). Furthermore, shoulder disability after neck dissection results not only from the spinal accessory nerve dysfunction but also from secondary glenohumeral stiffness caused by weakness of the scapulohumeral girdle muscles and postoperative immobility.

A number of studies have demonstrated that when compared with the RND, neck dissections that preserve the spinal accessory nerve are associated with less shoulder pain (158), better shoulder function, and overall quality of life (79–83,159). However, these studies also provide evidence that even procedures that involve minimal dissection of the spinal accessory nerve can result in shoulder dysfunction. Although this dysfunction is often reversible, it behooves the surgeon to make every effort to avoid undue trauma to the nerve, particularly stretching, during any neck dissection in which the nerve is preserved. In addition, every patient who undergoes neck dissection must be questioned about the function of the shoulder and must be evaluated by a physical therapist early in the postoperative period. If any deficit is detected, the patient should be properly counseled and coached to ensure proper rehabilitation of the shoulder. Physical therapy aimed to early recovery of passive motion and to avoid the occurrence of joint fibrosis has been shown to be beneficial (160). It has also been suggested that progressive resistance exercise training may be a useful adjunct to standard physical therapy (161). It should be kept in mind, as mentioned earlier, that shoulder pain after neck dissection may not be the result of dysfunction of the spinal accessory nerve. Consequently, if a patient experiences shoulder pain after neck dissection, the trapezius muscle and active bilateral abduction of the shoulder should be examined to determine if the spinal accessory nerve is involved (162).

COMPLICATIONS OF NECK DISSECTION

In addition to the medical complications that can occur after any surgical procedure in the head and neck region, several surgical complications can be related solely or in part to neck dissection.

Infection

Following clean neck dissections, those in which the upper aerodigestive tract is not entered, wound infections are not common. Interestingly, however, a recent prospective study, designed to evaluate the effects of a prophylactic antibiotic regimen (ampicillin–sulbactam for 24 hours) on the incidence of infection after clean neck dissection, showed that the infection rate in patients who were treated with the antibiotic was 1.7% compared to a significantly higher rate (13.3%) among patients who did not receive an antibiotic ($P = 0.02$) (163).

Air Leaks

Circulation of air through a wound drain is a common complication that usually is encountered during the first postoperative day. The point of entrance of air may be located somewhere along the skin incision. If the drains are connected to suction in the operating room near the completion of the wound closure, however, such an air leak usually becomes apparent then and can be corrected. Other points of entrance may not become apparent until after surgery, when the position of the neck changes or the patient begins to move. The typical example of this situation is the improperly secured suction wound drain that gets displaced, exposing one or more of the drain vents. A similar situation can occur when a skin graft to reconstruct a cutaneous defect is created in conjunction with the neck dissection. Movement of the neck can produce an air leak even after meticulous suturing of the skin graft. This can be prevented by applying an adhesive vinyl drape over the graft and surrounding skin to seal any possible air leak

instead of or in addition to the bolster of gauze traditionally used to immobilize a skin graft.

Air leaks with potentially more serious consequences are those that occur through a communication of the neck wound with the tracheostomy site or through a mucosal suture line. In addition to air, contaminated secretions may be circulated through the wound. Thus, early identification of the site of leakage is desirable but may not be a simple task, and correcting it may require revision of the wound closure in the operating room.

Bleeding

Postoperative hemorrhage usually occurs immediately after surgery. External bleeding through the incision, without distortion of the skin flaps, often originates in a subcutaneous blood vessel. In most instances, this bleeding can be controlled readily by ligation or infiltration of the surrounding tissues with an anesthetic solution containing epinephrine. On the other hand, pronounced swelling or ballooning of the skin flaps in the immediate postoperative period, with or without external bleeding, must be attributed to a hematoma in the wound. If detected early, milking the drains occasionally may result in evacuation of the accumulated blood and resolve the problem. If this is not accomplished immediately or if blood reaccumulates quickly, however, it is best to return the patient to the operating room and to explore the wound under sterile conditions, evacuate the hematoma, and control the bleeding. Attempting to do this in the recovery room or at the bedside may be ill-advised, because lighting may be inadequate, surgical equipment improvised, and sterile conditions precarious. Failure to recognize or to manage properly a postoperative hematoma may predispose the patient to the development of a wound infection. Although bulky pressure dressings may be useful in curtailing postoperative edema, they do not prevent hematomas and may in fact delay their recognition.

Chylous Fistula

The reported incidence of chyle fistula following neck dissection varies between 1% and 2.5%. In most patients who develop a postoperative chylous fistula, a chylous leakage is identified and apparently controlled intraoperatively (164). These observations behoove the surgeon to avoid injury to the thoracic duct proper and also to ligate or clip any visualized or potential lymphatic tributaries in the area of the thoracic duct, which may be accomplished with relative ease if the operative field is kept bloodless when dissecting in this area of the neck. Furthermore, as soon as the dissection of this area is completed and again before closing the wound, the area is observed for 20 or 30 seconds while the anesthesiologist increases the intrathoracic pressure.

Even the smallest leak of chylous material must be pursued seriously until it is arrested. Direct clamping and ligating may be difficult and sometimes counterproductive as a result of the fragility of the lymphatic vessels and the surrounding fatty tissue. Hemoclips are ideal to control a source of leakage that is clearly visualized. Otherwise, it is preferable to use suture ligatures with pliable material, such as 5 to 0 silk, that are tied over a piece of hemostatic sponge to avoid tearing. In the immediate postoperative period, serum and drainage levels of triglycerides and cholesterol obtained on the first postoperative day may be useful parameters to predict early the occurrence of a chyle fistula (165).

Management of a chyle leak noted postoperatively depends on the time of onset of the leak, the amount of chyle drainage in a 24-hour period, and the presence or absence of accumulation of chyle under the skin flaps (164,166). When the daily output of chyle exceeds 600 mL in a day or 200 to 300 mL/day for 3 days, especially when the chyle fistula becomes apparent immediately after surgery, conservative closed wound management is unlikely to succeed (167). In such cases, it is preferable to explore the wound early, before the tissues exposed to the chyle become markedly inflamed and before the fibrinous material that coats these tissues becomes adherent, obscuring and jeopardizing important structures such as the phrenic and the vagus nerves. Surgical exploration is also warranted when chyle accumulates under the skin flaps either because of inadequate drain size or because of the volume or consistency of the chyle causes partial or compete obstruction of the drains.

On the other hand, chylous fistulae that become apparent later in the postoperative period, after enteral feedings are resumed, or those that drain less than 200 to 300 mL of chyle per day are initially managed conservatively with closed wound drainage, pressure dressings (which are cumbersome to secure in this area of the neck), repeated aspirations, and diet modifications aimed at decreasing chyle drainage while maintaining nutritional support. Usually, nutrition can be provided enterally using elemental diets supplemented with medium-chain triglycerides, which are absorbed directly into the portal circulation bypassing the lymphatic system. In some patients, parenteral nutrition may be necessary (168). If these measures fail, the neck is surgically explored and the leak is identified and dealt with appropriately. Sometimes, this intervention is unsuccessful and the leak persists. The use of fibrin glue and a clavicular periosteal flap may be useful to control the leak in such cases (169). Percutaneous lymphangiography guided cannulation and embolization of the thoracic duct is an effective minimally invasive alternative to open surgical intervention (170). Success with this technique has been reported in as many as 45% to 70% of the cases (167). In a recent report, Nyquist et al. described a case in which a chylous fistula stopped draining 24 hours after the administration of octreotide (100 micrograms given subcutaneously three times a day). These authors postulate that the effect of octreotide on chylous fistulae may be due to its ability to reduce gastrointestinal and pancreatic secretions, decrease hepatic venous pressure, and reduce splanchnic blood flow, which may decrease thoracic duct flow and relative concentration of triglycerides (171).

Ipsilateral chylothorax can occur following neck dissection. Bilateral chylothorax as a complication of neck dissection is extremely rare, but it is potentially serious and sometimes fatal (172,173).

Facial or Cerebral Edema

Synchronous bilateral RNDs, in which both IJVs are ligated, can result in the development of facial edema, cerebral edema, or both. The facial edema sometimes can be dramatically severe. It appears to be a mechanical problem of venous drainage, which resolves to a variable extent with time as collateral circulation is established. It appears to be more common and more severe in patients who had previous radiation to the head and neck and in those patients in whom the resection includes large segments of the lateral and posterior pharyngeal walls. We have been able to prevent massive facial edema by preserving at least one external jugular vein whenever a bilateral RND is anticipated. The external jugular usually is separated from the tumor in the neck by the SCM and can be dissected free between the tail of the parotid and the subclavian vein. Others have reconstructed one internal jugular using various techniques including vein with saphenous vein grafts or by using a segment of one of the resected jugular veins, distal to the site of tumor involvement (174,175). The development of cerebral edema may be at the root of the impaired neurologic function and even coma that can occur after bilateral RND. Following neck dissection, a syndrome of inappropriate secretion of antidiuretic hormone (SIADH) occurs in 8% to 30% of patients. This is a disorder in which release of antidiuretic hormone is independent of plasma osmolarity, resulting in fluid retention and development of dilutional hyponatremia. It occurs significantly more often in patients who have a history of smoking and it has been noted to resolve within 72 hours (176). It is commonly believed that synchronous, bilateral RND causes the SIADH, presumably as a result of increased intracranial pressure. This belief is based mainly on the results of an experimental study published in 1978 in which occlusion of the superior vena cava in dogs resulted in increased intracranial pressure and SIADH. Using an animal model that more closely resembles the clinical condition of bilateral RND, Khafif and Medina (177) found that bilateral synchronous IJV ligation and bilateral RNDs did not result in SIADH in dogs. As these results contradict a commonly held belief in clinical practice, a prospective evaluation of the physiologic changes after bilateral RNDs is warranted. Nevertheless, it is possible that an expansion of extracellular fluids and dilutional hyponatremia that occurs in some patients after neck dissection could aggravate cerebral edema, creating a vicious cycle. In practice, this behooves the surgeon and the anesthesiologist to curtail the administration of fluids during and after bilateral RNDs. Furthermore, perioperative management of fluid and electrolytes in these cases should not be guided solely by the patient's urine output, but also by monitoring central venous pressure, cardiac output, and serum and urine osmolarity.

Blindness

Blindness after bilateral RND is a rare but catastrophic complication (178). The pathogenesis of it remains unclear. In one of the few cases reported in the literature, histologic examination revealed intraorbital optic nerve infarction, suggesting intraoperative hypotension and severe venous distention as possible etiologic factors. In another case, bilateral occipital lobe infarcts were demonstrated on CT scan (179).

Apnea

Some patients may become apneic as a result of loss of their hypoxic ventilatory responses due to carotid body denervation after bilateral neck dissection.

Jugular Vein Thrombosis

Preservation of the IJV during neck dissection does not ensure its patency after surgery, particularly when radiation therapy is also used. Cotter et al. (180) used preoperative and postoperative CT or MRI on 69 patients undergoing 79 vein-sparing neck dissections. Sixty-eight veins (86%) were patent postoperatively. Interestingly, radiation therapy appears to influence patency of the IJV. Cappiello et al. studied the patency of the IJV following selective lateral neck dissection in a cohort of 34 patients. A preoperative baseline study of vein patency and flow by US was obtained followed by postoperative evaluations at 1 week, 1 month, and 3 months. At 1 week postoperatively, 50% of the IJVs did not present any alteration in patency, 46% had reduced flow, and 4% showed absent flow. However, at 3 months, none of the patients showed evidence of IJV occlusion. Postoperative radiotherapy did not have a statistically significant impact on IJV patency ($P = 0.09$) (181).

A recent report describes the rate of complications after planned posttreatment neck dissections in patients enrolled in organ preservation protocols. The authors conclude that the rate is similar to that previously for neck dissections (37%) and that the rate increases when higher preoperative radiation therapy doses are used (182).

EMERGENCIES

Carotid Artery Rupture

The most feared and most commonly lethal complication after neck surgery is exposure and rupture of the carotid artery, the carotid blowout syndrome (CBS). Therefore, every effort must be made to prevent it. If the skin incisions have been designed properly, the carotid seldom becomes exposed in the absence of a salivary fistula. Fistula

formation and flap breakdown are more likely to occur in the presence of malnutrition, diabetes, and prior radiation therapy, which impair healing capacity and compromise vascular supply. Faced with any of these risk factors, the surgeon must use flawless surgical technique in closing oral and pharyngeal defects. Use of perioperative antibiotics and, more importantly, use of free and pedicled vascularized flaps (which provide skin for closure of mucosal defects and variably bulky muscle that can protect the carotid) have rendered nearly obsolete the use of "protective" measures such as dermal grafts, levator scapulae muscle flaps, and controlled pharyngostomies.

Fortunately, CBS has become less frequent; however, its frequency may increase again as more salvage procedures are done in patients whose tumors fail to respond to chemoradiation regimens. Therefore, it is essential for all head and neck surgeons to be familiar with the current management of CBS. In a retrospective review of all HNC patients with a diagnosis of CBS seen at our tertiary cancer hospital from 1994 to 2009, we found eight patients who developed CBS. Powitzky et al. (183) recently published an analysis of these cases and a review of 21 studies published in the English-language literature within the past 15 years. They summarized the presentation, treatment, and outcomes of a total of 132 patients. Patients with CBS typically have a history of radiotherapy (89%), nodal metastasis (69%), and neck dissection (63%). Rupture of the carotid usually occurs proximal to the carotid bifurcation and is commonly associated with soft tissue necrosis in the neck (55%) and mucocutaneous fistulas (40%). Half of CBS patients present with sentinel bleeding, but 60% of patients will develop a life-threatening hemorrhage requiring emergent intervention. Over 90% of the cases reported with initial and recurrent CBS were treated with endovascular embolization (56%) or stenting (36%). Ligation was used in only 7% for primary management of CBS. Those clinicians who used endovascular stenting did so because it provides constructive repair and allows preservation or revascularization of the cerebral blood flow. Overall, however, stent placement was associated with a higher risk of CBS recurrence (44%) than embolization (10%) or surgical ligation (25%). Cerebrovascular accidents occurred in 12 patients and were the most common cause of death next to tumor progression. The mortality rate of patients with CBS was high (63%). Only 23% of the patients have survived without evidence of disease (average follow-up of 17 months).

CBS has a spectrum of presentations that range from exposure of the carotid artery to hemorrhage from the carotid artery system. Three types of CBS can be recognized. Type I or threatened CBS, when exposure of the carotid artery is found on clinical examination or imaging studies (i.e., air surrounding the vessel, adjacent abscess, or tumor associated with a fistula or areas of arterial wall disruption found on vascular imaging studies). Type II or impending blowout, when bleeding episodes occur that resolve temporarily with pressure and wound packing. In many cases, these are self-limiting, single incidents that may cause little suspicion to those unaware of the patient's history and risk factors for CBS. Sentinel bleeding can occur moments to months before hemorrhage. High-risk head and neck cancer (HNC) patients should be educated to report any occurrences of soft tissue breakdown or bleeding so that they may be properly evaluated for potential CBS and associated risk factors. Management of the exposed carotid depends on the likelihood of rupture, based on the length of the exposed segment, the condition of the surrounding tissues, and the size of the oropharyngocutaneous fistula. Large cutaneous defects or large high-output fistulae in previously irradiated patients are not likely to heal by secondary intention in a timely manner. The likelihood of rupture of the carotid in these conditions is extremely high. Therefore, an attempt should be made to repair the defect and to cover the carotid using well-vascularized tissue early, before the vessel has been irreversibly damaged. Whenever the carotid is exposed, it is advisable to take the following carotid rupture precautions:

- Warn and instruct nursing personnel and house staff about the possibility of a carotid rupture, the site of potential rupture, and the steps to be taken in the event of bleeding.
- Have compatible blood available.
- Keep appropriate surgical instruments at the bedside.

Type III or hemorrhage from the carotid system is usually rapidly fatal especially when it occurs outside the hospital setting. Bleeding can occur externally through a neck wound or "internally" into the pharynx/mouth (less common). In the latter cases, the possibility exists for airway compromise. Identification of the early stages and prevention of type III CBS are crucial, as patients with CBS who undergo therapy before the development of hemorrhage have been shown to have a lower complication rate than do those who wait until hemorrhage develops. CT and MRI are helpful in finding type I situations, such as an exposed carotid vessel within a fistula tract or recurrent tumor with carotid space invasion. Computed tomographic angiography, magnetic resonance angiography, and arteriography can also be helpful in evaluating patents at risk for CBS. Findings include endoluminal and vessel wall irregularities and pseudoaneurysm formation and extravasation. Angiography is the gold standard for diagnosing arterial disorders and is preferred because of its therapeutic capabilities; however, it is important to be aware of the 8.5% complication rate associated with this procedure.

When a carotid rupture occurs, it is usually possible to stop the bleeding with manual pressure while blood and fluids are given to restore and maintain the patient's blood pressure. Often, in emergency situations, medical staff place multiple dressings over the wound, which will not apply focused pressure over the bleeding site, and the

patient may continue to exsanguinate around them. It is more effective to place a gloved finger for pressure to temporarily control the bleeding until definitive treatment is undertaken. Blood pressure must be addressed aggressively with proper resuscitation. Only then is the patient taken to surgery, since the risk of morbidity with ligation increases significantly in the setting of hypotension, which is the greatest predictor of a poor outcome in the acute treatment of CBS. Attempts to repair the area of rupture are futile. Introducing Fogarty catheters through the area of rupture helps control the bleeding temporarily while the artery is exposed and ligated proximally and distally to the area of rupture.

Endovascular embolization—whether it be with balloons, coils, or other materials—is more precise than ligation, as it targets the exact location of the arterial defect. It also decreases the hospital stay and causes less of the collateral morbidity that is sometimes associated with emergent open ligation procedures, such as injury of cranial nerves or ligation of the incorrect trunk or branch of the carotid system. Endovascular embolization also has the ability to help predict cerebrovascular complications with temporary balloon occlusion and collateral cerebral blood flow analysis. Carotid artery embolization is associated with 15% to 20% long-term neurologic morbidity rate and a much lower incidence of associated mortality.

More recently, constructive endovascular management of CBS became available for patients who have risk factors for neurologic sequelae after embolization. Constructive methods utilize intravascular stents to control vascular wall instability while allowing adequate cerebral perfusion. Some indications used for arterial stenting include an incomplete circle of Willis, significant contralateral carotid artery atherosclerosis or narrowing, inability to perform balloon occlusion tests (proximal atherosclerotic stenosis or unstable clinical scenario), and failure to tolerate balloon test occlusion on either clinical or cerebral blood flow criteria (decrease of cerebral blood flow of more than 20%).

Regardless of the treatment used, anticoagulation therapy may be required to prevent thrombosis distal to the ligation or endovascular occlusion site or to prevent stent thrombosis. Patients with an exposed carotid artery require wound management with flap placement to cover and protect these vessels.

Although endovascular treatment within the carotid system can have a significant risk of mortality and neurologic morbidity, it has become the treatment of choice for CBS.

Jugular Vein "Blowout"

This complication is seen more often because the IJV is preserved more frequently during neck dissection. Jugular vein rupture should be considered in patients undergoing primary tumor excision with MRND complicated by a pharyngocutaneous fistula. In a recent study of six patients who experienced rupture of the IJV, Cleland-Zamudio et al. (184) found that patients who have a complete circumferential dissection of the IJV low in the neck and go on to have fistulas develop may be more prone to this complication. Typically, bleeding is venous and occurs repeatedly. Treatment consists of surgical exploration and ligation of the jugular vein above and below the level of rupture.

HIGHLIGHTS

- A comprehensive knowledge of anatomy and physiology is necessary to understand the nuances of surgical planning and technique as well as the prevention and management of the sequelae and complications of neck dissection.
- At the present time, the role of imaging studies including PET/CT in the evaluation of the N0 neck is limited as it will not detect subclinical metastases in 20% to 50% of the cases.
- SLNB is feasible and useful as a staging procedure in patients with early carcinomas of the oral cavity, particularly for patients with cancers of the oral tongue.
- There is finally consensus about a classification of neck dissections that conveys more precisely the extent of lymphatic and nonlymphatic structures removed in a neck dissection.
- There is now a better understanding of the indications and limitations of the different neck dissections.
- The rate of tumor recurrence in the neck is decreased by the addition of postoperative radiation, when multiple nodes are involved at multiple levels of the neck, and when ECS of the tumor is found.
- The presence of ECS of the tumor is currently considered an indication for postoperative concurrent chemoradiation.
- The most common sequelae following any type of neck dissection is related to weakness or paralysis of the trapezius muscle. Early recognition and rehabilitation are paramount in the management of such patients.

Controversies in Management of the N0 Neck in Squamous Cell Carcinoma of the Upper Aerodigestive Tract

118

Ryan Case *Karen T. Pitman*

Cervical lymph node metastasis is the single most adverse prognostic factor in patients with head and neck squamous cell carcinoma (HNSCC) without distant metastases. The clinically negative neck (cN0) is defined by the absence of palpable or radiographically suspicious lymphadenopathy. Patients who are cN0 can harbor lymphatic metastases that are too small to be detected by imaging or palpation. A discordance between the clinical and pathologic nodal (pN) stage results when subclinical or occult metastases not appreciated on imaging are detected on pathologic examination of the lymph nodes (LNs) following neck dissection.

Management of the cN0 neck is controversial, the decision being to treat or observe the neck. Advocates of observation (OBS), or watchful waiting, will examine the neck during follow-up visits and reserve neck dissection for patients who develop regional metastases. Elective neck dissection (END) or elective neck irradiation (ENI) are management options when the decision is to treat the neck. These management options have been long discussed among head and neck surgeons and the controversy persists despite significant advances in imaging and surgical techniques. The extent of controversy is illustrated by two studies that examined the variability in management strategies of the cN0 neck among otolaryngologists (1,2). A survey of 763 otolaryngologists in the United States showed 13% of the responders would observe the neck in all cN0 patients, 66% would perform END and 19% would recommend ENI. There was also little agreement about the extent of neck dissection among surgeons who operate on the cN0 neck. Similarly, the most recent National Comprehensive Cancer Network (NCCN) treatment guidelines leave the decision of END for early stage (T1 and T2) oral cavity, oropharynx, and supraglottic cancers largely to the discretion of the surgeon (3). NCCN treatment guidelines are based on the consensus of a multidisciplinary panel of experts who have reviewed the best available evidence.

The controversy over management of the N0 neck arises for several reasons. Proponents of OBS argue that the risk of isolated regional recurrence is small and does not warrant the morbidity of END in the majority of patients. Another presumption of OBS is that patients who do recur can be detected early enough for salvage treatment to be effective. Advocates of END argue that pathologic staging provides objective data that guide decisions about adjuvant treatment, as well as accurate prognostic information. All are factors that contribute to the decision about how the cN0 neck is managed.

This chapter explores the controversies that surround management of the cN0 neck. As a starting point, consider the following questions as related to the management options. (a) What is the incidence of occult metastases in the cN0 neck? (b) Do occult metastases impact patient outcome? (c) Can radiographic imaging detect occult metastases with acceptable accuracy?

INCIDENCE OF OCCULT METASTASES

Tumor site, its stage, and in some sites tumor thickness are important determinants of the occult metastases. Estimates of the occult metastatic rate can be obtained by studying the regional recurrence rate in patients who are followed clinically, or by looking at the pN+ rate after END. Using the first method, studies that report on patients who develop isolated regional metastases during OBS are assumed to have had occult neck disease at the time of diagnosis. Data from four studies on the regional recurrence rate of early stage oral tongue and floor of mouth squamous cell carcinoma (SCC) during OBS suggest that the occult metastatic rate approaches 40% (4–7). Reports on the pathologic N stage following END are also available

TABLE 118.1 OCCULT METASTATIC RATE: PATHOLOGIC N STAGE

	pN+ (%)		
Primary Site	**Pitman et al.**	**Byers et al.**	**Shah**
Oral cavity	41	45	34
Oropharynx	36	39	31
Hypopharynx	36	56	17
Larynx (supraglottic/ advanced glottic)	30	26	37

and data from three studies reporting on the pN stage in oral cavity, oropharynx, larynx and hypopharynx SCC, and with the exception of the hypopharynx, showed an occult metastatic rate of greater than 30% for all sites, as shown in Table 118.1 (8–10).

IMPACT OF OCCULT METASTASES

Several studies have sought to correlate patient outcome with the presence or absence of occult metastases. A highly significant survival difference is reported in pN0 versus pN+ patients who are cN0 prior to neck dissection (11,12). Extracapsular spread (ECS) in occult metastases further downgrades disease-related survival, and some reports suggest that ECS in occult nodes has the same impact as it does in palpable nodes (11–14). The number of pathologically positive occult LNs also correlates with survival. Patients with two or more positive nodes have significantly worse survival compared to those with less than two positive nodes (15). Additionally, the impact of nodal ratio (positive:total LNs in the neck dissection specimen) on survival has been evaluated for HNSCC, with increasing nodal ratio negatively impacting survival (16). These data are strong evidence that occult metastases do impact the disease-specific survival. pN staging provides very accurate information about the risk of disease recurrence and is used to select those patients who will benefit from adjuvant radiation with or without chemotherapy.

RADIOGRAPHIC IMAGING

Clinical nodal staging is a multidisciplinary diagnostic problem that starts with palpation of the neck. It is estimated that 1.0 cm is the lower size limit that LNs can be appreciated by palpation, with accuracy of between 59% and 84%. Imaging studies provide an assessment of LN size and shape, as well as information about architecture. Suspicious LNs are spherical and greater than 1.0 to 1.5 cm. LNs that demonstrate central necrosis, surrounding soft tissue invasion, irregular borders, or groups of greater than 2 LNs also heighten suspicion for metastases. Imaging is also helpful in patients when palpation is less accurate, especially patients with a thick or previously treated neck or those who are at risk for metastases to the retropharyngeal and parapharyngeal space LNs. Today, computed tomography (CT), magnetic resonance imaging (MRI), ultrasound (US), and positron emission tomography (PET) scan are utilized to evaluate the N0 neck. Contemporary high-resolution imaging detects a certain percentage of suspicious LNs that are not appreciated on palpation and provides a slight to moderate increase in the detection rate. If imaging can reduce the risk of undetected occult metastases to less than 15%, head and neck surgeons may opt to observe cN0 patients. The question is whether imaging can achieve this aim.

COMPUTED TOMOGRAPHY AND MAGNETIC RESONANCE IMAGING

Studies that corroborate radiographic and pathologic staging provide meaningful information about the accuracy of radiographic staging. Curtin et al. (17) performed one of the most rigorous studies reporting on 213 cN0 patients with SCC of the oral cavity, oropharynx, hypopharynx, and larynx. All patients who had pretreatment CT and MRI of the neck and the imaging results were compared with pN staging. The results were used to calculate the negative and positive predictive value (NPV and PPV) for node sizes from 5.0 to 15.0 mm in 1.0-mm increments. The authors showed that a 5.0-mm node had a PPV of 44% and a NPV of 90%. When a 10-mm threshold was utilized, the PPV and NPV were 50% and 84%, respectively. Accordingly, for every increase in LN size the false-positive rate decreases, but so too does the ability to detect patients that are truly diseased. The accuracy of CT and MRI was approximately equal in this study. Dr. Curtin concluded, "It is unlikely that any imaging study will distinguish normal from metastatic lymph nodes in the 5 to 10 mm range, because nodes less than 5 to 10 mm rarely show internal abnormalities that are used to distinguish suspiciouslymph nodes."

Size measurements of metastatic LNs in END specimens reflect the difficulty with their clinical detection. Approximately two-thirds of occult metastases were less than 10 mm, and of these, up to 50% are less than 3 mm. Importantly, ECS was found in 33% to 36% of occult positive nodes (11).

More recent studies substantiate Curtin's findings. Yuen et al. (18) found that occult metastases were present in 34% of T1/T2 oral tongue SCC patients who were cN0 based on imaging. Another study demonstrated the differences between pathologic and clinical staging with CT and US were highly significant (P = 0.0001) (19).

Imaging can also show false positives when corroborated with pN stage. For example, Walvekar et al. (20) showed that 21% of patients were downstaged from cN+ to pN0 when CT findings and pathology were compared. In addition to downstaging, 26% patients who were cN0 by imaging were upstaged to pN+ following neck dissection. Overall, this study reported a discrepancy between pathologic and clinical nodal stage in 47% of patients with T1/T2 oropharyngeal cancer. The authors of these studies, all performed more recently than Curtin's original study, suggest that radiographic imaging is not accurate enough to take the place of pathologic staging for at-risk patients.

ULTRASOUND-GUIDED FINE NEEDLE ASPIRATION

Ultrasound-guided fine-needle aspiration (USGFNA) of suspicious LNs is another method to evaluate patients who are N0 by palpation. US examination of the neck and biopsy is typically performed by the head and neck surgeon familiar in lymphatic drainage patterns and risk factors for occult metastases. US criteria for suspicious nodes are similar to those used for CT and MRI and according to published protocols at least one suspicious node per patient is sampled by fine-needle biopsy under US guidance. US measurements of LNs are highly accurate making it an excellent method to detect serial changes in LNs during follow-up. When fine-needle aspiration (FNA) results are positive, the neck is treated. FNA negative patients are staged N0 and followed clinically with frequent US examination of the neck. The low cost of examinations, accurate measurements of LN size, the lack of exposure to ionizing radiation, and the ability to needle biopsy suspicious nodes during the examination highlight the appeal of this technique. Isolated regional recurrences detected with follow-up US examinations are reported by three groups studying early stage tongue cancer, ranging from 18% to 31% (21–23).

van den Brekel et al. (21) studied 77 patients with oral cavity lesions staged cN0 by USGFNA. Tumors were resected transorally and the neck was followed with US at 2- to 3-month intervals. The regional recurrence rate during follow-up was 18%. Six recurrences were detected on US, eight patients presented with palpable nodes, and the salvage rate was 71.4%. In two similar studies, patients with T1 and T2 oral tongue tumors who were cN0 by US were followed. The incidence of isolated regional recurrences was 28.5% and 31%, with salvage rates of 46% and 100% (22,23). The authors of these three studies advocate the use of USGFNA nodal staging. Close clinical follow-up and strict patient compliance are required for early detection of recurrences and meaningful salvage. Notably, the 100% salvage rate was reported by for patients enrolled in a prospective trial (23).

POSITRON EMISSION TOMOGRAPHY

PET is a functional imaging modality that provides information about the metabolic activity of tissues. Because the metabolic rate of SCC is higher than surrounding normal tissue, Fluorodeoxyglucose—the radioactively glucose analog used for imaging, accumulates in cancer cells at increased rates resulting in higher standard uptake values. Combined PET/CT scanners are now available and provide the anatomic detail of CT and the whole body sensitivity of PET. Three studies using PET for the cN0 neck showed NPVs of 88% to 92% (24–26) and found that false positives were possible in conditions that increased glucose metabolism including inflammation, sarcoidosis, and normal salivary tissue. False negatives occurred with necrotic LNs and when metastatic LNs were less than 5.0 mm, suggesting that a minimum tumor volume must be present to detect a difference in glucose utilization above background. Two studies have demonstrated that at least 5-mm tumor must be present to be detected and suggest PET does not achieve the diagnostic accuracy of END (26,27).

More recent studies using higher resolution fused PET/CT scanners show a significant false-positive rate of 16% to 27%. The authors of these studies conclude PET is a valuable test for detection of unknown and second primary tumors as well as distant metastases, but does not currently have the accuracy to replace END or guide therapeutic decisions in the N0 neck (27–30).

In 2011, Stoeckli et al. (31) compared CT, PET/CT, US, and USGFNA for neck staging in a prospective study of 76 patients. The study protocol included imaging with all four radiographic modalities prior to surgery that included neck dissection. Results showed that USGFNA overstaged the fewest, with only 7% false positive (7% to 16%). Understaging was equivalent for all modalities with false-negative rates of 21% to 25%. Despite significant improvements in imaging technology over the past decade, even recent data suggest no imaging study can assess N stage with 100% accuracy. Size and changes in LN architecture or metabolic activity determine if a study is positive or negative. Since a significant percentage of occult nodes fall outside of these radiographic parameters, both the false-positive and false-negative rates are significant. Further prospective studies that correlate the pN stage with combined PET/CT findings are required to determine if it can reduce the risk of undetected metastases to an acceptable level.

MANAGEMENT STRATEGY FOR THE N0 NECK

Patient and tumor-related factors impact the decision to electively treat the neck. Many clinicians cite unreliable patient follow-up as justification for elective treatment

of the neck. ENI is used when radiation is used to treat the primary tumor so the patient is treated with a single modality. If the neck will be entered for resection of the tumor or reconstruction, most surgeons advocate END. Accordingly, END becomes a question when treatment of the primary does not involve access to the neck. Examples include transoral resection of oral cavity and oropharyngeal tumors and transoral laser or robotic excision of laryngeal or pharyngeal tumors.

Surgeons typically use a 15% to 20% or greater risk of occult metastases as the threshold to perform END. Table 118.2 shows estimates of the likelihood of occult metastases based on the site and stage of the primary tumor. The threshold of 20% is based on a decision analysis performed by Weiss et al. published in 1994 (32) that compared survival outcomes for patients managed by END versus OBS. The method for a decision analysis concerning management of the N0 neck involves the use of decision trees using the alternative management options and probabilities based on published data. It is used to guide management decisions when no clear consensus emerges from the available data. Weiss et al. (32) reviewed outcome data for END versus OBS published in the 1980s, and some authors believe older results no longer be relevant given advances in technology and surgical technique. Using more recent data, the decision analysis by Okura et al. (33) suggested that a threshold of 44% could be utilized because detection of occult metastases, salvage rates, and the morbidity of END had all improved. In contrast, Song et al. (34) suggested that an 18% risk of occult metastases would provide benefit for END in patients with early stage tongue cancer. Their model showed that OBS would be an acceptable strategy only if the occult metastatic rate is less than 18% and salvage rates for regional recurrences is 73% or greater. These three decision analyses use theoretical models based on published data from the literature reporting on the risk of occult metastases and salvage rates.

TABLE 118.2 RISK OF OCCULT METASTASES BY SITE AND STAGE OF PRIMARY TUMOR

	Stage	Site
<15%–20%	T1	Glottis (T1/T2), retromolar trigone, gingiva, hard palate, buccal mucosa
>20%–30%	T1	Oral tongue, soft palate, pharyngeal wall, supraglottic larynx, tonsil
	T2	Floor of mouth, oral tongue, retromolar trigone, gingiva, hard palate, buccal mucosa
		T1–4 nasopharynx, piriform sinus, base of tongue
	T2–4	Soft palate, pharyngeal wall, supraglottic larynx, tonsil
	T3–4	Floor of mouth, oral tongue, retromolar trigone, gingiva, hard palate, buccal mucosa

Modified from Mendenhall et al. (42).

Elective Neck Dissection

The procedural details of END have evolved from the use of radical neck dissection (RND) over 100 years ago, to more targeted, selective operations that are widely used today. Based on OBSs that regional recurrence rates were lower in some cN0 patients whose necks were dissected electively, Crile (35) introduced the concept of END in 1905. Hayes Martin popularized the concept of RND and described it as en bloc resection of levels I to V that included the sternocleidomastoid muscle, CN XI, and internal jugular vein and this became the standard for END in the United States (36,37). Martin's precepts were not challenged until the 1960s when Bocca proposed a conservation technique that preserved major structures (38). The rationale for preserving structures was based on OBSs that the lymphatic system of the neck is contained within the adipose tissue and does not extend beyond the fascial sheaths. By removing the fascia surrounding the sternocleidomastoid muscle, internal jugular vein, and CN XI, the cervical LNs in level I to V are completely excised. Subsequent studies have shown that modified radical neck dissection (MRND) is as effective as RND for both elective and therapeutic neck dissection when the preserved structures are not involved by tumor. Aside from the obvious functional and cosmetic advantages, MRND made simultaneous bilateral neck dissections a safe alternative when operating on both necks. The concept of selective neck dissections (SNDs) emerged as clinical studies suggested that metastases travel from the primary site to predictable first echelon nodal groups and then on to adjacent nodal basins. Retrospectively analyzing the location of occult metastases following elective MRND, Shah and Byers independently reported on the patterns of occult metastases from primary sites of the head and neck (8,9,39). SNDs were defined as a dissection that removes only the cervical levels that are at greatest risk for metastases. Today most surgeons remove levels I to III or I to IV for oral cavity primaries and levels II to IV for laryngeal, hypopharyngeal, and oropharyngeal primaries, and may include level VI in select laryngeal and hypopharyngeal sites. Treatment of the contralateral neck is given consideration for supraglottic, base of tongue, palate, and primary tumors that approach or cross the midline (3). Advantages of selective procedures are the reduction in surgical morbidity and cosmetic impact compared to RND and MRND. During the 1980s and 1990s surgeons at most centers in the United States adopted SNDs as the preferred procedure for END.

Regional recurrences following END occur at a rate of 3% to 6% regardless of the procedure utilized (RND, MRND, or SND) (10). Regional recurrences can be thought of as either an error in surgical technique or in the pathologic sampling technique. If the surgeon does not completely dissect the levels at risk, or the tumor has metastasized to levels not predicted by the primary tumor recurrences are possible. The accuracy of pathologic staging also depends on how carefully the pathologist examines the neck specimen. The detection rate is higher when cervical nodes are serially sectioned with thin cuts versus bisecting LNs; and a small percent of occult metastases are likely beyond the resolution of light microscopy. Immunohistochemical (IHC) analysis for several tumor markers in electively dissected neck specimens showed that 20% to 30% of the nodes that were pN0 on light microscopy had evidence micrometastases of on IHC analysis (40,41).

Elective Neck Irradiation

The factors that influence the decision to irradiate the cN0 neck are similar to those for END. ENI is the treatment of choice when the primary tumor is irradiated and the risk of occult metastases is greater than 15% to 20%. It is also an option for patients who are poor surgical candidates. Patients' compliance with follow-up and the morbidity of ENI are also considered. Patients who are cN0 receive substantially lower radiation doses to the neck than cN+ patients and have an associated reduction in the treatment-related morbidity. The availability of conformational and intensity modulated radiation therapy has minimized the volume of normal tissue that is included in the treatment portals further reducing the morbidity of ENI. Mendenhall et al. (42) have reported regional recurrences in less than 5% of patients following ENI. One advantage of ENI is the ability to address groups of nodes that are not typically included in END. These include the retropharyngeal and parapharyngeal space LNs that are at risk of harboring occult metastases in tumors of the oropharynx, hypopharynx, nasopharynx, and nasal cavity.

A significant shortcoming of ENI is that the prognostic information from pathologic staging is not known. It is also more difficult to detect recurrences following ENI and the use of reirradiation can be limited.

END Controversies

Central to the debate surrounding the value of END is whether removing occult neck disease affords a survival advantage when compared to a policy of clinical OBS. There are four prospective randomized reports comparing END to OBS for oral cavity cancers treated with transoral excision or irradiation. They span 30 years and report a wide range of salvage rates. Disease-free survival rates for the OBS groups range from 49% to 87% in these studies. Only one study showed a statistically significant advantage for END (43), and another showed an advantage but state their study group was too small to achieve statistical significance (6). One study randomized patients after receiving interstitial radiation to tumors of the oral tongue (44). The most recent study followed patients in the OBS group with monthly neck US examination and reported a 100% salvage rate for isolated regional recurrences in the OBS group (23). The results of this prospective study are in marked contrast to a retrospective study published 10 years earlier by the same group. Their earlier study reported a 50% salvage rate and a statistically significant improvement in disease-free survival for END (45). The authors attribute disparate results to the rigorous schedule of follow-up with monthly US for patients enrolled in the prospective clinical trial. All four studies showed that END markedly improved the regional control rate with regional recurrences in 6% to 30% of the END group versus 37% to 58% in the OBS group. Fansula et al. (46) performed a meta-analysis of these four studies. By combining outcomes for the 283 patients from these reports, they showed that END significantly reduced the disease-specific mortality and acknowledged the advantage for END in early tongue cancer. Meta-analysis was used in this case to increase the sample size, hence the statistical power, to provide a more accurate estimate of the true effect of END.

Retrospective studies also show mixed results. Smith et al. (47) reported on the outcome of 150 patients with T1 to T4 N0 oral cavity and oropharyngeal tumors. There were 75 patients in the END group based on a greater than 20% risk of occult metastases or if the neck was entered for the tumor resection or microvascular reconstruction. The other 75 patients were managed with OBS based on less than 20% risk of occult disease. Despite a statistically significant difference in the regional recurrence rate, 5% for the END group and 20% for the OBS group, the difference in the 5-year survival rate between the two groups was not significant. The authors did show highly significant differences in 5-year survival rates based on the number of pathologically positive nodes ($P < 0.001$).

Duvvuri et al. (48) compared the outcome of 359 patients with T1 to T4 N0 oral cavity and oropharyngeal tumors managed with END versus OBS. The treatment groups were based on time period they were treated, for example, before or after 1990 when the management strategy changed END was performed routinely in N0 patients. The 5-year overall survival between END and OBS groups was not different, but the difference in the regional recurrence rate, 15% versus 27% for the END and OBS groups, respectively, was highly significant ($P < 0.0001$). In both studies, more patients in the END group received adjuvant radiation, a direct result of the pathologic staging information.

A similar study (49) analyzed 54 patients with T1 to T3 N0 oral cavity tumors managed with END versus OBS. There was no difference in the overall survival between treatment groups. But when stratified by T stage, for T1 tumors there was no difference between the treatment

groups for the regional recurrence rate or overall survival. But for patients with T2 and T3 tumors, the regional recurrence rate and the associated mortality were significantly higher in the patients in the OBS group and the authors advocated END.

Other retrospective studies have shown a significant survival advantage for patients who receive END. Yuen et al. (45) performed a retrospective review of 63 patients with T1 and T2 oral tongue tumors. For the 33 patients in the END group, both regional recurrences and 5-year overall survival rate were significantly improved compared to the 30 patients who were observed (P = 0.0008 and P = 0.01, respectively). Despite surgical salvage of 50% of the regional recurrences in the OBS group, the regional recurrence-related mortality in this group was 23% compared to 3% in the END group and this benefit translated to a significant improvement in 5-year overall survival. In another study that examined 153 patients with T1/T2 oral SCC with thickness 4 mm or more showed a statistically significant (P = 0.001) improvement in regional recurrence-related survival for END compared to OBS (50).

In a detailed analysis of patients with T1 and T2 N0 oral tongue tumors, Haddadin et al. (51) compared the outcome of 64 patients who were observed to that of 37 who received END. The institutional policy was to observe the neck in all patients with T1 or T2 oral tongue tumors unless the neck was entered to resect the primary or perform reconstruction. The authors did show a trend toward improved 5-year overall survival for the END cohort. Subset analysis of the T2 tumors demonstrated a highly significant survival advantage for END (P = 0.0007). The authors also showed that the incidence of greater than 2 LNs and/or ECS was significantly higher in the patients who required therapeutic neck dissection than in patients who received END (P = 0.001 and P < 0.0001). The impact of this finding is illustrated by comparing the 5-year survival of patients who were pN+ after END versus therapeutic dissections, which was 69% versus 35%, respectively (P = 0.04). Another retrospective report showed no significant difference in survival outcomes for patients treated with END versus observation for oral cavity, larynx and pharynx (52).

These seven retrospective studies all show significant improvements in the regional recurrence rate for patients managed with END. The benefit in disease-related survival is less clear and retrospective studies will probably never conclusively answer the question. Rodrigo et al. (53) performed a meta-analysis of 21 prospective and retrospective studies comparing END to OBS in N0 patients with early stage oral, oropharyngeal, and supraglottic cancers. Their conclusion was that based on the best available evidence, END does not appear to provide a survival advantage over OBS, but the studies analyzed are not of sufficient quality to provide definitive recommendations for management of the cN0 neck. These patient cohorts are difficult to analyze because of differences in institutional treatment plans, time period, and the significant number of patients who succumb to local and distant recurrences or medical comorbidities, ultimately leaving the number of patients who develop isolated regional recurrences and can be analyzed relatively small. While END may not show benefit when the entire cohort is analyzed, scrutinizing the outcome of pN+ patients may demonstrate a benefit.

Other Considerations

END is a consideration for patients with unilateral N+ disease and contralateral N0 disease in a malignancy for sites that bilateral END is not usually recommended, such as tonsil, oral tongue, and piriform sinus cancers. This was addressed for tonsil cancer by Lim et al. (54), who found that in patients with tonsillar cancer who were ipsilateral N+, there was a 21% rate of contralateral neck disease which portended a poorer survival. Contralateral neck disease was also influenced by T stage, and the authors concluded that the contralateral neck should be addressed in patients with ipsilateral neck metastasis or advanced T stage (T3 to T4). Koo et al. (55) examined patients with piriform sinus SCC and found that ipsilateral neck disease and extension of the primary across midline was associated with occult disease in the contralateral neck and therefore recommended bilateral neck treatment in the aforementioned situations. In the oral cavity, END of the contralateral N0 neck has not shown to improved survival in patients with early stage SCC of the oral tongue (56).

Salvage surgery for recurrent head and neck tumors that were treated with primary radiation and remain N0, with isolated primary recurrences is another area of discussion. If the necks received ENI, the dilemma in patients who remain N0 is whether to perform END at the time of salvage surgery. Bohannon et al. (57) compared 38 patients who underwent END with salvage laryngectomy with 33 whose necks were not dissected. Their results were mixed with higher fistula and complication rates in patients undergoing END, but lower rate of regional failure (7.9% vs. 15%). There was no statistically significant survival difference between the two groups. A similar study examined 57 patients with recurrent oropharyngeal, hypopharyngeal, and laryngeal cancers treated with primary radiation and were N0 at recurrence. Dagan et al. (58) concluded that adding END to the salvage surgery increased morbidity while there was no benefit in survival or locoregional control when initial treatment included ENI.

FUTURE DIRECTIONS

More accurate, less invasive methods to evaluate the cN0 neck are active areas of investigation. Sentinel lymph node biopsy (SLNB) and pathologic predictors of occult metastases are two techniques that demonstrate potential for routine clinical use in the future. The concept of the sentinel lymph node (SLN) is described as the first echelon lymph node that is most likely to contain metastases if they are

present. Morton et al. at the John Wayne Cancer Center are credited with the development of the technique for selective identification and biopsy of the SLN in patients with intermediate thickness cutaneous melanoma (CM). SLNB is based on the premise that metastases travel sequentially from the primary tumor, to the SLN and then on to the remaining regional LNs. Therefore, the histopathologic status of the SLN accurately reflects the pathologic status of the remaining regional lymphatics and patients with pathologically negative SLNs can be spared the morbidity of regional lymphadenectomy. Since Morton's original description of the SLNB technique, investigators worldwide have contributed to the evolution and refinement of the technique that is currently used. Multiple studies show highly acceptable sensitivity and false-negative rates for SLNB (59) and today SLNB is considered the standard of care for patients with intermediate thickness CM (60).

Preoperative lymphoscintigraphy performed by nuclear medicine uses peritumoral injection of a radiotracer, directing the surgeon to the lymphatic regions at risk (Fig. 118.1). In the operating room, the surgeon uses a gamma probe to identify radioactive SLNs and may use blue dye injections around the tumor for visual identification.

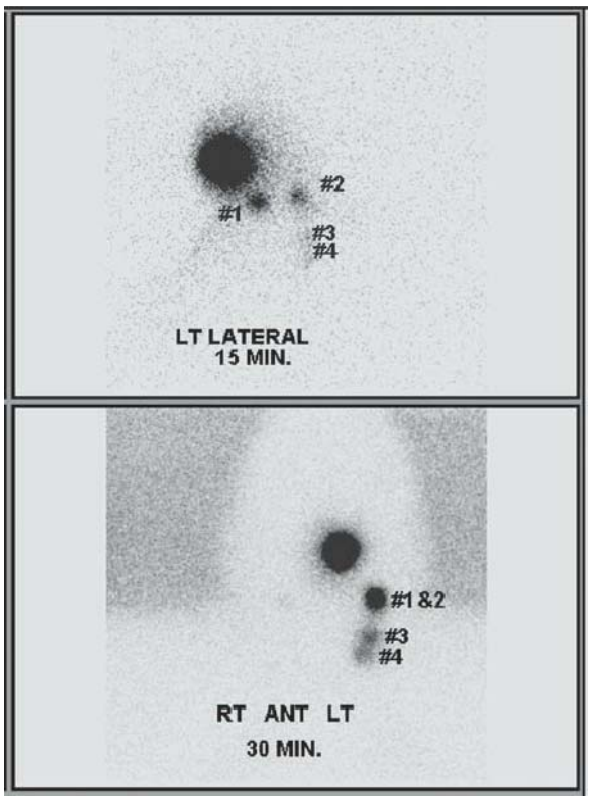

Figure 118.1 Lateral and anterior-posterior lymphoscintigraphy images at 15 and 30 minutes postinjection of Technetium–sulfa colloid. The patient is a 42-year-old man with a cT1N0M0 SCC of the left lateral tongue. Surgical pathology was SCC, 1.2 cm in greatest diameter, with maximum depth of invasion 4.1 mm. SLNB results: SLN 1 was a 7 × 5 × 2 mm LN with a 1-mm focus of SCC. SLN 2–4 showed no evidence of carcinoma on H&E or cytokeratin immunohistochemical staining.

The SLN is exposed through a small skin incision and is identified by the presence of blue staining and/or radiotracer uptake detected by the gamma probe. The SLN(s) are removed and sent to the pathologist for histologic and IHC analysis. Therapeutic node dissection is performed only in patients whose SLN is positive.

SLNB has been studied in head and neck cancer patients who are cN0. Guidelines published in 2010 describe the indications as well as the radiologic, surgical, and pathologic techniques for localizing, obtaining, and processing SLNB in patients with oral/oropharyngeal SCC (61). The preliminary experience in HNSCC was summarized by Ross et al. (62) and included data from 22 centers. Analysis of 316 cN0 necks showed that the SLN was identified in 95% with an overall accuracy of 90%. When the results from centers that performed less than 10 cases were excluded, the sensitivity of SLNB was 94% relative to simultaneous END. The ACOSOG multi-institutional study compared the accuracy of SLNB versus END in patients with T1/T2 N0 oral cavity SCC. SLNB compared favorably to END, with a 96% NPV for SLNB (63). SLNB for oral cavity tumors appears to offer patients a reduction in the overall morbidity and cost compared to a blanket policy of END (64).

Advantages of SLNB specific to head and neck tumors include the ability of preoperative lymphoscintigraphy to map the patient's unique lymphatic drainage pattern and direct the surgeon to cervical levels that may not have been predicted by the site and stage of the primary tumor. Results of preoperative lymphoscintigraphy show a significant rate of aberrant lymphatic draining for the head and neck. Three independent studies have shown that 15% to 20% of ENDs for HNSCC, and over 30% for head and neck CM would have been misdirected had they been based solely on classical anatomic studies (59,65,66). Another advantage is that SLNB is a cost-effective method for pathologic examination of select LNs. Rather than examining all of the nodes in a neck dissection specimen, SLNB identifies an average of two or three nodes per patient. This facilitates the routine use of more costly and time-consuming serial sectioning and IHC required to accurately diagnose occult metastases. Using SLNB and IHC, several investigators have shown significant improvements in the accuracy of staging the cN0 neck (61,67,68). A recent review of the literature of SLNB for the cN0 head and neck patients confirms the conclusions of preliminary reports: that SLNB is safe and efficacious, although a learning curve does exist with high volume centers better equipped to achieve consistent results (69).

Ferris et al. (70) have designed a rapid, quantitative PCR assay that accurately identifies positive SLNs in the operating room. Further study and validation at other institutions will rectify one of the major drawbacks of SLNB, namely that for patients whose SLNs are positive, neck dissection is deferred to a separate procedure due to the time required for accurate step sectioning on permanent section.

PATHOLOGIC PREDICTORS OF METASTASES

The site and stage of the primary tumor are important considerations in assessing the risk of occult metastases. While there is a direct correlation between tumor stage and the occult metastatic rate for some sites, for example, in glottic SCC, tumor thickness has been shown to be a predictor of occult metastases for some sites including the oral tongue, floor of mouth, and oropharynx (71). Tumor thickness has been most intensively studied for oral tongue tumors (72,73). Yuen et al. (74) examined several histopathologic characteristics of 72 patients with T1 and T2 oral tongue tumors that were correlated with occult metastases. On multivariate analysis, tumor thickness was the only factor that correlated with occult metastases and 5-year survival. The pN+ rate for tumor thickness 3 mm or less was 8%. Metastases occurred in 44% of tumors between 3 and 9 mm, and in 53% of those tumors with thickness greater than 9 mm. The 5-year survival by thickness grouping was 100%, 77%, and 66%, respectively. Other studies have examined other histomorphologic features including perineural, lymphovascular, and the mode of invasion and grade of differentiation as risk factors for occult metastases and shown correlations (75–78).

Pathologic findings highlight one of the shortcomings of the current tumor nodal metastasis staging system. For instance, oral cavity tumor stage is defined primarily by tumor size and these studies suggest that some early stage tumors may have very aggressive characteristics. Investigators seeking to improve the prognostic capabilities of tumor staging have focused on characteristics of the primary tumor that are correlated with nodal metastases. Pathologic predictors of occult metastases that can be characterized with light microscopy, IHC (79), DNA analysis (80), and expression profiling (81) are currently under investigation. Many studies suggest that the specific correlates of metastases may be different for different anatomic sites. Additionally, combinations of parameters may more accurately predict the risk of metastases because it is unlikely that a single characteristic of the tumor will have a distinct cut off point in differentiating metastatic from nonmetastatic disease. A histologic malignancy score for oral cavity tumors based on a several histologic findings such as the keratinization, frequency of mitotic figures, pattern of invasion, perineural and perivascular invasion has been proposed (75,77). When these were applied prospectively to newly diagnosed patients, metastases were accurately predicted in these reports. Takes et al. (82) used a combination of histologic and IHC findings and showed that LN metastases from laryngeal tumors were accurately predicted ($P = 0.002$).

Once the characteristics of primary tumors that correlate with occult metastases are accurately identified, biologic tumor staging will be possible. One of the goals of these studies is to integrate the biologic correlates of metastases into the tumor staging system so clinicians can make management decisions about the neck based on the results of the pretreatment biopsy.

CONCLUSION

Management of the cN0 neck is controversial. The aim of the pretreatment evaluation of cN0 patients is to accurately identify patients with occult metastases who will benefit from treatment of the neck. Review of the methods that are currently in use for evaluation of the cN0 neck shows that radiographic imaging, and even PET/CT does not distinguish patients with microscopic cervical metastases from N0 patients with acceptable sensitivity and specificity. Biologic tumor staging and SLNB are promising techniques that have the potential to accurately stage the cN0 neck patients before treatment is initiated. Until these investigational staging methods are refined and validated in prospective trials, pathologic examination of the neck contents remains the most accurate method to assess cervical LNs, accurately estimate disease-free survival, and guide the administration of adjuvant therapies.

HIGHLIGHTS

- The incidence of occult cervical metastases is greater than 20% for most head and neck mucosal sites. The exceptions are T1 tumors of the retromolar trigone, buccal mucosal, gingiva, hard palate, and T1 and T2 glottic tumors (Table 118.1).
- The pN status of cN0 patients is strongly correlated with the disease-related outcome.
- Radiographic imaging provides anatomic information that identifies lymph nodes that are suspicious for metastases. It does not have the accuracy to determine whether the N0 neck requires treatment.
- END is currently the most accurate method to stage the cN0 neck. END is a staging procedure that is used to guide subsequent treatment. Its therapeutic value has not been conclusively documented.
- Elective versus therapeutic neck dissection describes the indication for neck dissection. A neck dissection is performed *electively* when there is no clinical evidence of metastases. *Therapeutic* neck dissection refers to procedures that are performed for suspicious adenopathy that is palpable or detected on radiographic imaging.
- Comprehensive versus SND describes what cervical levels are removed. *Comprehensive* neck dissection removes levels I to V. RNDs and all three types of MRNDs are comprehensive procedures. SND removes less than five levels and are named according to the levels removed, for example, SND I to III. Both selective and comprehensive procedures can be used for END.
- Techniques that are less invasive than END and more accurate than radiographic imaging for staging the cN0 neck are under active investigation and hold promise for routine clinical use in the future.

Oral Cavity Cancer

119

Daniel G. Deschler *Audrey B. Erman*

ANATOMY

The oral cavity represents one of the most anatomically diverse regions within the head and neck. Within this relatively confined space operate highly specialized and important physiologic activities, beginning with the ability to communicate through facial animation and articulation. Deglutition originates with the maintenance of oral competence at the anterior oral cavity and then relies on subsequent lubrication, mastication, bolus formation, and then bolus transfer to the oropharynx. Similarly, within the oral cavity, sensory innervation for touch, pressure, temperature, and taste function is notable for its high degree of cortical representation. In order to achieve these critical functions, numerous tissue types are represented within the oral cavity including the mucosal lining, muscle, bone as well as unique tissues including teeth, salivary glands, and epithelium for taste. These tissues are supported by the region's vast and redundant blood supply and innervation (Figs. 119.1 to 119.3).

The oral cavity itself has a strict anatomic demarcation as a head and neck subsite. The boundaries of the oral cavity begin with the lips anteriorly and extend posteriorly to the vertical plane beginning at the junction of the hard and soft palate, continuing inferiorly through the circumvallate papillae at the sulcus terminalis and ending at the hyoid bone. The oral cavity is further divided into subareas including the *"lips, alveolar ridge, floor of mouth, oral tongue, hard palate, retromolar trigone, and the lateral buccal mucosa"* (Fig. 119.4). Each of these subareas has distinct anatomic features and lymphatic drainage pathways, the knowledge of which is imperative in the management of neoplasms of the oral cavity (Table 119.1).

At the most anterior boundary of the oral cavity are the specialized myomucosal element of the *"lips."* Anatomically the region of the lip begins anteriorly with the vermilion border and extends posteriorly along the red lip into the mucosal elements at the labial sulcus. The lateral demarcations of the lip are the bilateral commissures. The philtrum, or Cupid's bow, occupies the midline superiorly and directly opposes the labial tubercle in the midline of the lower lip. The lip has a dense sensory innervation provided by the third branch of the trigeminal nerve and consists of its epithelial lining, muscle, and minor salivary glands. The blood supply is provided bilaterally by the labial arteries, which originate from the facial arterial system. The lymphatic drainage of the lower lip is primarily to the submental and submandibular triangles with subsequent drainage to the upper jugular chain. The lower lip demonstrates propensity for contralateral drainage and therefore bilateral metastasis. The upper lip does not demonstrate significant lymphatic crossover, and lesions of this region will usually metastasize to ipsilateral lymph nodes in level IB, periparotid lymph nodes, and level II jugulodigastric lymph nodes.

The *"lower alveolar ridge"* begins immediately behind the lower lip and its labial sulcus, and is composed of the specialized tooth-bearing bone of the mandible. The oral cavity components of the mandible include the symphysis, perisymphysis, and the bilateral mandibular bodies extending toward the ramus. The visible component of the alveolar ridge has a tightly adherent mucosal and gingival coverage that surrounds dentition where it is present. The bone of the alveolus, or the tooth-bearing component of the mandible, is characterized by thin bone surrounding the tooth with the tooth roots extending deeply into the cortical bone of the mandible. This becomes important as this thin bone can be susceptible to bone erosion by tumors, while the tooth root allows access to the deeper components of the mandible including the marrow space. The inferior aspect of the mandible is composed of dense cortical bone, which provides sufficient support, and this is the supporting bone that remains when teeth are lost and there is regression of the alveolus.

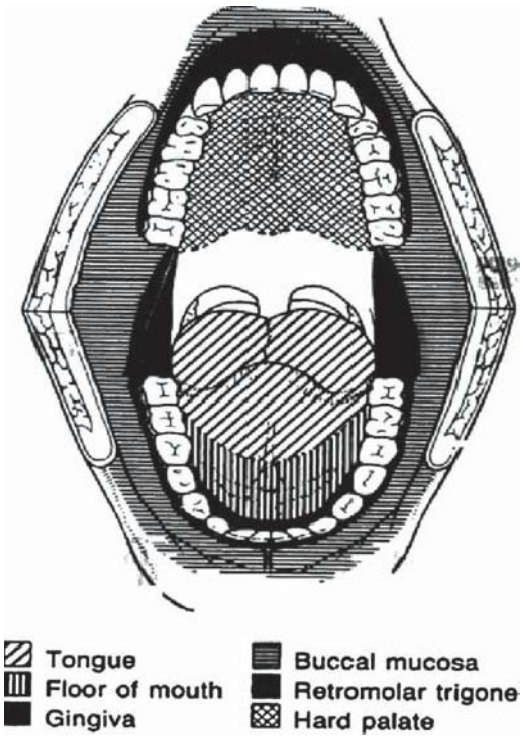

Figure 119.4 Labeled diagram from AJCC Staging Manual.

TABLE 119.1 PATTERNS OF LYMPHATIC DRAINAGE BY SUBSITE OF ORAL CAVITY

Subsite	Common Level of Regional Lymph Node Metastasis
Upper lip	Ipsilateral level IB, perifacial, periparotid, level II
Lower lip	Bilateral levels IA and IB, perifacial, level II
Upper alveolar ridge	Ipsilateral levels IB and II If midline—bilateral
Lower alveolar ridge	Ipsilateral levels IA, IB and II If midline—bilateral
Floor of mouth	Ipsilateral levels IA, IB and II If midline—bilateral
RMT	Ipsilateral levels IIA, IIB and III
Hard palate	Bilateral levels IB and II, retropharyngeal and perifacial
Buccal mucosa	Ipsilateral levels IB, level II

Medially, the mucosal surface of the alveolar ridge extends down the mandibular surface to the mylohyoid muscle and becomes one with the floor of mouth. Laterally, this region will extend to the gingival buccal sulcus and the insertion of the buccinator muscle. The notable tissues within the alveolar ridge include the mucosal and gingival lining as well as bone, muscle, marrow, minor salivary glands, and the teeth. The blood supply to the lower alveolar ridge is comprised of both an endosteal and a periosteal blood supply. Primary innervation is via the inferior alveolar nerve from V3, which enters the mandible at the mandibular canal within the medial ramus and exits at the mental foramen, as the mental nerve. The drainage of the alveolar ridge is dependent upon its location. Anterior lesions drain to level I and have bilateral drainage to level IB. Lateral lesions will drain to level IB as well as level II.

Directly within the lower alveolar ridge lies the crescent-shaped region known as the "*floor of mouth*" (Fig. 119.5). The floor of mouth extends from the attached gingiva of the medial alveolar ridge to the muscular tongue. Anteriorly, the region begins just posterior to the incisors and extends bilaterally to the anterior tonsillar pillars. The mucosal covering here is a very thin layer with a high degree of mobility. Within the floor of mouth are numerous salivary glands including minor salivary glands, the sublingual glands, as well as the ductal apparatus of the paired submandibular glands. All of these salivary glands have a drainage pathway within the floor of mouth, with the submandibular glands draining through Wharton duct and emptying anteriorly into the oral cavity on either side of the midline frenulum. The primary vascular supply to the floor of mouth is from the lingual artery and elements of the facial system with the primary neural supply being from the third branch of the trigeminal nerve via the lingual nerve. Anatomic injection studies demonstrate both a superficial and deep lymphatic drainage system for the oral cavity (1). This superficial system can demonstrate bilateral drainage, whereas the deep system will drain primarily to the ipsilateral level I and upper jugular chain. Anterior floor of mouth lesions will have propensity to drain to the levels of IA and IB.

The "*oral tongue*" consists of that portion of the tongue that extends from the tip to the region of the circumvallate papillae and constitutes two-thirds of the entire tongue. The oral tongue has four distinct anatomic regions: the tip, the lateral borders, the dorsum, and the ventral surface. The oral tongue is a highly specialized muscular unit with a similarly specialized mucosal lining having a dense innervation for touch and specialized epithelium for taste. The muscular component of the oral tongue is composed of six paired muscles (Fig. 119.6). The three extrinsic muscle groups include the paired genioglossus, hyoglossus, and styloglossus muscles that achieve the gross movements of the body of the tongue. The intrinsic musculature of the tongue includes the lingual muscles and the vertical and transverse muscular units that provide most of the tongue's bulk. These muscles have intricate mobility and interaction critical for the functions of speech and deglutition. The motor innervation of the tongue is provided by the twelfth cranial nerve with sensory innervation from the lingual nerve via V3. Taste sensation is delivered from thousands of gustatory receptors located within the taste buds of the oral cavity through the chorda tympani and the glossopharyngeal nerve. Lesions on the tip of the tongue and midline dorsum can have a propensity for bilateral lymphatic spread as well as spread to level IA. Lateral tongue lesions will primarily spread to the ipsilateral level IB and level II. Additionally, there are anatomic and clinical series alerting practitioners to the potential of spread to levels III and IV of the neck from tongue carcinomas even in the absence of spreads to level I or level II.

Proceeding posteriorly from the upper lip, begins the "upper alveolar ridge." In parallel to the lower alveolar ridge, this region is characterized by dense tooth-bearing bone and has similarly specialized tissues. Most anteriorly in the upper alveolar ridge is the triangular-shaped premaxilla. This portion of the maxillary alveolar ridge

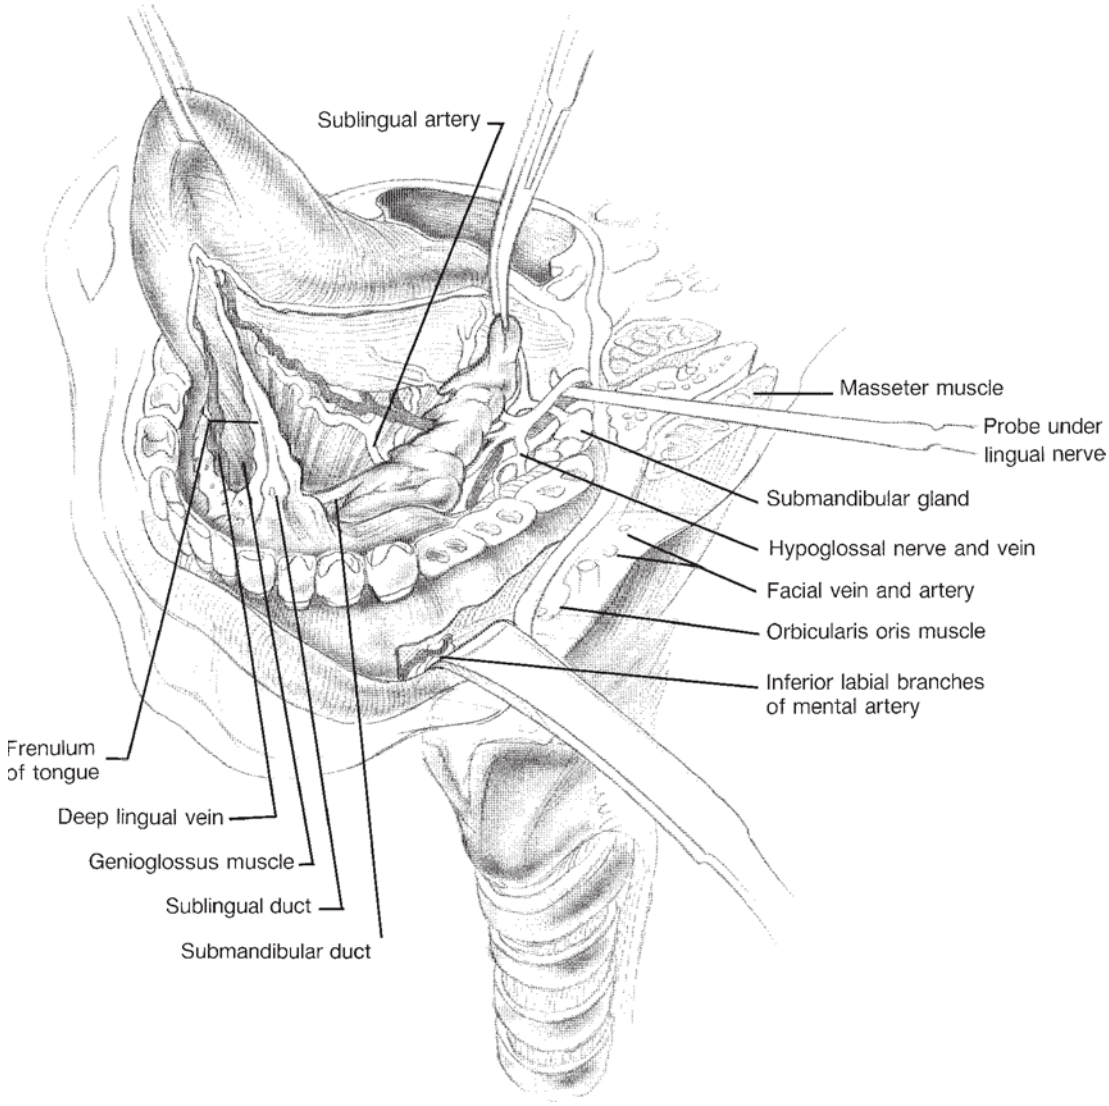

Figure 119.5 Floor of the mouth.

contains the incisors and has its apex at the incisive foramen. Posteriorly, the upper alveolar ridge extends to the maxillary tuberosities bilaterally. Similar to the lower alveolar ridge, the mucosa and gingiva are firmly adherent to the underlying bone, conferring the same propensity for cortical erosion, and spread down tooth roots, which exit in the lower alveolar ridge. In contrast to the lower alveolar ridge, the deep bone of the upper alveolar ridge lacks the same dense cortical characteristics of the mandible and instead thins as the maxillary sinuses begin. The thin bone at this interface is less resistant and readily allows tumor spread into the sinuses. The upper alveolar ridge is innervated by the second branch of the trigeminal nerve and has a considerable blood supply from the facial artery as well as branches of the internal maxillary artery including the sphenopalatine artery. Lymphatic drainage is to level IB, periparotid lymph nodes, and level II.

Within the bony borders of the upper alveolar ridge rests the anatomic unit of the "hard palate." The hard palate is primarily thin bone with a very tight mucosal layer overlying it on both the oral and nasal surfaces. The paired palatine processes of the maxilla extend to the level of the second posterior molar and form the bulk of the hard palate. At the most posterior edges are the paired horizontal processes of the palatine bone through which the greater palatine nerve and vessels exit via the greater palatine foramen. Although the periosteum overlying the hard palate is very dense and resistant to tumor invasion, there are important areas of potential tumor spread related to the foramen of the hard palate including the greater palatine, the lesser palatine, and the incisive foramen. In addition to its mucosal covering, there are numerous minor salivary glands throughout the hard palate region. Primary lymphatic drainage is to levels I and II.

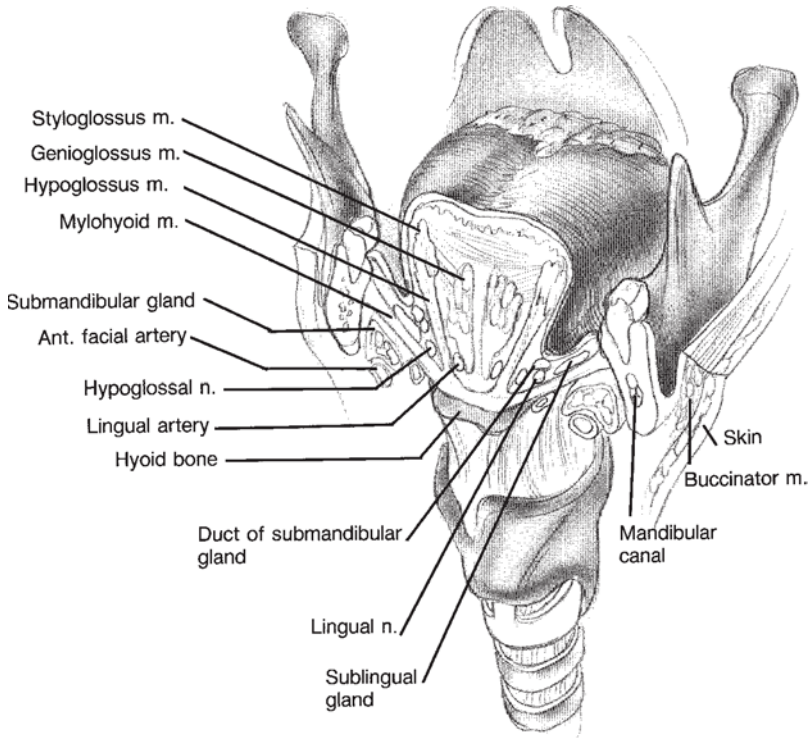

Figure 119.6 Intrinsic muscles of the tongue.

At the most posterior margin of the oral cavity is the *"retromolar trigone or RMT."* This region consists of a mucosally covered triangular area that overlies the ascending ramus of the mandible. The base of this triangle rests at the last lower molar of the lower alveolar ridge and the posterior body of the mandible. The apex of the RMT is the maxillary tuberosity. The medial border is the anterior tonsillar pillar, and the lateral border is the buccal mucosa. The mucosa of the RMT is very tightly adherent to the underlying mandible and is an area prone to mandibular invasion even with small lesions. The lymphatic drainage of this area is to levels I and II, but because of its proximity to the oropharynx, a special consideration must be given to both levels IIA and IIB with RMT lesions.

The last and most lateral component of the oral cavity is represented by the *"buccal mucosa."* This region extends from the RMT and the pterygomandibular raphae posteriorly to the oral commissure and lips bilaterally. The region has a mucosal lining surface that extends from the upper alveolar ridge superiorly to the inferior alveolar ridge inferiorly. Deep to the mucosal lining is the pharyngobuccal fascia and the buccinator muscle. The parotid duct pierces the buccinator and the pharyngobuccal fascia to exit at the Stensen duct lateral to the upper second molar. Tumors penetrating these anatomic layers can readily involve the laterally placed buccal fat pad and the subcutaneous as well as cutaneous structures of the cheek. Sensation to this region is provided by nerves from the second and third branch of the trigeminal system, whereas the buccinator muscle is innervated by the seventh cranial nerve. The lymphatic drainage to the buccal mucosa is quite dense and primarily drains to levels I and II but may extend to the periparotid lymph nodes as well.

EPIDEMIOLOGY

Assessment of statistics related to oral cavity cancer must done with care as often cancers of the oropharynx, a distinct subsite of the head and neck with a unique epidemiology, are included under the term "oral cancers." True oral cavity malignancies are the 10th most common cancer worldwide in men with over 170,000 new cases per year and a mortality rate approaching 50% and the 15th most common in women with over 83,000 cases and a similar mortality rate (2). Globally, the incidence of oral cavity cancer is 1.5 times higher in men than women (3), whereas in the US the male:female ratio is 2:1 (4). Certain geographic regions have a very high incidence such as Micronesia with 24 cases per 100,000 in men compared to 6.7 per 100,000 men in Western Europe (5).

In the US, head and neck cancer—inclusive of all subsites—is the sixth most commonly occurring cancer. Review of the Surveillance, Epidemiology and End Results (SEER) data base indicates that 38% of these occur in the oral cavity, making it the most common subsite. Thirty-two percent will occur in the oral tongue and 20% in the floor of mouth, making these the most commonly affected sub areas within the oral cavity (6). In 2011, the American Cancer Society estimated that 25,820 new cases of oral cavity cancer would occur in the US of which nearly 12,000 would

originate in the tongue (7). Five to six thousand oral cavity cancer–related deaths occur per year (7). Yet, the incidence and mortality rates of oral cavity cancer have been declining, albeit in small increments, over the past few decades. From 1975 to 2008, the incidence of oral cavity in the United States decreased by 1%, and the mortality declined by 1.3% (8). This likely reflects decreases in tobacco consumption within the population. Racial disparities also exist. Although the incidence of oral cavity and oropharynx cancers is essentially equal among African American and White US males, death rate of African American males is nearly twice that of Whites (9). Although the average age of occurrence of an oral cavity cancer is approximately 60 years and nearly 95% of patients will be over 40 years old at the time of presentation, there is concern that the incidence of tongue cancer in younger patients has been steadily increasing over the same time period (10,11).

The overwhelming majority, nearly 95%, of oral cavity cancers will be squamous cell carcinomas (SCCA) arising from the squamous epithelium lining the oral cavity. The next most common histology is tumors of salivary gland origin. Because of the diverse tissues within the oral cavity, a wide variety of tumors may occur in this region. Sarcomas of bone (osteosarcoma), muscle (rhabdomyosarcomas), and other soft tissues (fibrosarcomas and liposarcomas) may occur. Similarly, lymphomas, mucosal melanomas, and nerve sheath tumors may also present in the oral cavity. Tumors of dental origin, both benign and malignant, complete the differential of primary lesions within the oral cavity. Metastatic lesions, albeit rare, can also occur (Table 119.2).

TABLE 119.2 TUMORS OF THE ORAL CAVITY

- Metastatic lesions

ETIOLOGY

Use of tobacco and related products, as well as alcohol consumption, are the greatest risk factors for developing the most common carcinoma of the oral cavity—SCCA. Approximately 75% of oral cavity carcinomas will be related to tobacco and alcohol use (12). The risk of developing oral cavity cancer is correlated with tobacco use in a dose-dependent fashion. Oral cavity cancer risk increases 1.5-fold in light smokers (less than 10 cigarettes per day) and increases to a fourfold greater risk in smokers of greater than 30 cigarettes per day (13). The risk markedly increases with a smoking history of longer than 20 years and greater than 20 cigarettes daily (13). In Europe and South America, non–alcohol users who smoked had a threefold greater incidence of oral cavity SCCA than nonsmoking nondrinkers. In former smokers, the risk of developing cancer declines with time. After 9 years of cessation, patients had a 50% reduction of risk of cancer (14), and patients have only a 1.5-fold increase in cancer rates after 20 years of cessation in comparison to nonsmokers (14). In patients cured of a primary oral cancer malignancy, 40% recurred or developed a secondary head and neck primary, whereas only 6% of patients recurred after smoking cessation (15).

Tobacco use in any form has been associated with oral cancer. Although not as strongly and directly correlated with oral cavity SCCA, smokeless tobacco (snuff) may confer as great as a fourfold increase in oral cavity carcinoma (16). A cohort study of women in India revealed a greater than ninefold increase in the incidence of oral cavity cancer in women who used chewing tobacco greater than 10 times per day and was also related to duration of use (17). Pipe smoking has been associated with cancers of the oral cavity, pharynx, and esophagus, with heavy drinking increasing the risk multiplicatively (18). Pipe smoking associated with cancer of the lip is due to both the temperature and permeability of the pipe stem (19). The lateral tongue and floor of mouth also warrant close consideration.

Similar to tobacco for the stimulant and carcinogenic effects, the areca nut is the seed of the Areca palm and when wrapped in the betel leaf is referred to as "betel nut." In India and Southeast Asia, the betel nut is chewed with a mixture of other flavorings, cured tobacco, and lime and called "quid." Betel nut quid has been shown to be highly carcinogenic (20). Buccal mucosa cancers are nearly eight times more prevalent in betel nut users and in high-use regions such as India, Southeast Asia and northeast Brazil, where oral cavity cancers can account for between 25% and 50% of all cancers (21). In a cohort study of over 10,000 participants in Taiwan, users of tobacco, alcohol, and betel nut quid had a greater than 46-fold increase in oral cavity cancers (22). Other alternative uses of tobacco and like products also increase the risk of oral cancers. The practice of reverse smoking—placing the lit end of the cigarette in the mouth during inhalation—is associated with a 47-fold increase in rates of hard palate carcinoma among women in India (23).

The synergistic effect of tobacco and alcohol consumption has long been recognized in the development of head and neck cancer. An estimated 75% of all head and neck cancers are caused by tobacco and alcohol combined, and those who smoke two packs per day and drink four units of alcohol per day are 35 times more likely to develop cancer compared with healthy controls (12). Significant overlap in the consumption of tobacco and alcohol can confound epidemiologic attempts at risk stratification. Yet, studies indicate an independent role for alcohol in inducing malignancy of the oral cavity, in a dose-dependent fashion (24,25). Dose–response curves demonstrate a doubling in relative risk for light users of alcohol (30 g/day) compared to a nearly 10-fold increase in relative risk for heavy users of alcohol (130 g/day) (26). The effect is consistent across types of alcoholic beverages including beer, wine, and hard alcohol (27). No clear trend is identifiable for duration of alcohol use. Decreased risk of head and neck cancer can be achieved with alcohol cessation but requires years of abstinence, and the return to the risk level of nonalcohol users does not standardly occur until 20 years after cessation (27).

The human papilloma virus (HPV) infects epithelial cells and has been implicated as an early carcinogenic event in head and neck cancer with the HPV-16 subtype being the most common. There has been a significant increase in HPV+ oropharyngeal cancers, which demonstrate an overall favorable prognosis when compared to traditional oropharyngeal squamous cell cancers (28). However, HPV+ oropharyngeal SCCA is a distinct clinical entity highly selective to the oropharyngeal subsites. HPV DNA has been variably isolated from a wide range of oral cavity cancer specimens (29). Review often indicates significant overlaps with the oropharyngeal subsites and not true oral cavity origin. The same increase in cure rates of oral cavity cancers has not yet been observed, and therefore, current treatment methods for oral cavity squamous cell cancers should not be altered. Efforts to test oral cavity cancers for HPV and related markers may be helpful in future treatment algorithms, but a clear trend needs to be established prior to altering management.

Nonsmokers and nondrinkers may also present with oral cavity cancers, and fortunately, many of these present with early-stage disease affording a favorable prognosis. A greater proportion of these patients are female, and the common sites include the lateral tongue, maxillary alveolar ridge, and buccal regions. There is also an observed trend for an increased incidence in patients under 40 years of age (6).

Lichen planus is a chronic, inflammatory process affecting the oral cavity with a predilection for the buccal regions. Reports describe squamous cell cancers arising within areas of lichen planus, but the true malignant transformation rate is demonstrated to be less than 2% (30). Lichen planus has an unclear etiology and often responses to topical steroids. Patients with lichen planus should be observed closely for the formation of dominant and rapidly progressive lesions more consistent with carcinoma. Such observation and the use of judicious biopsy will prevent concerning lesions from proliferating under the supposition of a benign process.

Another small but important subgroup of patients warranting close observation are those who have undergone allogenic bone marrow transplantation. A chronic inflammatory process accompanies graft versus host disease (GVHD) in these patients, and although the most common second cancers noted after transplantation are hematologic, squamous cell cancer is the most common solid tumor seen in GVHD patients (31). All regions of the oral cavity are susceptible to GVHD and therefore warrant close observation.

PRESENTATION

Oral cavity neoplasms present in a variety of forms (Fig. 119.7A–F). Growths will usually present as an atypical area affecting the lining of one of the specific subsites of the oral cavity. This may be as simple as a small rough

A B

Figure 119.7 **A:** Leukoplakia at the junction of the floor of mouth and tongue. **B:** Erythroplakic lesion of the floor of mouth positive for SCCA.

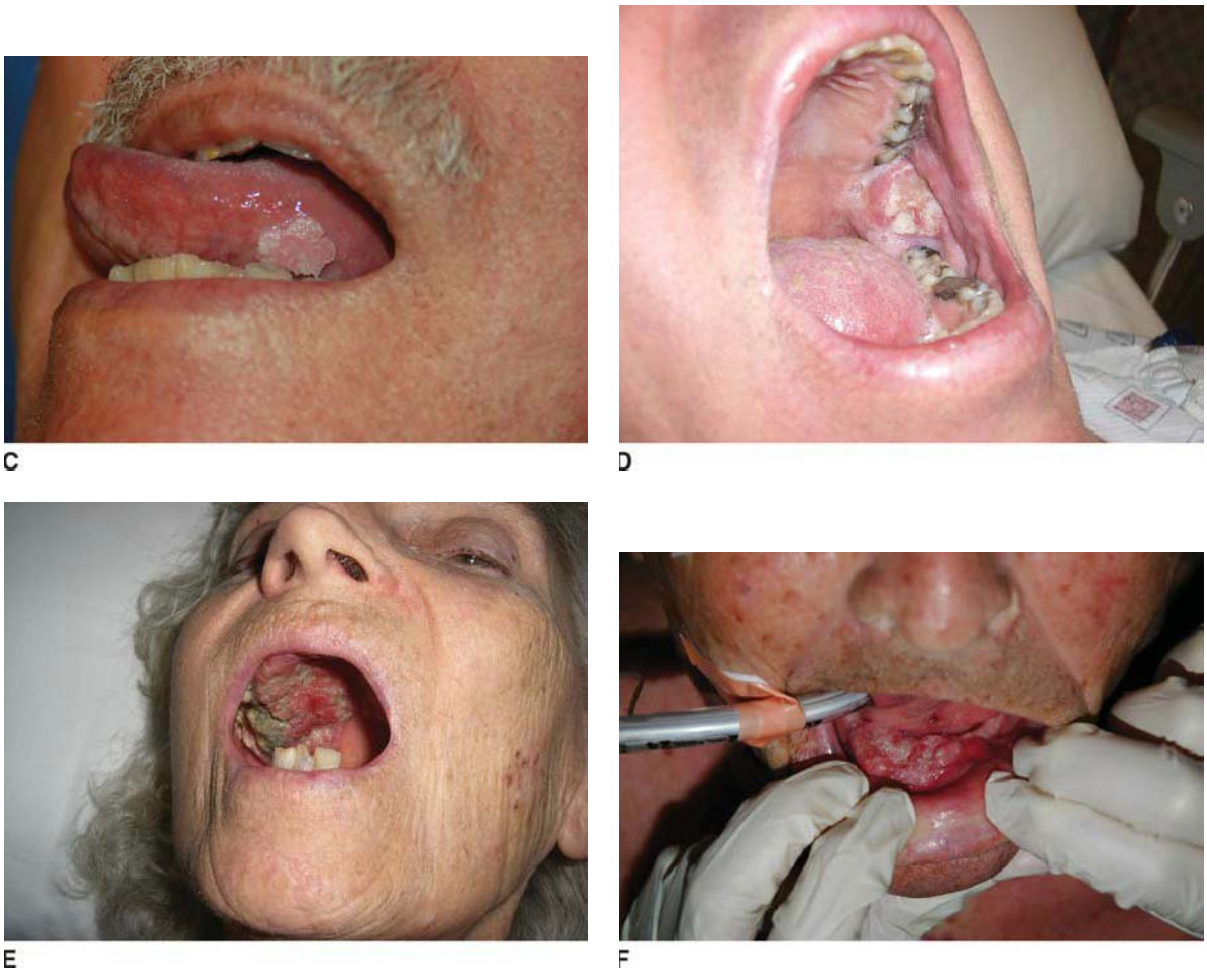

Figure 119.7 *(Continued)* **C:** Exophytic and pedunculated lesion of the lateral oral tongue positive for SCCA. **D:** SCCA at the junction of the RMT and the posterior buccal mucosa. **E:** SCCA of the right upper alveolar ridge. **F:** SCCA of the lower alveolar ridge invasion into cortical bone.

area or may be quite extensive involving multiple subsites. Leukoplakia is a commonly used term to describe a discrete persistent white patch in the oral cavity. These areas cannot be wiped off and are usually the result of chronic irritation. The malignant potential of leukoplakia is rather small, but it is generally felt that between 5% and 15% of these lesions can harbor malignancy (32). A baseline biopsy is not an unreasonable initial approach to the management of the leukoplakic lesion. Erythroplakia, a red plaque, is a more concerning entity. Erythroplakic lesions are felt to have a much greater potential for malignant transformation that can be five to seven times that of leukoplakia. All erythroplakic lesions warrant a biopsy for full evaluation and close follow-up if found to be nonmalignant.

Oral cavity lesions may also present as an ulcerative lesion within one of the subsites. This can be a shallow area without deep infiltration but also can manifest a significant infiltrative pattern into involved regions such as the tongue, floor of mouth, or alveolar ridges. Often, these deeply infiltrative ulcerative lesions are quite painful. At the other extreme, some lesions may be highly exophytic and present with a small base of true invasion. Likewise, an exophytic lesion can have a broad base with deep infiltration. These lesions also can present with pain.

Other manifestations of oral cavity neoplasms include bleeding without any predisposing trauma. As noted, persistent pain of the oral cavity lasting longer than 3 weeks is concerning for a neoplasm. Patients may also complain of new loose teeth in either the upper or lower alveolar ridges without any significant predisposing trauma, dental issues, or lack of hygiene. Another less common presentation is that of bad breath secondary to necrotic tumor. Oral cavity neoplasms can also present as a painless submucosal masses that can be quite extensive. Neoplasms such as this should raise concern for an etiology other than that from the squamous mucosal lining of the oral cavity. Salivary gland neoplasms would be the most common such lesions, especially in the floor

of mouth or a buccal region. Tumors originating from the mandible or maxilla, as well as from the teeth, also warrant consideration.

DIAGNOSIS AND EVALUATION

Although lesions of the oral cavity are usually quite visible compared to other head and neck subsites such as the oropharynx, larynx, hypopharynx, and sinonasal tract, a large proportion will present at an advanced local stage. A complete history will elucidate the clinical course. The timing of presentation and relative growth of the primary lesion will alert to rapidly progressive tumors that require urgent intervention before nutritional and airway issues become critical. Similarly, the presence and growth pattern of any clinical neck disease will be informative. Associated symptoms such as otalgia can portend more advanced disease than may be initially noted. Trismus also carries significant implications as it can be a harbinger of deep infiltration into the pterygoid musculature. Oral pain and odynophagia are often early symptoms but indicate advanced disease. Functional issues such as dysphagia and dysarthria may be related to tumor-associated pain or the physical presence of tumor in the oral cavity. Tumors may also involve cranial nerves, V, VII, IX, X, and XII. Weight loss, halitosis, or loose teeth can indicate advanced disease. Dysarthria may be secondary to pain or signal involvement of the hypoglossal nerve. A thorough past medical history should be obtained including current medications (anticoagulants), previous interventions (biopsies, lesion excisions, or aerodigestive malignancy treatments), and medical comorbidities that will be of critical importance for surgical planning (coronary artery disease, chronic obstructive pulmonary disease).

A history of salient risk factors is mandatory not only for assessment of causation but also to begin treatment planning. Smokers should be advised to stop and cessation counseling undertaken. Numerous studies indicate that patients who smoke tobacco during head and neck cancer treatment have significantly worse treatment courses and overall survival compared to those who stop smoking (33). Continued alcohol use and abuse may also have significant negative impact. Alcohol use comorbidities, including cirrhosis and encephalopathy, can seriously affect treatment planning and long-term care. Furthermore, the abrupt cessation of alcohol use, which normally accompanies impatient surgical care, may place patients at significant risk for alcohol withdrawal syndrome and its sequalae (34,35).

Cancers involving the oral cavity are readily assessed by physical examination in the clinic. The overall quality of the tumor should be described: exophytic, ulcerative, pedunculated, etc. A clear demarcation of the specific subsite of the oral cavity affected by the neoplasm is essential: tongue, floor of mouth, etc. As tumor staging in the oral cavity is size based, the dimensions of the lesion need to be clearly defined with particular attention to the demarcation points of 2 and 4 cm. If a lesion extends from one head and neck subsite to another, this too must be noted such as a tongue cancer extending into the floor of mouth. Palpation is essential to determine factors such as depth, degree of infiltration, immobility, and adherence to bone—all of which portend more serious disease. Likewise, palpation of the base of tongue, although unpleasant for the patient, offers critical information.

As the primary risk factors for oral cavity malignancies are also prime risk factors for other upper aerodigestive tract subsites, such as oropharynx and larynx, a complete head and neck physical examination and assessment is required of not only the primary tumor and its associated anatomical extension, but a thorough appraisal of the upper aerodigestive tract to evaluate for second primary tumors. The process of field cancerization—*"the development of premalignant clones of cells throughout the aerodigestive tract because of repeated exposure of the tissue to carcinogens in tobacco products"* (36)—accounts for the significant rates of second primary tumors in head and neck cancer patients with primary tumors of subsites separate from the second lesion. Mirror exam or fiberoptic examination of all visible upper aerodigestive tract mucosal surfaces should be undertaken as part of the initial clinical evaluation.

Assessment of regional spread is required. The entire neck should be palpated for potential metastatic spread of disease with particular attention paid to the assessment of the lymphatic levels at greatest risk for each specific region of the oral cavity (Table 119.1). Bimanual palpation, with one gloved finger in the mouth and the other palpating the external neck, is beneficial for assessment of the submental and submandibular triangles. Mobility of suspicious nodes should be noted. Fixed adenopathy is a poor prognostic feature and can indicate carotid encasement as well as deep muscle infiltration, factors ultimately affecting resectability.

The appropriate use of imaging for the evaluation of the primary tumor, regional lymph node basins, and chest imaging further augments the comprehensive assessment of oral cavity neoplasms and should be addressed at the earliest clinical time point. If possible, imaging is usually recommended prior to tissue acquisition by biopsy or fine needle aspiration (FNA) to limit any effect these interventions may have on radiologic findings. Plain films currently have little utility in evaluation of oral cavity cancers. With recent technologic advances such as reformatting, image acquisition speed, and low-dose scanning, much greater detail can be obtained with computed tomography (CT) imaging in a similar amount of time with minimal increase in radiation dosage. CT imaging provides excellent bony definition, which is critical in many oral cavity

subsites. When combined with contrast utilization, CT imaging can also provide excellent soft tissue definition. The rapid acquisition time of CT scans is also an important consideration as some patients with advanced oral cavity cancers may not be able to tolerate the positioning and necessity of prolonged immobility required for other imaging techniques.

Magnetic resonance imaging (MRI), with contrast enhancement and use of differential weighting, can provide truly outstanding soft tissue definition and demarcation of tumor involvement. Similarly, evidence of perineural spread and cranial nerve involvement may be obtained with MRI. MRI evaluates mandibular invasion with greater sensitivity than CT, though with less specificity (37). Although delivering no ionizing radiation, MRI does have disadvantages of increased cost, geographic inaccessibility, and longer acquisition times.

As both CT and MRI have specific advantages and disadvantages, choice of imaging modality will be determined by the primary site of the lesion and the specific clinical information desired in the evaluation of the primary site and the regional lymphatics (Figs. 119.8 to 119.11). Assessment of bone involvement is best evaluated with CT scan and is critical in alveolar ridge, RMT, and hard palate sites. The RMT can be particularly challenging to assess, and studies demonstrate that bone invasion may not be notable on preoperative CT imaging in one-quarter of patients evaluated (38). Bone involvement by tumors originating in soft tissue sites such as tongue and floor of mouth has significant impact on treatment planning. Specifically, the evaluation of mandibular involvement is important in primary tumor staging and surgical planning. Again, high-resolution CT scanning is the current imaging modality of choice, although recent studies indicate the increasing utility of MRI, especially for marrow and nerve involvement. The

use of CT scanning has been shown to be helpful in clinical evaluation of the primary tongue tumors (39). Due to the well-established fascial planes surrounding the lingual artery and hypoglossal nerve, a CT scan will aid in the surgical evaluation for a partial glossectomy, as the surgeon evaluates the ability to save the neurovascular bundle on one side of the tongue. This has been greatly aided by high-quality reformatting allowing assessment of the coronal, sagittal, and axial planes. Yet, MRI provides superior definition of tumor extent and involvement in soft tissue areas such as the tongue, floor of mouth, and buccal region and should be considered for these lesions. Patients with clinical evidence of neural involvement and with tumors predisposed to perineural involvement, such as floor of mouth adenoid cystic carcinomas or palatal or alveolar ridge carcinomas, can also benefit from MRI to assess potential proximal neural involvement.

In the United States, CT and MRI are the most commonly used imaging modalities to evaluate for regional metastasis, though with somewhat limited accuracy (40). Definition of clinical evident adenopathy is straightforward with attention focused on overall size, multifocality, evidence of extracapsular spread, deep muscle involvement, carotid involvement, and skull base involvement. The clinically negative neck provides a greater challenge. Criteria for positivity can vary but often include size greater than 10 mm, evidence of central necrosis, loss of ovoid shape, loss of fatty hilum, and the presence of extracapsular extension (41). Though not widely used in the United States, ultrasound has been shown to be more accurate in the assessment of metastatic lymph nodes, specifically in assessing the integrity of the hilar architecture and blood flow in benign appearing lymph nodes (42). In the evaluation of the combination of selective ultrasound-guided FNA biopsy, several European studies indicate the usefulness of these techniques for assessment of the occult metastatic neck disease (43–45).

The role of positron emission tomography (PET) scans in the staging of oral cavity cancer has not yet been defined. The combination of the PET imaging with CT scanning to provide PET/CT modality has increased the applicability of this imaging technique, yet limitations remain. The CT images obtained with combined PET/CT are often not of the detail and quality obtained with dedicated high-resolution, contrast-enhanced CT scans and therefore should not be considered a replacement. PET imaging offers little added information over standard imaging for assessment of primary lesions. In the assessment of regional disease, PET is often confirmatory, not enlightening. PET also demonstrates limitations in the assessment of the clinical negative neck especially for nodes less than 1 cm. Despite equivocal evidence, PET/CT scans are often obtained in the preoperative setting. Although PET/CT may be of limited use in management of the primary disease, it can aid in the detection of distant metastatic disease (46). Therefore, patients at high risk for metastatic disease such as those with recurrent disease, large primary site tumors, extensive and low neck adenopathy, as well as patients requiring surgical intervention with significant potential morbidity should be considered for evaluation of potential distant metastatic disease with PET/CT. Thus, although of limited utility in the evaluation of the primary disease (47), the more significant role of PET/CT imaging may be in posttreatment assessment in distinguishing posttreatment effect from neoplasm in cases of recurrence or persistent tumors (48).

Pulmonary metastasis is the most common site of distant disease spread in oral cavity, and formal evaluation of the chest is mandatory. Furthermore, widespread tobacco use by patients with oral cavity cancer predisposes this risk group to increased rates of synchronous primary lung cancers. For patients at low risk for distant spread or primary lung cancer, chest x-ray (CXR) is sufficient for evaluation of the chest. If there is greater concern for pulmonary metastasis because of risk factors noted above, excessive tobacco use, or suspicious chest plain film, then chest CT is indicated. When clinical circumstances warrant it, PET/CT imaging may be alternatively employed.

Comprehensive staging of the oral cavity tumors performed in the clinic setting requires tissue for diagnosis. As the oral cavity subsites are quite accessible in the office exam, a biopsy of the primary site can readily be obtained with minimal issue under local anesthesia. This can be completed with an incisional technique or cup forceps.

Care must be taken to obtain adequate and analyzable tissue with biopsy. A specimen of adequate depth, to assess invasion, and viability should be the goal. Biopsies of frankly necrotic tumor or superficial biopsies can be of limited usefulness. The use of a 3- to 4-mm dermatologic punch is an excellent means of obtaining an adequate tissue specimen with minimal morbidity. Acquiring a tissue sample will have minimal effect on subsequent treatment. An exception is the mobile submucosal mass in the floor of mouth or buccal region without evidence of mucosal involvement. Because salivary gland neoplasms can present in this fashion, a mucosa-disrupting biopsy should be avoided, and tissue diagnosis can be achieved with transoral FNA. Finally, if lymphoma is a serious consideration at the time of biopsy, the specimen should be sent fresh in saline to allow assessment by flow cytometry.

Palpable and suspicious lymphadenopathy can be further assessed with outpatient FNA. In experienced centers, FNA is highly accurate in diagnosing metastatic SCCA (49). Again, adequate specimen acquisition and fixation are critical (50,51). Although confirmatory, an FNA of clinically evident lymphadenopathy in the setting of a biopsy-confirmed, primary oral cavity cancer is not mandatory.

Upon completion of the outpatient evaluation, patients with oral cavity malignancies should undergo formal evaluation under anesthesia (EUA). This should include direct laryngoscopy and pharyngoscopy, with consideration of flexible bronchoscopy and esophagoscopy if warranted. During the EUA, complete assessment of the primary site can be achieved without the limitations of patient discomfort and compliance. Thorough palpation for size and extent of involvement can be undertaken. The remaining subsites in the upper aerodigestive tract can also be thoroughly evaluated to rule out second primary disease. Finally, initial or additional tissue sampling can be obtained (Table 119.3).

TABLE 119.3 DIAGNOSIS AND EVALUATION

Complete history and physical examination

(1) History
- (a) Length, severity, and quality of symptoms, with specific attention to dysphagia, odynophagia, otalgia, and dyspnea
- (b) Previous treatments relating to oral lesion
- (c) Social history including drug and alcohol exposure
- (d) Comorbid factors important in surgical planning

(2) Physical
- (a) Assess overall characteristics of tumor including subsite, invasion of local structures; assess for reconstructive options
- (b) Assess for multiple primary sites and regional spread
- (c) Stage tumor using AJCC staging TNM guidelines

(3) Biopsies
- (a) Biopsy of the primary tumor in the office if possible and appropriate
- (b) FNA of regional neck metastatic disease if present

Imaging

(1) CT and/or MRI of the primary tumor and regional lymph node basins
(2) CXR or CT of the chest
(3) PET/CT if concerns for metastases
(4) May consider panorex or barium swallow

Laboratory tests

(1) Complete blood count, electrolytes, and liver function panel based on preoperative assessment and anesthetic considerations
(2) Electrocardiogram and further cardiac evaluation based on patient's medical history

Consultations

(1) Dental evaluation
(2) Radiation oncology evaluation
(3) Medical oncology evaluation
(4) Pretreatment medical evaluation
(5) Appropriate subspecialty consultations
(6) May also consider speech pathology, internal medicine, and anesthesiology

Examination under anesthesia

(1) Direct laryngoscopy and pharyngoscopy
(2) Esophagoscopy if physical examination warrants further evaluation
(3) Bronchoscopy if physical examination warrants further evaluation
(4) Palpation of oral cavity and oropharynx

STAGING AND PROGNOSIS

The staging for oral cavity carcinoma follows the American Joint Committee on Cancer (AJCC) staging format, most recently updated in 2010. Staging criteria may be found in Table 119.4. The standard TNM classification system is utilized to arrive at a stage rated from I to IV. The T status is determined by the size of the tumor for T1, T2, and T3 and the degree of associated involvement for T4 lesions. Tumors achieve a T4a status with invasion: through cortical bone, into deep, extrinsic muscles of the tongue, into the maxillary sinus and skin of the face. T4b tumors invade one or more of the following structures—Masticator space, pterygoid plates, the skull base, and carotid artery—and may therefore be unresectable. The N status is determined by size, location, and number of lymph nodes involved ranging from N0 to N3. The presence of metastatic disease is denoted by the M status.

Though the current AJCC staging criteria are based on clinical and radiologic diagnoses, multiple histologic characteristics of the primary tumor have been shown to impact prognosis. These are discussed under the "Management of the N0 Neck" but include depth of invasion of the primary tumor, perineural spread, perivascular spread, perilymphatic spread, poorly differentiated tumors, and infiltrative tumors. Tumors of the oral tongue and floor of mouth with invasion less than 2 mm have a 13% metastatic rate to the regional lymph node basin and

TABLE 119.4 CLINICAL CLASSIFICATION OF SQUAMOUS CELL CARCINOMA OF THE ORAL CAVITY

Primary Tumor (T)

Tx	Unassessable	
T0	No evidence of primary tumor	
Tis	Carcinoma *in situ*	
T1	Tumor 2 cm or less in greatest dimension	
T2	Tumor 2 cm but not >4 cm in greatest dimension	
T3	Tumor >4 cm in greatest dimension	
T4a	Moderately advanced disease (resectable)	
	Lip	Tumor invades through the cortical bone, inferior alveolar, floor of mouth, or skin of face (chin, nose, etc.)[a]
	Oral cavity sites	Tumor invades through adjacent structures only such as cortical bone (mandible or maxilla), into deep extrinsic muscles of tongue (genioglossus, hyoglossus, palatoglossus, styloglossus), into maxillary sinus or skin of face[a]
T4b	Very advanced disease (unresectable) Tumor invades masticator space, pterygoid plates, or skull base and/or encases internal carotid artery	

Regional Lymph Nodes (N)

NX	Unassessable
N0	No regional lymph node metastasis
N1	Single ipsilateral lymph node, 3 cm or less in greatest dimension
N2a	Single ipsilateral lymph node >3 cm but not >6 cm in greatest dimension
N2b	Multiple ipsilateral lymph nodes, none >6 cm in greatest dimension.
N2c	Bilateral or contralateral lymph nodes, none >6 cm in greatest dimension.
N3	Any lymph node >6 cm

Distant Metastasis (M)

MX	Unassessable
M0	No distant metastasis (no pathologic MO; use clinical M to complete stage group)
M1	Distant metastasis

Stage Grouping

M0	T1	T2	T3	T4a	T4b
N0	I	II	III	IVA	IVB
N1	III	III	III	IVA	IVB
N2	IVA	IVA	IVA	IVA	IVB
N3	IVB	IVB	IVB	IVB	IVB

All M1	IVC

[a]Superficial erosion alone of bone/tooth socket by gingival primary is not sufficient to classify a tumor as T4.

a 95% disease-specific survival, while tumors 2.1 to 9 mm in depth have a metastatic rate of 46% and survival drops to 85% (52). Patients with tumors exhibiting perineural invasion have both decreased locoregional control of their disease and decreased disease-specific survival. The border of the tumor with the native tissue as well as the type of invasion also affect prognosis. Tumors with well-defined or "pushing" borders confer a better prognosis than those with less well-defined borders and deep infiltration (53).

The single most important factor in overall survival is the presence of positive cervical lymph nodes, and is reflected in the current AJCC staging guidelines. Extracapsular extension, as evaluated in the excised specimen, has been shown to be an independent predictor of development of regional recurrence and distant metastatic disease (54). In one single-institution study, the "lymph node density," or ratio of metastatic to benign lymph nodes in the surgical specimen, was found to have important prognostic implications. Patients with a higher lymph node density had decreased overall and disease-specific 5-year survival rates, though replication of these results may be hindered by institutional variation in both surgical neck dissection technique and pathologic examination (55).

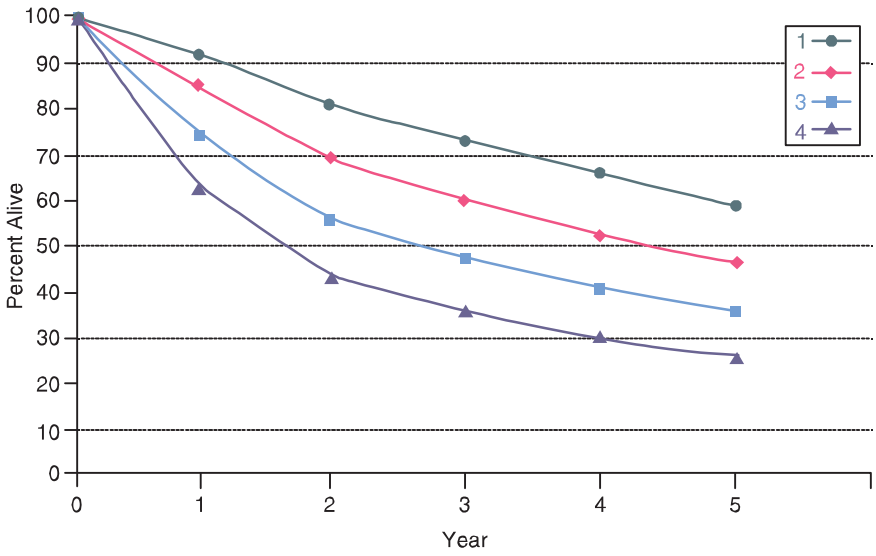
Overall survival rates based on stage alone are detailed in Figure 119.12. Statistics for each individual patient, however, remain difficult to predict, as many important prognostic features are not included in the current staging system. Recently, a nomogram including various other patient and tumor characteristics has been developed and externally validated, which may aid in the assessment of each individual's locoregional recurrence-free survival (56). This study validated the negative poor prognostic influence of advanced T stage, advanced N status, and close or positive margins.

TREATMENT

Treatment options for oral cavity carcinoma include surgery, radiation, chemotherapy, or some combination of the above. For early-stage tumors, both primary surgery and radiation have been shown to be equally effective. Therefore, treatment decisions are based on anatomical subsite and the associated morbidity of surgery or of radiation to that region, the patient's comorbidities, and physician and patient preference. Chemotherapy has no role as a single-modality curative therapy, but recent experience has demonstrated usefulness in the adjuvant setting. For later-stage tumors, or tumors with other poor prognostic features, patients benefit from multimodality treatment with the proper sequence of surgery and radiation with or without chemotherapy.

Radiation

Early-stage tumors may be treated with primary radiation therapy. The standard dosing regimen for external beam radiation is 1.8 to 2 gray (Gy) daily for a total dose of 62 to 70 Gy. For locally advanced head and neck cancer, hyperfractionated radiation dosing with concomitant boost protocols provides better locoregional control than standard daily dosing, although no significant differences were seen in overall survival. Furthermore, patients



Observed Survival	1	2	3	4	5	95% CIs	Cases
1	92.4	81.3	73.6	66.4	59.2	57.5–60.8	4660
2	85.8	69.8	60.2	52.8	46.9	45.0–48.9	3315
3	74.9	56.4	47.9	41.1	36.3	34.1–38.6	2239
4	63.6	43.7	35.8	30.7	26.5	25.2–27.8	5431

Figure 119.12 AJCC graph of survival by stage.

receiving hyperfractionated dosing experienced more severe acute side effects including radiation burns to the skin, mucositis, and xerostomia (57). Indications for postoperative radiation therapy to the primary site include positive or close surgical margins (less than 5 mm), perineural or perivascular invasion, or T_3 or T_4 tumors (58). Patients with multiple positive nodes or lymph nodes with extracapsular extension in the neck also benefit from postoperative radiation therapy. In any treatment protocol, every effort should be made to reduce the total treatment time (from surgery to the completion of radiation therapy) to less than 100 days, as decreased treatment time increases locoregional control and overall survival (59). Curative unimodality radiation therapy can be limited by several technical challenges in delivering consistent dosage to the target area. These challenges include mobility of the target tissue such as the tongue and the presence of dense materials such as bone and dental restorations in the field. These factors can often be overcome with the use of interstitial implant and brachytherapy. The most common use of radiation therapy for oral cavity cancer is in the adjuvant setting with planned surgery. Adjuvant radiation is usually done in the postoperative setting as no survival benefit exists when radiation is given preoperatively (60).

Radiation toxicities to the oral cavity include xerostomia, dysgeusia, dysphagia, dental decay, and osteoradionecrosis of the mandible. The duration of treatment is also significant with treatment courses averaging 6 to 7 weeks. Due to the extensive side effect profile, primary surgical resection is favored over radiation for early-stage oral cavity carcinoma. The use of intensity-modulated radiation therapy (IMRT) for advanced-stage oral cavity carcinoma has improved side effect profiles, in which dosing is maximized to tumor volume but minimized to surrounding normal structures. The use of IMRT decreases the incidence and severity of late xerostomia (61). Though sparing of the submandibular and parotid glands when possible may minimize xerostomia, this technique is more feasible for sites outside of the oral cavity (62,63).

Chemotherapy

Chemotherapy, as a single treatment modality, has no role in the primary treatment of oral cavity carcinoma but has a well-established role in the adjuvant setting for advanced-stage disease. Randomized studies by both the European Organization Research and Treatment of Cancer and the Radiation Therapy Oncology Group show that adding concomitant cisplatin to postoperative radiation improves both locoregional control and disease-free survival in patients with advanced-stage disease (64,65). Side effect profiles, however, remain poor, and the addition of chemotherapy adds significant adverse toxicity to therapy (64). Retrospective subgroup analysis of these studies demonstrated that only patients exhibiting either extracapsular extension or positive margin status were found to have significant survival benefits from the addition of chemotherapy. Though there was a trend toward increased survival with advanced-stage (III and IV) tumors, these results were not statistically significant. Interestingly, the presence of multiple positive lymph nodes without ECS was not shown to have benefited from the addition of chemotherapy (66).

The use of primary chemoradiation therapy for surgically resectable advanced-stage oral cavity cancer is currently under investigation in several centers. Various treatment protocols have been proposed using neoadjuvant, concurrent, and sequential treatment algorithms, with potentially encouraging results in selected patient groups. Further investigation is necessary before widespread adoption is advocated.

Surgery (By Subsite)

Cancers of the oral cavity are best managed by primary surgery. Many early T-stage tumors may be managed by transoral resection. For larger intraoral tumors, or tumors extending posteriorly towards the base of tongue, transoral approaches may not be sufficient for access. Adequate access and visualization are maximized by various surgical approaches. For buccal lesions, the addition of a lip-split incision may be required. This can be expanded to include mandibulotomy to afford the surgeon excellent posterior visualization for resection, and wide access for reconstructive options. This approach does, however, place the patient at risk for postoperative nonunion of the mandible, especially in patients who will be receiving postoperative irradiation. Furthermore, patients are left with a midline lip-split scar, and numbness in the distribution of the inferior alveolar nerve. In lieu of a mandibulotomy approach, most tumors without mandibular involvement may be approached through a visor flap and some form of lingual release. Liberal transcervical access allows for adequate visualization for ablation and access for reconstructive efforts. No significant difference in locoregional control or margin status has been found between the two approaches (67,68).

Surgical decision making must also take into consideration the management of the neck as well as the primary site. For clinically, radiographically, or pathologically positive regional neck disease, formal neck dissection is recommended. Historically, the use of the modified radical neck dissection for node positive disease was advocated. Currently, thorough selective neck dissections of involved lymph node levels and levels at risk for specific subsites are reported as equally effective in controlling neck disease. Advanced neck disease with sternocleidomastoid involvement, jugular vein involvement, and accessory nerve encasement warrants treatment with classic radical neck dissections and consideration of accessory nerve reconstruction.

Management of the N0 Neck

The management of patients with oral cavity malignancies and N0 neck stage deserves specific consideration. The N0 status must be strictly demonstrated by both physical exam and radiologic criteria. Regardless of negative assessment on both these factors, between 20% and 40% of patients with oral cavity cancer and N0 neck will demonstrate regional metastasis (69–71). The salvage rates for subsequent neck recurrence are poor, approximately 25%, and underscore the importance of adequate up-front treatment of the N0 neck (72).

Therefore, judicious surgical and pathologic assessment of the lymphatic basins at risk with specific oral cavity subsites is warranted. Such intervention not only provides a therapeutic benefit of removing any potentially occult metastatic disease within the neck but also provides more thorough pathologic staging information. Pathologic information from the surgical specimen can guide the appropriate decision making for adjuvant therapy such as radiation therapy or a combination of chemoradiation therapy. Factors taken into account include multifocality of the metastatic disease, evidence of extracapsular spread, and further assessment of potentially important biologic markers.

Classic evaluation of the N0 neck was defined using the modified radical neck dissection and clearance of levels one through five. Experience over the last two decades has demonstrated that the selective neck dissection of levels I, II and III, *the supraomohyoid neck dissection*, is as efficacious as the modified radical neck dissection (72,73) with less morbidity (74,75). The selective neck dissection demonstrates similarly low recurrence rates of less than 5% when compared to the modified radical neck dissection.

Specific consideration should be given to thorough dissection of level 1A for all anterior tongue and anterior floor of mouth lesions. Similarly, potential dissection of bilateral necks should be considered for such anterior lesions. Studies have indicated that level IIB is a rare site for occult metastasis from most oral cavity malignancies (76). This has significant importance as the dissection of only level IIA carries significantly lower risk of 11th cranial nerve dysfunction secondary to surgical issues related to direct trauma, tissue retraction, and decreased vascularity involved with circumferential neural dissection. Eleventh nerve dysfunction along with praxis of the lower seventh nerve branches and resultant smile dysfunction as well as contour deformity are the main postoperative issues associated with selective neck dissection and deserve specific consideration in discussing such intervention with patients (74,75). A consideration for level IIB dissection can be undertaken with RMT carcinomas and lesions with a more posterior location that abut or potentially cross into the oropharyngeal subsite.

Advanced oral cavity lesions, T3–T4 tumors, have a significantly higher degree of occult metastasis in the N0 neck and should be addressed with a selective neck dissection. This issue is less controversial as surgical exploration of the neck is usually required as a component of the ablative approach to the resection of such tumors. Similarly, necessary reconstructive efforts such as regional and free tissue flap reconstructions may require intervention in the neck.

The more challenging question is the management of the early-stage oral cavity cancer, T1–T2 tumors, with the N0 neck. Currently, between 15% and 20% of such early-stage malignancies will demonstrate occult metastasis on formal surgical evaluation of the neck. This risk of occult metastasis increases with certain factors, most notably, size of the tumor with T2 lesions having a greater metastatic potential than smaller T1 lesions. Depth of invasion has been evaluated in numerous studies and found to be significantly correlated with occult metastatic disease (52). Varying cutoff points between 2 and 4 mm have been evaluated to demonstrate an appropriate threshold for proceeding with surgical treatment and evaluation of the selective neck dissection (77). Studies support the cutoff of 4 mm or greater depth of invasion as an indication to proceed with selective neck dissection. Although not as strongly correlated with occult metastasis as depth of invasion, other factors such as poorly differentiated tumors, tumors demonstrating lymphovascular invasion, and tumors with an infiltrative growth pattern can confer and increased risk (78). Neck dissection should also be recommended in such cases.

For early-stage tumors, one clinical approach is to proceed with the surgical management of the early-stage primary tumor and allow the presence of poor pathologic features on final pathology to determine the need for adjuvant treatment of the neck with radiation therapy. Yet, even in tumors with poor prognostic features, this would lead to significant overtreatment with radiation therapy and its associated short- and long-term side effects. Similarly, after surgical treatment of the primary cancer and the identification of poor prognostic pathologic features, a recommendation could also be made to then formally proceed with surgical management of the neck with neck dissection. Results of this intervention can guide potential adjuvant treatment. This approach has the drawback of requiring two distinct anesthetic procedures.

The most thorough and streamlined approach in patients with T1/T2 primary site cancers and the N0 neck is to proceed with selective neck dissection at the same time as the primary surgical therapy. Results of the primary site pathologic assessment as well as the pathologic assessment of surgical basins at risk will then form the basis of adjuvant treatment planning.

As a corollary to the positive experience with sentinel lymph node biopsy techniques in the management of malignant melanoma, the use of radionucleotide-guided sentinel lymph node biopsy for T1 and T2 oral cavity carcinomas with an N0 neck is currently under evaluation. Prospective studies have indicated a negative

predictive value in the 90% range utilizing radionucleotide-guided sentinel lymph node biopsy techniques (79). These studies also indicate that the optimal utilization of the sentinel lymph node biopsying technique requires experienced operators to increase the negative predictive value. More intensive pathologic analysis is required including immunohistochemistry techniques not standardly utilized in the pathologic assessment of standard neck dissection specimens. Also of note, a greater accuracy has been shown when focusing on the oral tongue subsite as compared to other subsites within the oral cavity (80). Other accurate, but effort-intense means of assessing the N0 neck include the use of ultrasound-guided FNA, which has demonstrated a favorable experience in numerous European studies (43–45,81). Although ultrasound-guided FNA and a radionucleotide-guided sentinel lymph node biopsy demonstrate potential benefit in selected cases, utilization of the selective neck dissection in T1 and T2 N0 carcinomas of the oral cavity is recommended.

Mandibular Involvement

As discussed earlier in regards to preoperative imaging, tumors of the oral cavity should be assessed for mandibular involvement both clinically and radiographically. The mandible may be either abutted or completely invaded by tumor, and anticipating mandibular involvement will help in both ablative and reconstructive planning. Two forms of mandibular resection are available. The *marginal mandibulectomy* removes a portion of the mandibular cortex but does not interrupt the continuity of the mandible nor significantly alter its function. The *segmental mandibulectomy* involves the removal of an entire segment of the mandible—through the entire cortex—and, by definition, interrupts the continuity of the mandible significantly affecting function. Reconstruction of marginal mandibulectomy defects primarily involves soft tissue coverage, whereas reconstruction of the segmental defect usually requires the restoration of mandibular continuity. Marginal mandibulectomy is considered for tumors abutting the periosteum or superficially involving the alveolar mandible, whereas segmental resection is reserved for patients with clear bone involvement with significant cortical bone erosion and potential marrow involvement. The mandibular periosteum is thought to act as a barrier to tumor spread, and patients with microscopic disease may undergo marginal mandibulectomy of either cortex with preservation of at least 1 cm of alveolar height. Patients with invasion of the periosteum or superficial invasion of either cortex may also undergo marginal mandibulectomy without limitation in oncologic control. In these cases, multiple studies have demonstrated no changes in locoregional control or disease-specific survival with marginal mandibulectomy over segmental mandibulectomy (82,83). Segmental mandibulectomy is reserved for patients with extensive mandibular destruction or bone marrow involvement. Intraoperative frozen sections of bone marrow or the inferior alveolar nerve may help intraoperative decision making. Suspicion of significant bone involvement should expand preoperative planning—raising the consideration of necessary reconstructive options (84).

Lip

Cancers of the lip present more often on the lower lip than on the upper lip, most likely secondary to the increased sun exposure of the lower lip. The majority of lip lesions are SCCA, while basal cell carcinomas can also occur. The majority of patients present with early-stage primary tumors without cervical metastases, and surgery is the preferred method of primary treatment (85).

Reconstructive principles of the lip include cosmesis as well as maintaining oral competence. Reconstruction is based on the percentage and site of lip resection. In general terms, for defects less than 33%, a wedge excision and primary closure provide excellent results. For lesions involving a greater percentage of the lip length, a procedure mobilizing the available remaining lip is preferred. Options include the Abbe, Estlander, and Karapandzic flaps. Distinct advantages of the Karapandzic flap include the maintenance of lip sensation, mobility, and oral competence. Resultant microstomia needs to be carefully considered. Larger defects require utilization of nonlip tissue such as modified Webster flaps and the radial forearm free flap. The lower lip drains bilaterally, most commonly affecting the perifacial, submandibular, and submental lymph nodes. Cancers of the upper lip and oral commissures are often more aggressive and confer a worse prognosis. Drainage patterns remain ipsilateral for upper lip carcinoma, and the cervical metastatic rate is slightly higher than for lower lip though the overall rate remains low. The 5-year survival for stage I and II lesions is 90%, and survival drops to 50% with the involvement of cervical lymph nodes (86). Further discussions of lip cancer and its management are provided in Chapter 116.

Alveolar Ridge

The majority of primary alveolar ridge carcinomas occur in the mandible with the posterior body being most common. Although SCCA are by far the most common, consideration to tumors of dental origin, osteosarcomas, and salivary gland cancers must be given. The prognosis of early-stage disease remains relatively favorable with 70% to 80% survival, while prognosis significantly worsens with advancing stage based on size, bone invasion, and nodal metastases. Unimodality treatment for early-stage disease is primarily surgical with the consideration of adjuvant radiation therapy for advanced-stage disease.

The surgical approach to resection of both upper and lower alveolar ridge carcinoma follows the same basic principles as outlined above in the section on mandibular involvement. Tumors with minimal bone disruption at the dental interface can be addressed with marginal resections and acceptable oncologic control. Potential contraindications to marginal mandibulectomy include previous loss of alveolar height, radiographic evidence of marrow involvement, intraoperative evidence of deep bone erosion, and previous radiation therapy. Intraoperative assessment is critical in the treatment of these lesions, and evidence of disease that is more advanced than previously appreciated needs to be addressed with appropriate expansion of the ablative procedure. For lesions with significant erosion and bone involvement, *en bloc* removal of the affected segment with maxillectomy for upper alveolar ridge lesions and segmental mandibulectomy for mandibular lesions is recommended.

Reconstruction will be dictated by the specifics for the surgical defects. Limited upper and lower alveolar ridge resection can be allowed to heal secondarily or augmented with intraoral local flaps. Larger upper alveolar ridge lesion will result in connection to the sinonasal tract and are most often addressed with obturating prostheses. Soft tissue and bone containing free flaps are effective and necessary for large upper alveolar ridge defects.

The marginal mandibular defect will often require intraoral soft tissue coverage, and skin flaps such as the submental and radial forearm free flap are effective in achieving coverage without compromising oral function. Segmental mandibular defects provide a greater challenge. Reconstructive options are many and are determined by the location of the bone deficit and the associated soft tissue defect. The lateral defect can be addressed with a large soft tissue flap, such as the pectoralis major flap, without restoring mandibular continuity. This will result in malocclusion and mandibular shift but can be appropriate in select cases. Attempts to restore continuity of the mandible are the standard. This can be achieved with an appropriately sized reconstruction plate and soft tissue coverage that can include regional flap and free tissue transfer. Risks include potential plate fracture and plate exposure. The restoration of mandibular continuity with vascularized bone is the gold standard for segmental mandible reconstruction (87). Although optional in the lateral defect, vascularized bone is mandatory for the anterior defect as synthetic prostheses will uniformly erode secondary to tissue contracture. The fibula osseocutaneous flap in the most commonly used free flap for mandibular reconstruction secondary to numerous favorable qualities. Other options include the scapular osseocutaneous flap, the iliac crest osseomyocutaneous flap, and the radial forearm osseocutaneous flap.

Floor of Mouth

More than one-third of patients with floor of mouth cancer present with advanced T-stage disease, and nearly 40% of patients have clinically positive regional metastases (88,89). For T_1 tumors, the rate of occult metastasis is 21%, and it is 62% for T_2 tumors (89). Early in the disease process, cancer of the floor of mouth is often asymptomatic, with pain, bleeding, and submandibular duct obstruction more common as tumor size progresses. The floor of mouth musculature, specifically the mylohyoid muscle, as well as the mandibular periosteum may act as barriers to tumor spread, though when involved by tumor require comprehensive clearance. Many patients require either marginal or segmental mandibulectomy for small, but invasive lesions. Involvement of the ventral aspect of the tongue may require partial glossectomy. Such tumors can also readily involve the root of the tongue necessitating significant resection into the tongue base, which can place the neurovascular pedicles of the tongue at risk. Invasion through the submandibular duct is best treated with resection of the submandibular gland and sublingual glands with the primary specimen.

Mucosal lesions sparing the mandible are optimally managed with transoral surgical resection. Anterior defects larger than 2 cm have the potential to tether the ventral aspect of the tongue, and formal reconstruction should be considered. For smaller mucosal lesions, a split-thickness skin graft may be used with the application of a bolster dressing. For larger lesions, tissue flap reconstruction may be required. Multiple pedicled flap options are available including the submental flap, the nasolabial flap, and the platysma flap. The myocutaneous pectoralis flap may be used, although it can be somewhat bulky. For larger defects requiring vascularized tissue reconstructions, microvascular free flaps are the superior choice with the radial forearm free flap offering the greatest coverage and flexibility for large mucosal defects, although the perforator anterior lateral thigh flap is another excellent option.

As discussed above, partial mandibulectomy does not compromise oncologic control. Required marginal mandibulectomy may involve the lingual cortex or the alveolar ridge, as dictated by the disease location. Care must be taken to leave the outer cortex or 1 cm of inferior cortex respectively for such marginal bone resections. Segmental mandibulectomy is reserved for patients with gross destruction of the mandible seen on clinical or radiographic examination (82,83). Mucosal defects with a marginal mandibulectomy may be reconstructed with appropriate tissue flaps as discussed above. Segmental mandibulectomy defects may be left unreconstructed if lateral, but usually an effort is made to restore continuity. Lateral defects can be reconstructed with a reconstruction bar and soft tissue flap, but do benefit from the use of vascularized osseocutaneous flaps such from the fibula, radius, scapular and iliac crest. Microvascular free flap reconstruction is mandatory for anterior defects as alloplastic techniques will break down and extrude.

The floor of mouth drains directly to the submental and submandibular lymph node basins, with the

submandibular lymph nodes the most frequently involved. Bilateral neck disease should be addressed at the time of primary resection, as cervical metastatic disease confers a grim prognosis with poor rates of surgical salvage. The 5-year survival rates for floor of mouth carcinoma are 90%, 80%, 65%, and 30% for stages I to IV disease respectively (88,90).

Oral Tongue

Though early T-stage tumors of the oral tongue have equivalent survival rates when treated with surgery or radiation, surgical treatment is preferred to avoid the acute and late side effects of radiation (91,92). Another drawback of radiation is the prolonged treatment course and recovery period. The majority of tongue cancers will present on the lateral border of the tongue, and patients have minimal symptoms. Dorsal tongue cancer is rare, representing 3% to 5% of oral tongue cancers, but can have significant delay in diagnosis because of the unusual location (93). Recent reviews of the SEER database revealed that early-stage oral tongue carcinoma confers a poorer prognosis than carcinoma of other sites of the oral cavity. Five-year overall survival rates from the dataset for oral tongue cancers revealed 67% and 51% for stage I and stage II tumors, respectively (94), whereas other oral cavity subsites reviewed in the same series noted disease-specific 5-year survival rates at 94% and 85% for stage I and stage II disease, respectively. Yet, other studies reveal a less dramatic difference while reiterating the negative effect of advanced disease stage on the survival statistics for oral tongue cancer, with overall 5-year survival of 75% for stage I or II tumors, and 40% for stage III or IV tumors (95,96).

Standard surgical management of oral cavity cancers includes a partial glossectomy with at least 1-cm margins. As both specimen shrinkage and muscle distortion after resection may alter incised planes, margin status at the mucosal level and along the deep tongue musculature must be assessed with caution. Intraoperative frozen sections can be utilized to confirm clear margins around the tumor, and are best taken from the patient along the resected mucosal and muscular borders. Means of resection can affect margin assessment. Animal studies demonstrate that the use of scalpel will give the most representative tissue margin and the other techniques, such as electrocautery and ultrasonic device will have varying degrees of tissue disruption affecting margin assessment (97). Due to the difficult nature of assessing muscle margins, postoperative radiation may be considered in patients with initial positive surgical margins, despite further resection to clear margins (98).

Once complete surgical resection of the tumor has been achieved, attention can be focused on appropriate reconstructive efforts. The primary goal of tongue reconstruction is to limit tongue tethering and any other restraints on mobility that would significantly affect speech and swallow function. Partial glossectomy defects including less than one-third of the tongue may heal by secondary intention, or a split-thickness skin graft may be used for limited extension along the floor of mouth to decrease tongue tethering. For larger defects of the tongue or floor of mouth, multiple reconstructive options may be explored. In addition to maximizing mobility, reconstructive efforts should include augmenting tongue volume as needed. Increasing tongue volume, while maintaining mobility in reconstructing the tongue defect, helps in secretion management, transfer of the food bolus posteriorly, and articulation. Maintaining premaxillary contact and palatal contact aids in speech production, while having full excursion past the alveolar ridge aids in the clearing of secretions (99). Fasciocutaneous free flaps such as the radial forearm or anterolateral thigh flap offer adequate tissue for larger partial glossectomy reconstruction, with or without a floor of mouth component. A comparative study of the submental flap and the radial forearm flap used to reconstruct partial glossectomy defects demonstrated equivalent speech and swallow results, while patients receiving a submental flap had decreased operative time and hospitalization (100).

For advanced disease, multimodality treatment is required. Surgery followed by either radiation or chemoradiation has better disease control than either surgery or radiation alone (95,101). Postoperative radiation therapy has been shown to increase locoregional control rates, with a positive surgical margin the only factor predictive of recurrence, though the majority of patients in this study recurred within 2 years (95).

Hard Palate

SCCA makes up the vast majority of oral cavity cancers, but the hard palate has equal incidence of minor salivary gland tumors. In one series, SCCA represented only 50% of cancers originating in the hard palate (102). Other tumors include adenoid cystic carcinoma, polymorphous low-grade adenocarcinoma, adenocarcinoma, and mucoepidermoid carcinoma (103). Early lesions of any pathology of the hard palate most often involve the underlying bone, and are therefore best treated with primary surgical therapy (104).

Transoral resection of the tumor may include an alveolectomy or inferior maxillectomy in addition to palatectomy (105). Because of the dense innervation of the hard palate and the foramina through which the nerves run, consideration must be given to perineural spread of disease and direct extension via the foramina. Adequate margin assessment of these regions is required.

Reconstruction of oroantral fistulae may be accomplished by intraoperative placement of palatal prosthesis

after packing the remaining maxillary sinus. The prosthesis and packing is removed in clinic, and a more long-term prosthesis fitted. For larger defects, or defects involving the premaxilla, free tissue transfer is indicated and offers the benefit of providing stable projection in this region. Reconstruction of the premaxilla maintains facial contour and prevents erosion of the prosthesis through the upper lip. Often, a combination of a free flap with a prosthesis offers the best cosmetic and functional result for hard palate defects (106).

The hard palate drains to level I and level II lymph nodes but also may involve retropharyngeal and perifacial nodes. Historically, the rate of occult cervical metastatic disease has been considered low, and routine elective neck dissections have not been recommended (102,107). More recently, however, studies have indicated higher occult rates than previously thought, from 27% to 30%, with variable rates of surgical salvage for regionally recurrent disease (108,109). Regional failure was associated with increasing T classification, which also was an independent predictor of recurrence-free survival on multivariable analysis (109). Elective treatment of the neck with either surgery or radiation is therefore recommended (108,109).

Retromolar Trigone

Cancer of the RMT is often diagnosed at a later stage than other oral cavity tumors, due to both a difficult clinical examination of the site and its close proximity to the mandible. Again SCCA is the most common pathology, but salivary gland malignancies require consideration. The mucosa of the RMT directly abuts the periosteum of the mandible, and mandibular invasion occurs in up to 50% of tumors on initial diagnosis (59). Because of the critical anatomic location, this can occur even with small tumors. Trismus indicates involvement of the pterygoid musculature, and extension to the tonsillar pillars, soft palate, and base of tongue is common.

A transoral surgical approach is appropriate for many tumors of the RMT if adequate visualization and access for instrumentation is available. In cases where this is not achievable, the combined use of a transcervical visor flap or cheek flap will be helpful and may be required if there is significant extension to multiple subsites or with large tumors. Patients requiring segmental mandibulectomy will require a transcervical approach for extirpative and reconstructive access. Small defects may be closed primarily, left to heal by secondary intention, or reconstructed with a pedicled buccal fat graft. Larger mucosal defects or defects including a marginal mandibulectomy benefit from free tissue transfer technique providing adequate, pliable lining such as the radial forearm free flap. Defects including a segmental mandibulectomy benefit from restoration of mandibular continuity by reconstruction with osseocutaneous free flaps.

The RMT drains to lymph nodes in levels II and III. As RMT tumors usually present with advanced stage, elective neck dissection should be performed in any patient undergoing transcervical approach for primary tumor resection, regardless of clinical nodal stage. Patients with clinically positive disease should be managed with a therapeutic neck dissection followed by radiation therapy. Overall survival decreases with N stage, with a 69% 5-year survival in patients with N_0 disease, 56% for N_1, and a 26% survival rate for those with N_2 disease (60).

Buccal Mucosa

SCCA of the buccal mucosa represents 5% to 10% of oral cavity cancers in the United States (110), though in India it accounts for over 40% due to betel nut use (20). Buccal cancer often presents as advanced-stage disease, as there is no lateral anatomic barrier to spread. The buccal fat pad and musculature are easily invaded by carcinoma, and facial paralysis, skin invasion, and trismus are not unusual in primary presentation.

Surgery is the treatment of choice for buccal cancer, most often through transoral excision (111). Larger lesions may require a combined oral and transcervical approach. The addition of a lip splitting incision can add critical access to visualization and surgical resection of this region. For smaller lesions, primary closure or skin grafting may be considered. For larger lesions, soft tissue reconstruction with pedicled regional flaps such the submental flap or temporoparietal fascial flap or fasciocutaneous free flaps may be required to avoid contracture and trismus. The risk of cervical metastatic disease is related to both T stage and the depth of invasion of the primary tumor. Advanced T stage III and IV and invasion greater than 5 mm has been associated with increased risk of cervical metastatic spread, and elective neck dissection for those with clinically negative lymph node basins should be considered (112).

Buccal carcinoma can bestow a grave prognosis, with some evidence that it is worse than other sites of the oral cavity (111). For patients with unresectable disease, primary chemoradiation therapy may be considered, though patients treated with radiation alone have high recurrence rates and decreased overall survival (113,114).

COMPLICATIONS

Complications from treatment of oral cavity neoplasms depend on not only the type of treatment but the extent and location of the original lesion. Acute complications due to treatment effects are usually managed without treatment breaks, but complications may continue to arise many years after treatment has finished.

Radiation to the oral cavity has close proximity to the salivary tissues and the mandible, and thus treatment is wrought with acute and long-term complications.

Universally, patients develop superficial burns to the skin and the mucous membranes during treatment, which may persist for weeks after treatment has completed. Mucositis is very painful and may become suprainfected with bacteria or fungus (115). Mouthwash with a mixture of lidocaine and an antifungal may provide some relief, and many patients benefit from enteral nutrition via nasogastric or gastric tube. After treatment, many patients are permanently left with xerostomia and dysgeusia (116). While not painful, the decreased saliva production and altered taste leaves eating difficult and less enjoyable. Tooth decay results from decreased saliva production, and impeccable dental hygiene is essential (117). Though the introduction of IMRT and salivary-sparing techniques have relieved the severity of xerostomia (118), the problem still exists, especially for those with tumors located in the floor of mouth with close proximity to the submandibular glands. Mastication can also be significantly affected, especially when combined with surgery (119). Other late complications of radiation include soft tissue radionecrosis and osteoradionecrosis of the mandible. Soft tissue necrosis presents as a nonhealing ulcer, and biopsies must be taken to exclude the possibility of recurrent cancer. Osteoradionecrosis presents as bone loss and mandibular exposure, either intraorally or externally through the skin. This is often precipitated by dental trauma, underscoring the need for extensive pretreatment evaluation by a dentist. Exposed mandible often becomes infected and results in an orocutaneous fistula. Treatment with antibiotics, conservative sequestrectomy, and hyperbaric oxygen may help early lesions (120). Pathologic fractures due to radiation damage, or osteoradionecrosis not helped by other measures, benefit from free tissue transfer of bone. Microvascular reconstruction replaces necrotic tissue and reestablishes blood flow to the hypoxic bed.

Surgical complications are varied and depend on the extent of the tumor resection and reconstruction (Table 119.5). Due to the causative effects of oral cavity cancer, most patients present with numerous comorbid states, placing them at increased surgical risk. Patients with head and neck cancer are at increased risk for postoperative pulmonary embolism, cardiac complications, delirium tremens, and aspiration pneumonia (121,122). Careful preoperative optimization of other medical problems helps minimize intra- and postoperative medical complications.

Airway management must remain a priority. The most drastic and emergent complication of oral cavity cancer and its treatment is acute airway obstruction. This may evolve from increasing mass or edema from the tumor itself obstructing the oral cavity. Less commonly, primary radiation may result in tissue edema causing acute airway obstruction before treatment. Postoperatively, tissue swelling or hematoma formation may occlude the airway, and patients undergoing extensive surgical resection and reconstruction may require a tracheotomy or prolonged intubation to avoid airway difficulty. Though rare, this devastating complication may be prevented. Thorough evaluation of the patient's airway at the time of presentation and at every subsequent interaction either in clinic appointments or in the pre- or postoperative setting will alert the clinician to impending airway obstruction. Signs such as tachypnea, drooling, inability to lie flat, stridor, anxiety or the sense of impending doom all may indicate an airway problem. Desaturation seen on pulse oximetry is a late finding necessitating immediate intervention. For prevention and treatment of all airway obstruction, tracheostomy is the treatment of choice.

TABLE 119.5 SURGICAL COMPLICATIONS RELATED THE TREATMENT OF ORAL CAVITY CANCER AND MANAGEMENT

- Airway obstruction: prophylactic or emergent tracheotomy
- Postoperative hemorrhage: secure airway, cardiopulmonary stabilization, operative or interventional radiology control
- Postoperative fistula: local wound care with salivary diversion from vascular structures
  - Prevent great vessel compromise with appropriate vascularized flap coverage if warranted
  - Secondary wound closure with appropriate flap reconstruction
- Graft compromise or loss
  - Split thickness skin flap: debride and allow secondary intention
  - Pedicled or free flap compromise
    - Explore and assess pedicle integrity, if hematoma or seroma—drain, if vessel compromise—revise
    - If partial loss—debride, if complete loss—remove and revise with second flap
- Final margins return positive: Re-resect is possible, consider adjuvant treatment

Immediate postoperative surgical complications such as bleeding or hematoma formation warrant immediate intervention in the operating room. Further postoperative complications include many related to wound healing problems, especially for patients with poor nutritive status, or those who have been previously treated with radiation. Wound breakdown may occur along the reconstructed areas or neck flaps. Salivary contamination, wound infections, and fistulae can occur with varying frequency and may be managed conservatively with meticulous wound dressings and antibiotics. Optimization of thyroid function, nutrition status, and blood glucose levels provides significant benefit. Neck wounds with potential great vessel exposure require tissue coverage with either a local or a free flap, and surgical diversion of salivary contaminants to aid in healing and to prevent carotid rupture.

Late surgical complications may involve both the soft tissue and the bone involved in the resection and reconstruction. Soft tissue loss due to graft loss or inadequate

graft volume may result in tethering of the tongue or oral commissure. Recent studies indicate significant decrease in mastication function after treatment of oral cavity cancer. In addition to osteoradionecrosis discussed above, surgical complications of the bone may also occur. In patients who have undergone marginal mandibulectomy, at least 1 cm of height should be left to prevent pathologic fracture (123). Despite these guidelines, some patients go on to develop fractures, especially in the setting of previous radiation treatment. A midline mandibulectomy for access will predispose the patient to nonunion, causing infection, pain, and possibly an orocutaneous fistula.

FUTURE DIRECTIONS

Despite decades of research on head and neck cancer, the overall mortality for oral cavity cancer remains high, without significant improvement. Patients with clinically similar disease may have variable response to treatment, and specific outcomes can be difficult to assess. The current staging system based on clinically obtainable data may not be predictive of outcome for all patients, as oral cavity cancer proves itself a heterogeneous disease.

Surgery remains the mainstay of treatment for oral cavity cancer, and there have been many additions to the extirpative arsenal in the hopes to make surgical ablation faster, more accurate, and with less blood loss. Most surgeons prefer electrocautery over cold techniques for ablation, though this may affect the examination of surgical margins. The addition of the ultrasound scalpel in tongue ablations may help minimize surgical distortion while maintaining hemostasis (97). Some surgeons use the laser or the surgical robot to help ablative visualization, though this may be more useful in oropharyngeal primaries with less surgical access than the oral cavity. Though industry will no doubt provide further technology with which to ablate, it is unclear whether these tools will provide drastic improvement over the scalpel.

Over the past 30 years, the single most important surgical advancement in the treatment of oral cavity cancer has been the addition of free tissue transfer. For large ablative defects, a free flap affords the patient increased speech and swallow function and without the donor site morbidity of a pectoralis major flap. Further advances in technique and critical examination of function will likely elucidate additional surgical measures important in maintaining oral function.

Quite possibly, however, the greatest advancements in overall cancer survival may come from greater precision in selecting patients who will benefit from adjuvant postoperative treatment. As we continue to learn about individual tumor biology, it is becoming clear that biomarkers will play an increasingly important role in prognosis and treatment of oral cavity cancer. Multiple prognostic biomarkers have been identified to date: some predicting overall survival, others predicting lymph node or distant metastatic disease (124). Further research will hopefully illuminate biomarker profiles indicating not only prognostic information but also specific sensitivity to various treatments (125). As an early example, some centers use epidermal growth factor receptor expression as a contributing factor in the decision to add adjuvant treatment. As we gain more information of biomarkers and their importance, we hope to individualize treatment, with the molecular profile of any specific tumor dictating treatment decision trees.

Fortunately, the rates of oral cavity cancer are relatively rare in comparison to other solid tumors. This does, however, make large clinical studies difficult. The vast majority of current oral cavity cancer research comes from single-institution, retrospective studies. While useful, these studies do not provide the level-1 evidence needed for sweeping changes in clinical practice, and result in inter- and even intrainstitutional variation in treatment. Powering large prospective studies to answer clinically relevant questions will require standardization of protocols and multicenter involvement.

HIGHLIGHTS

- In the United States, oral cancer is the most common of the head and neck sites involved by cancer.
- Tobacco and alcohol use remain the carcinogens most commonly linked to oral cancer.
- Cervical metastases are frequently associated with oral cancer.
- PET/CT may be indicated to complete staging for patients with advanced tumors.
- Surgery remains the mainstay of therapy for early cancer.
- Adjuvant chemoradiotherapy is indicated for advanced cancer after resection.

Nasopharyngeal Carcinoma

120

William Ignace Wei *Daniel T. T. Chua*

Anatomically, the nasopharynx is situated behind the posterior choanae and is continuous with the posterior aspect of the nasal cavities. Inferiorly, it is separated from the oropharynx by the soft palate and it is the air passage during breathing. Because of its bony framework, it remains patent under normal circumstances. Nasopharyngeal carcinoma (NPC) is a squamous cell carcinoma (SCC) arising from the epithelial lining of the nasopharynx. This neoplasm may arise from any site in the nasopharynx and is more frequently seen at the lateral wall, from the fossa of Rosenmüller, the recess located medial to the medial crura of the opening of the auditory tympanic tube or the Eustachian tube.

A group of 14 patients suffering from this malignancy was first reported in the English literature in 1901 (1). The first comprehensive series reporting clinicopathologic features of 114 patients suffering from NPC in Hong Kong was published in 1941 (2).

NPC is a relatively uncommon malignant disease in most countries with its age-adjusted incidence being less than 1 per 100,000 (3). It constitutes 0.7% of all cancers, and is rated the 23rd common new cancer in the world (4). It occurs frequently in the Inuits of Alaska (5) and ethnic Chinese in Southern part of China, especially from the province of Guangdong. The recent reported incidence of NPC among men and women in Hong Kong, in the southern part of the Guangdong province, was 17.8 per 100,000 and 6.7 per 100,000, respectively (3). A range of intermediate rates are observed in populations of North Africa (6) and the Middle East (7). The incidence of NPC remains high among those Chinese who have immigrated to Southeast Asia countries or North America, but is low among those Chinese born in North America (8,9). This suggests that genetic, ethnic, and environmental factors may play a role in the etiology of the disease.

One of the etiologic factors of NPC frequently referred to is the consumption of salted fish. This may be related to the carcinogenic compound, nitrosamine, detected on the salted fish (10). A case–control study has shown that weekly consumption of salted fish before 10 years of age is associated with a threefold increased risk of developing NPC (11). The consumption of salted fish at childhood rather than adulthood contributes to the increased incidence (12). The Epstein-Barr virus (EBV) has also been considered to play an oncogenic role in this tumor, as the EBV genome is frequently detected in the biopsy specimens of NPC (13). Additionally, patients suffering from NPC also have higher EBV antibody titers than controls, especially the IgA antibodies to viral capsid antigen (VCA) and early antigen (EA) (14,15).

In view of the ubiquitous presence of this virus in the human population, it is unlikely that EBV is the only causative agent of NPC. In the first-degree relatives of patients suffering from NPC, their incidence of developing this malignancy is 4 to 10 times higher than controls (16). This suggests that genetic factor might have an important role in the etiology of NPC. Comparative genomic hybridization studies have demonstrated several genomic spots where chromosomal losses and gains were identified in NPC (17). These losses on chromosomes 3p, 9p, 11q, 13q, and 14q suggested that tumor suppressor genes at these loci might be involved in NPC development (18,19).

HISTOPATHOLOGY

The malignant epithelial cells of NPC are large polygonal cells with a syncytial character. Their nuclei are round or oval with scanty chromatin and distinct nucleoli. The cells are frequently intermingled with lymphoid cells in the nasopharynx, giving rise to the term lymphoepithelioma (20). Electron microscopy studies have confirmed the squamous origin of these cells including those undifferentiated

carcinoma that are a form of epidermoid SCC with minimal differentiation (21).

The histologic classification of NPC proposed by the World Health Organization (WHO) (22) in 1978 categorized tumors into three groups:

1. Type I included those typical keratinizing SCCs with intercellular bridges, similar to those found in the rest of the upper aerodigestive tract (Fig. 120.1).
2. Type II included nonkeratinizing epidermoid carcinomas. They showed evidence of maturation but without definite squamous differentiation (Fig. 120.2).
3. Type III included undifferentiated carcinomas or poorly differentiated carcinoma. These cells have indistinct cell margins with hyperchromatic nuclei (Fig. 120.3).

In North America, around 25% of patients have tumor with Type I histology, 12% with Type II, and 63% with Type III. The corresponding histologic distribution in southern Chinese patients is 3%, 2%, and 95%, respectively (23).

An alternative classification divided tumors into two histologic types, namely, SCCs and undifferentiated carcinomas of the nasopharyngeal type (UCNTs) (24). This second classification took into consideration the correlation of the tumor with EBV serology. Patients with SCCs have a lower EBV titer, while those with UCNTs have elevated titers.

On clinical grounds, biopsies obtained from patients suffering from NPC sometimes show a mixed histologic pattern. The recent WHO classification has taken this mixed pattern into account as well as the association of the EBV with Type II and III tumors. The histologic types of NPC are classified into two groups; the first group comprises the SCCs or nonkeratinizing carcinomas, and the second group is subdivided into differentiated and undifferentiated carcinomas (25). This new classification has also been shown to have a prognostic bearing; the undifferentiated carcinomas have a higher local tumor control rate with radiotherapy (RT) and a higher incidence of distant metastasis (26,27).

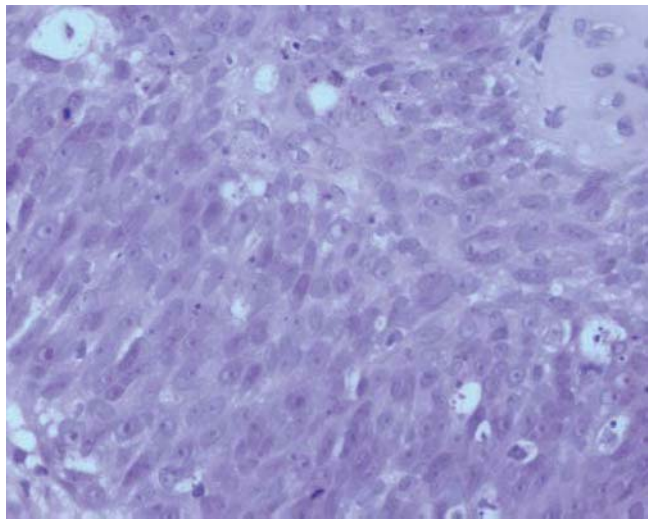

Figure 120.2 Nonkeratinizing differentiated carcinoma of the nasopharynx. The tumor cells have a papillary configuration and the cells appear more hyperchromatic than the undifferentiated carcinoma. The nuclei at the periphery show palisading (hematoxylin and eosin ×400).

CLINICAL PRESENTATIONS

Comparing with other head and neck cancers, NPC affects relatively younger age group of patients (28). Patients suffering from NPC may present with one or more of the four groups of symptoms. These groups of symptoms are

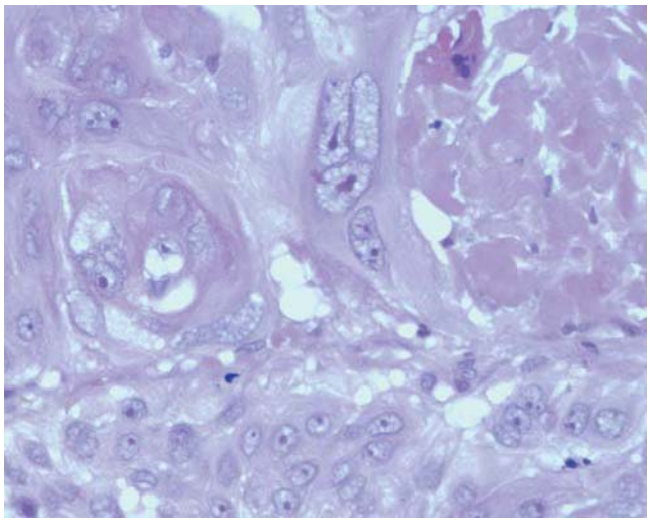

Figure 120.1 SCC of the nasopharynx. The tumor cells are large with eosinophilic cytoplasm and show features of keratinization (hematoxylin and eosin ×400).

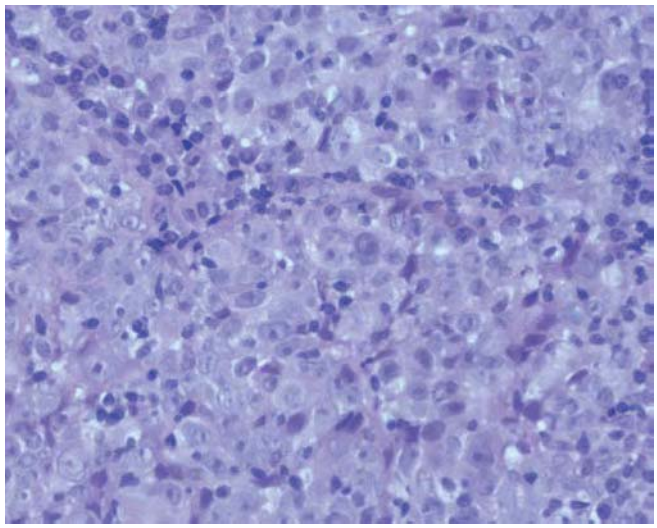

Figure 120.3 Undifferentiated carcinoma of the nasopharynx. Tumor cells are typically composed of nests or islands of pleomorphic polygonal cells with large vesicular nuclei and prominent nucleoli. The tumor nests are often surrounded by a lymphoid stroma, which is part of the nasopharyngeal stroma (hematoxylin and eosin ×400).

related to the location of the primary tumor, infiltration of structures in the vicinity of the nasopharynx, or metastasis to cervical lymph nodes.

The presence of tumor mass in the nasopharynx may lead to the symptoms of nasal obstruction and discharge. With a small tumor, the obstruction is unilateral and with tumor growth the symptoms may become bilateral. When the tumor ulcerates, the patient may present with epistaxis. The amount of bleeding is usually trivial and the frequent presentation is the presence of altered blood in the postnasal drip, especially in the morning.

The tumor bulk in the nasopharynx with or without posterolateral extension into the paranasopharyngeal space is frequently associated with dysfunction of the Eustachian tube. This may lead to the collection of fluid in the middle ear and the patients may experience unilateral deafness that is conductive in nature and other otologic symptoms such as otalgia and tinnitus. When a Chinese adult patient presents with serous otitis media, the otolaryngologist should consider the possibility of NPC (29).

When the primary tumor grows superiorly to infiltrate the skull base, the patient experiences headache. When the upward extension of tumor affects the cavernous sinus and its lateral wall, cranial nerves III, IV, and VI may be affected and the patient will present with diplopia (Fig. 120.4). When the tumor extends to involve the foramen ovale, the cranial nerve V may be affected (30) and there may be facial pain and numbness. Cranial nerve involvement in patients suffering from NPC is in the region of 13% (31) to 30% (32) depending on the stage of the disease.

In view of the high propensity of NPC to metastasize to cervical lymph nodes, the most frequent presenting symptom is painless neck masses, frequently appearing in the upper neck (Figs. 120.5 and 120.6). As the nasopharynx is a midline structure, it is not uncommon to see patients presenting with bilateral cervical lymph nodes.

Patients presenting with symptoms related to distant metastasis are relatively uncommon in NPC. Common distant metastatic sites are the vertebra, liver and lung.

Unfortunately, because of the nonspecific nature of the nasal and aural symptoms and the inconspicuous nature of the painless cervical lymph node, the majority of NPC patients are only diagnosed when their tumor have reached advanced stages. A retrospective analysis of 4,768 patients showed that the symptoms at presentation were neck mass

Figure 120.4 Clinical photograph showing a patient with paralyzed right eye lateral rectus muscle due to involvement of the right abducent nerve by NPC.

Figure 120.5 Clinical photograph showing a patient with an enlarged upper cervical lymph node (lateral view).

Figure 120.6 Clinical photograph of the same patient showing enlarged upper cervical lymph node (anterolateral view).

in 76%, nasal symptoms in 73%, aural symptoms in 62%, and cranial nerve palsy in 20% of patients (33). In most reports, the male-to-female ratio was 3:1, and the median age was 50 years.

DIAGNOSIS

When patients present with symptoms of NPC, they should be evaluated clinically for physical signs of NPC such as the presence of lymph nodes in the neck, fluid in the middle ear, and cranial nerve involvement. Indirect examination of the postnasal space should be carried out with a mirror although, in some patients, the anatomical variation of the nasopharynx precludes an adequate evaluation of the region. Other investigations toward the diagnosis of NPC are the estimation of antibody levels against EBV, imaging studies and endoscopic examination of the nasopharynx, and biopsy.

SEROLOGY

EBV affects human in various forms. It may cause infectious mononucleosis and has also been found to be associated with Burkitt lymphoma and NPC. EBV belongs to the herpes virus family, and the EBV-specific antigens can be grouped into early replicative antigens, latent-phase antigens, and late antigens. In patients suffering from NPC, their antibody, immunoglobulin A (IgA), response to the EA of the first group, and the VCA of the third group have been shown to be of diagnostic value (34). When a spectrum of antibodies against one of the latent-phase antigens, the EBV-associated nuclear antigen (EBNA), was evaluated, both the specificity and sensitivity of the test exceed 92% (35).

Most of the studies on the EBV serology for early diagnosis of NPC were carried out in the 1980s. In a recent meta-analysis on 20 these types of studies showed that IgA anti-VCA when elevated has a sensitivity of 91% and specificity of 92% in the diagnosis of NPC (36). A recent report from Taiwan studied 9,699 men, who had a one-off blood sample for their EBV serology, and this was subsequently correlated with the cancer registry and death registry over a 15-year period. Those with elevated anti-EBV titers have a 30 times more chance of developing NPC (15). The level of IgA anti-VCA in monitoring tumor response to treatment and in the detection of recurrence has not been established.

In recent years, cell-free DNA of the EBV in NPC patients was detected by real-time quantitative PCR, and it has been evaluated as a tumor marker (37). Increased copies of EBV DNA were found in the blood during the initial phase of RT as the viral DNA was released into the circulation after cell death (38). This has been shown to be more sensitive than the antibody titers against the various EBV antigens in the diagnosis of NPC (39). The quantity of free plasma EBV DNA has been shown relating to the stage of disease (40), and it is reliable in detecting distant metastases (41). The quantities of EBV DNA copies detected before and after treatment were significantly related to the rates of overall and disease-free survival (42). It has also been used to monitor recurrent disease following treatment (43); however, elevated levels of EBV DNA were only detected in 67% of patients with small locoregional recurrence (44).

IMAGING STUDIES

Clinical examination together with endoscopic examination can provide valuable information on tumor extension on the mucosal surface in nasopharynx. This procedure cannot determine the third dimension of tumor growth, that is, its deep extension and this includes skull base erosion and intracranial spread. This information is provided by cross-sectional imaging studies (45). These investigations are essential to document the extent of disease in the nasopharynx and its involvement of surrounding tissue. They are mandatory for the planning of RT.

Computed tomography (CT) can demonstrate the soft tissue extension in the nasopharynx and laterally into the paranasopharyngeal space (Fig. 120.7). It is sensitive in detecting bone erosion especially that of the skull base (46) (Fig. 120.7). Intracranial tumor extension through the foramen ovale with perineural spread can also be detected and this provides evidence of cavernous sinus involvement without skull base erosion (47). The information provided through CT is important for staging and also the choice of therapeutic measures for some patients (48). CT is capable of showing bone regeneration after therapy and this indicates complete eradication of tumor (49). CT, however, in general has poor tumor enhancement and in contrast magnetic resonance imaging (MRI) has better soft tissue specificity. Besides its ability to provide multiplanar imaging abilities (Fig. 120.8),

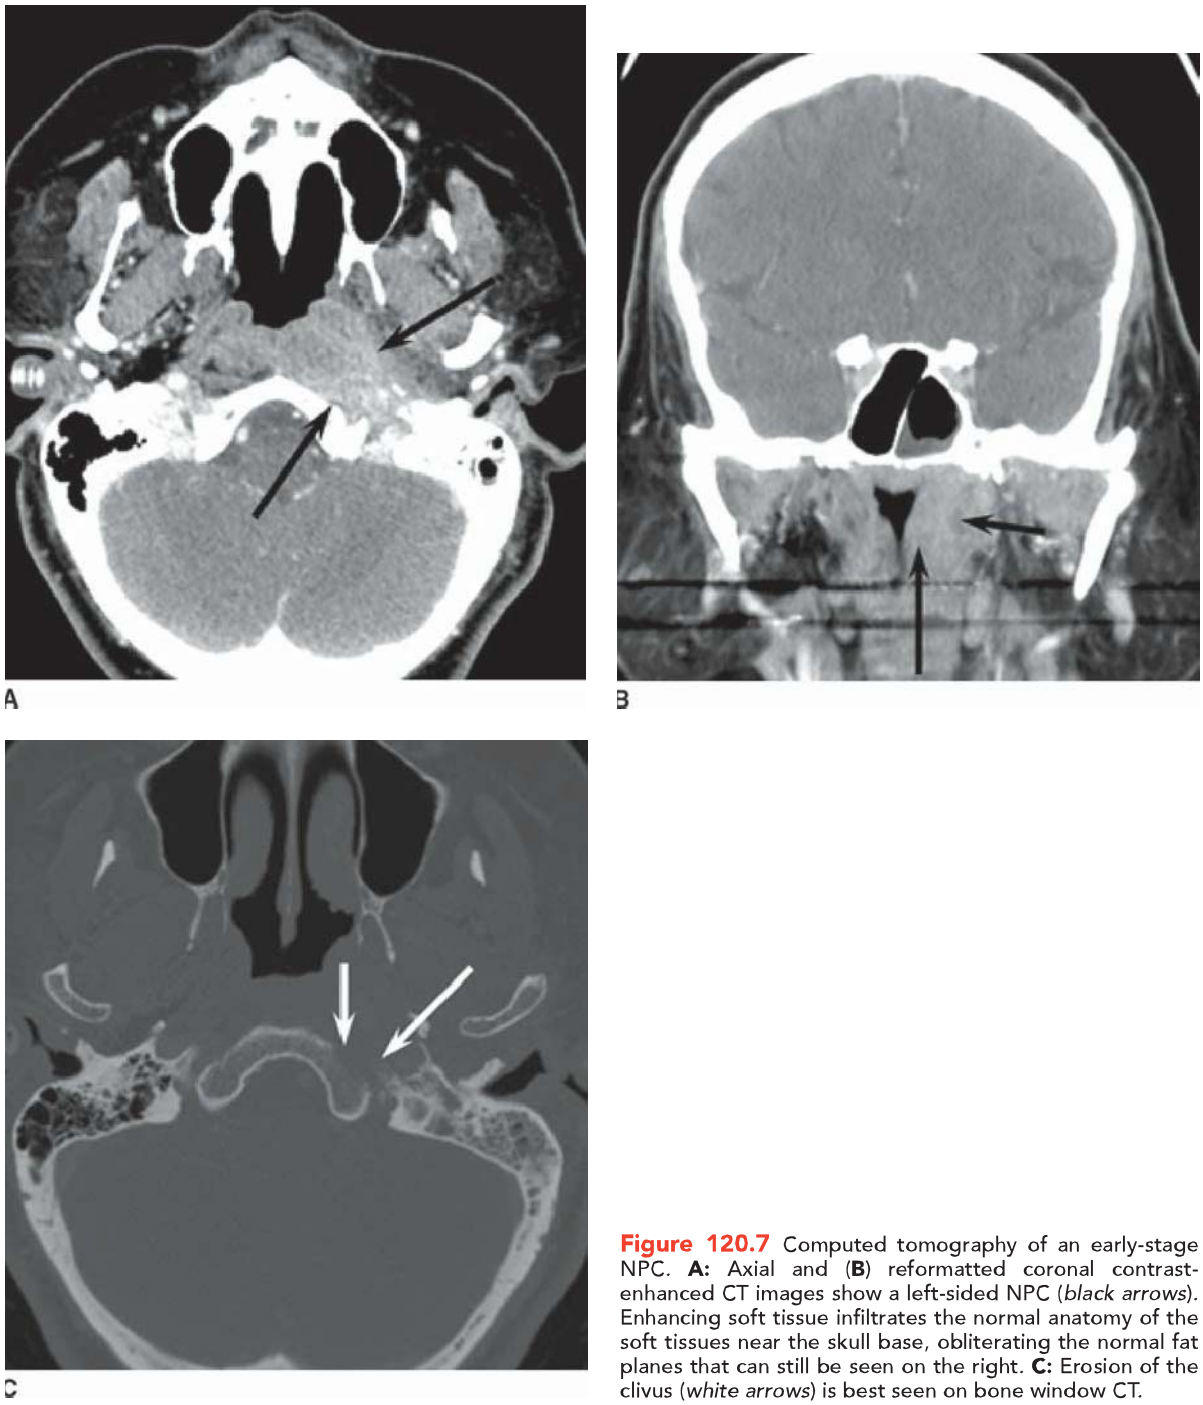

Figure 120.7 Computed tomography of an early-stage NPC. **A:** Axial and (**B**) reformatted coronal contrast-enhanced CT images show a left-sided NPC (*black arrows*). Enhancing soft tissue infiltrates the normal anatomy of the soft tissues near the skull base, obliterating the normal fat planes that can still be seen on the right. **C:** Erosion of the clivus (*white arrows*) is best seen on bone window CT.

MRI is better than CT in the differentiation of tumor from soft tissue inflammation, especially in the paranasal sinuses (Fig. 120.9). MRI is also more sensitive at evaluating retropharyngeal and deep cervical nodal metastases (Figs. 120.10 and 120.11). MRI is able to detect bone marrow infiltration by tumors (50), while CT can only detect this kind of infiltration when there is associated bony erosion. MRI, however, is unable to evaluate details of bone erosion.

Another contribution of cross-sectional imaging in NPC is the therapeutic aspects. As CT or MRI determines the primary tumor extent with precision (Figs. 120.12 to 120.14), it enables RT treatment to be designed and administered accurately and effectively, resulting in an improved outcome (51). This is particularly applicable with the intensity modulated radiotherapy (IMRT), which makes use of composite CT-MRI targets (52), enabling radiation energy to be targeted even more accurately to

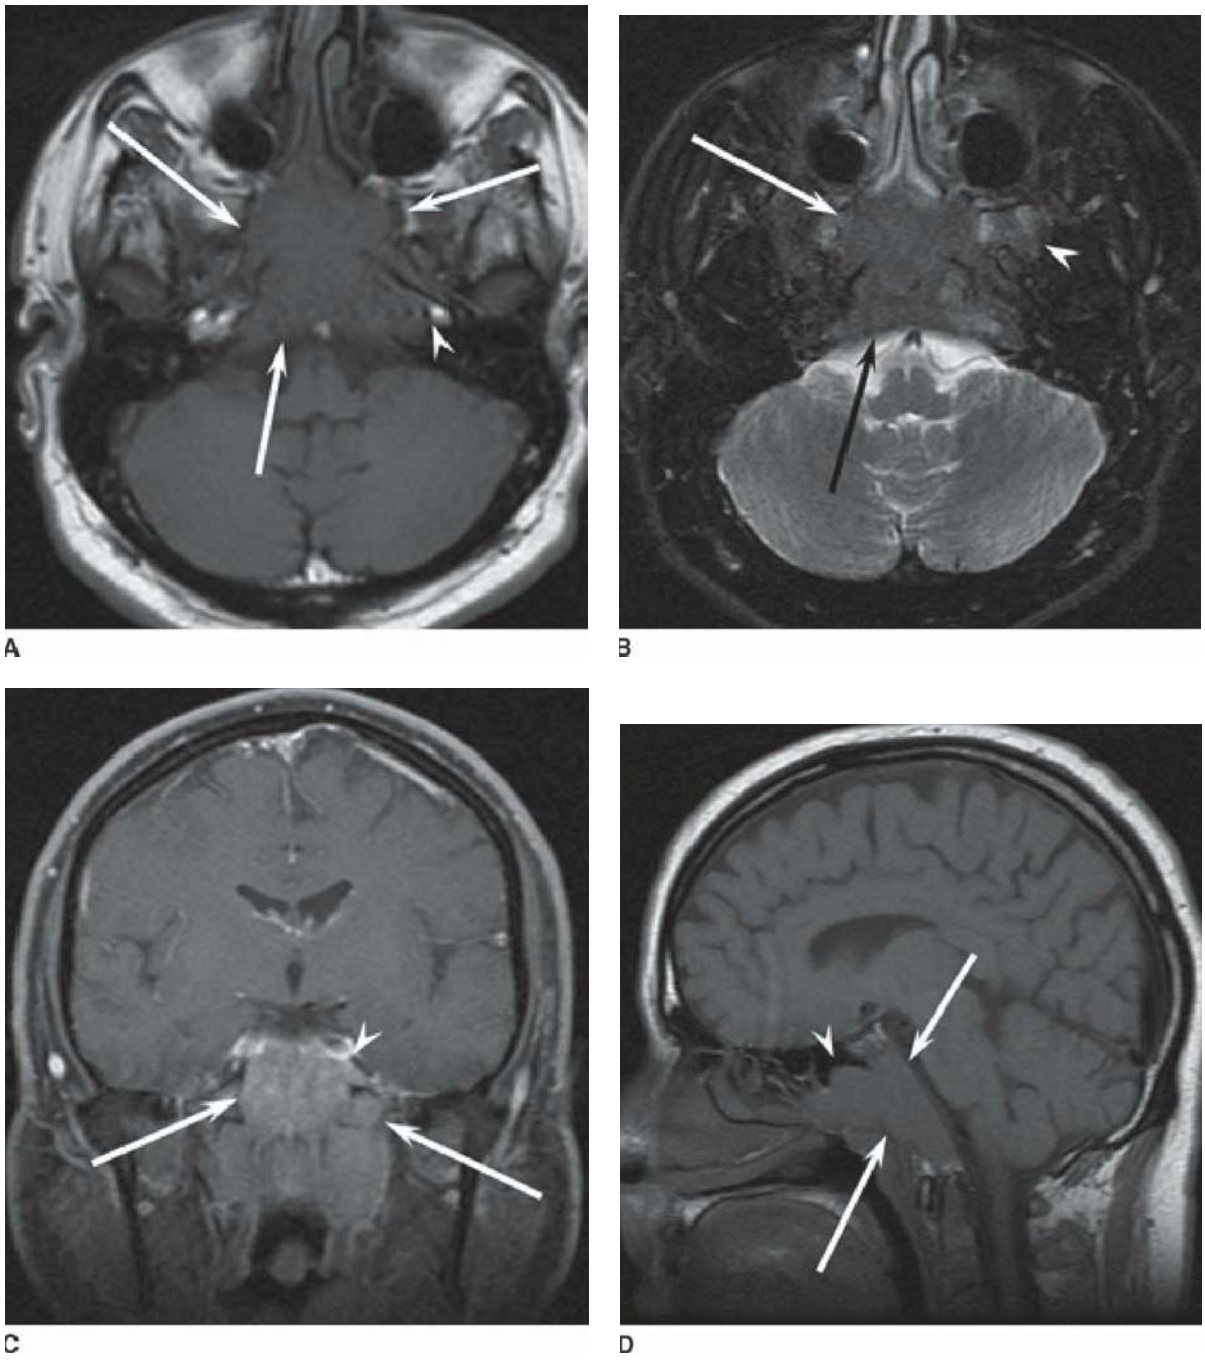

Figure 120.8 MRI of an advanced NPC. **A**: Axial unenhanced T1-weighted, (**B**) axial fat-suppressed T2-weighted, (**C**) coronal postcontrast fat-suppressed T1-weighted, and (**D**) sagittal unenhanced T1-weighted images of the nasopharynx demonstrate a large tumor (*arrows*) that has destroyed most of the central skull base. The tumor is isodense to brain (**A**), but dark on T2 (**B**) because of its high nuclear-to-cytoplasmic ratio. This tumor enhances uniformly (**C**), although many large NPCs have central necrosis resulting in heterogeneous enhancement. There is extensive involvement of surrounding structures such as the petrous carotid (*arrowhead* in **A**), the pterygopalatine and infratemporal fossae (*arrowhead* in **B**), the cavernous sinus (*arrowhead* in **C**), the clivus (*arrows* in **D**), and the sphenoid sinus (*arrowhead* in **D**).

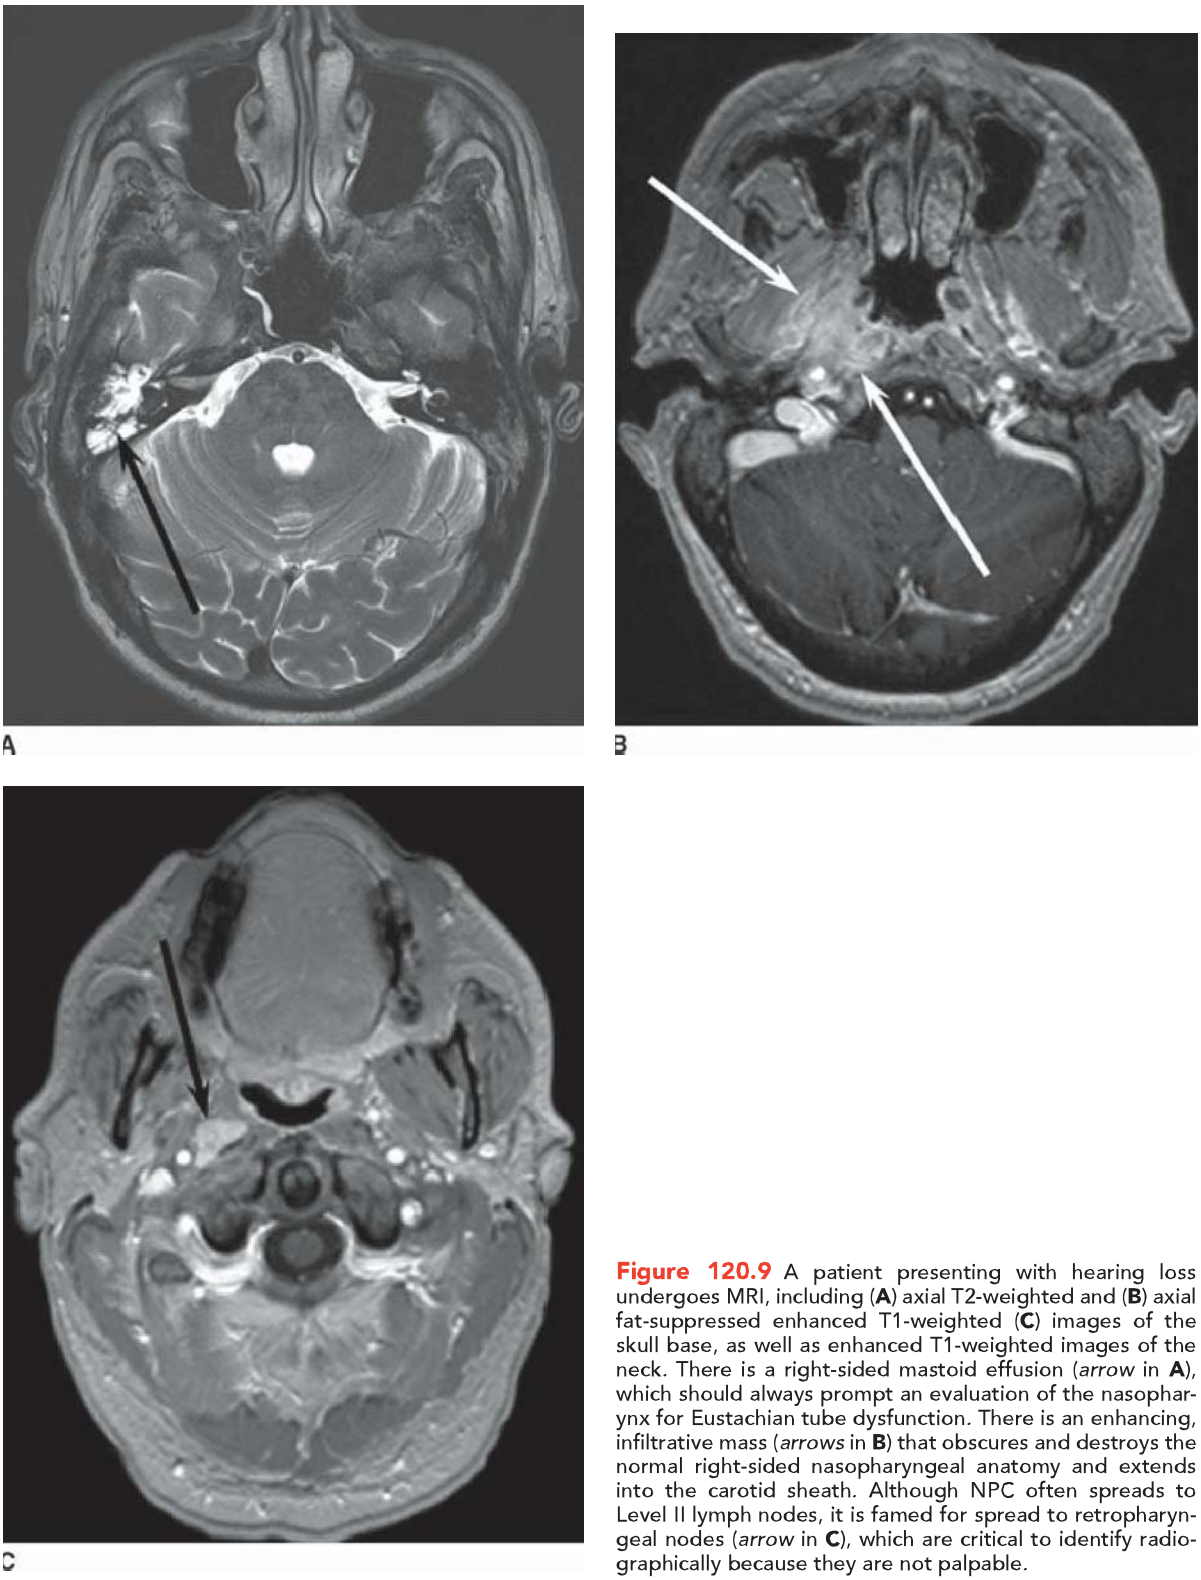

Figure 120.9 A patient presenting with hearing loss undergoes MRI, including (**A**) axial T2-weighted and (**B**) axial fat-suppressed enhanced T1-weighted (**C**) images of the skull base, as well as enhanced T1-weighted images of the neck. There is a right-sided mastoid effusion (*arrow* in **A**), which should always prompt an evaluation of the nasopharynx for Eustachian tube dysfunction. There is an enhancing, infiltrative mass (*arrows* in **B**) that obscures and destroys the normal right-sided nasopharyngeal anatomy and extends into the carotid sheath. Although NPC often spreads to Level II lymph nodes, it is famed for spread to retropharyngeal nodes (*arrow* in **C**), which are critical to identify radiographically because they are not palpable.

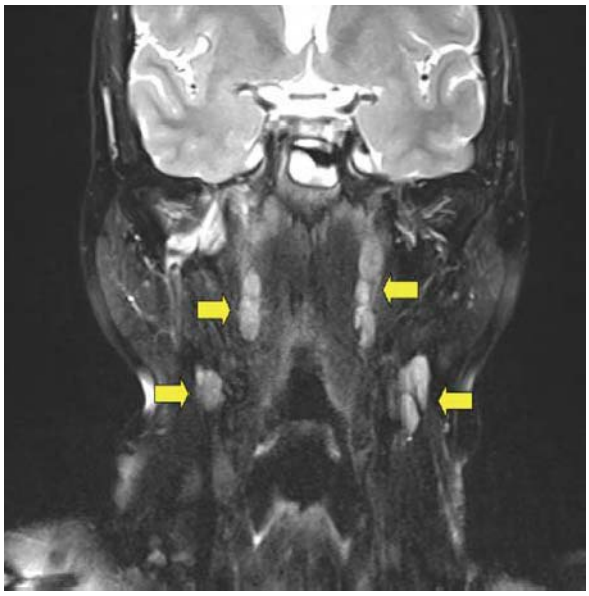

Figure 120.10 Coronal T2-weighted MRI demonstrates multiple bilateral pathologically enlarged cervical lymph nodes (*arrows*), representing metastatic NPC.

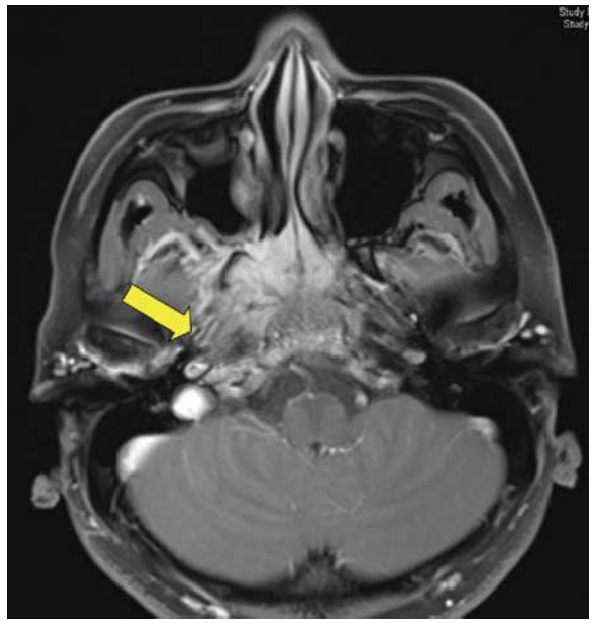

Figure 120.12 Axial fat-suppressed enhanced T1-weighted MRI shows NPC invading the greater sphenoid wing (*arrow*).

tumor while at the same time sparing adjacent normal tissues.

Positron emission tomography (PET) is useful to show the primary NPC with the metastatic lymph nodes (Figs. 120.15 and 120.16). For locally advanced NPC, the fluor-18-fluorodeoxyglucose (^{18}F-FDG) uptake as measured by standard uptake value (SUV_{max}) has been shown to have prognostic significance (53); those patients with SUV_{max} of higher than five have poor outcome (54). The hypermetabolic site locates the presence of tumor (Fig. 120.17).

The detection of distant metastases at diagnosis is difficult. Conventional studies such as bone scans, liver scintigraphy (55), and marrow biopsy (56) are of little value. They should only be carried out for those patients with high risk of distant spread such as those with N3 disease (57).

The role of PET in the detection of distant metastases in NPC and other malignancies was first noted in 2003 (58) (Fig. 120.18). In newly diagnosed NPC, PET is not more sensitive than MRI in the detection of distant metastasis (59). PET, however, has also been reported to

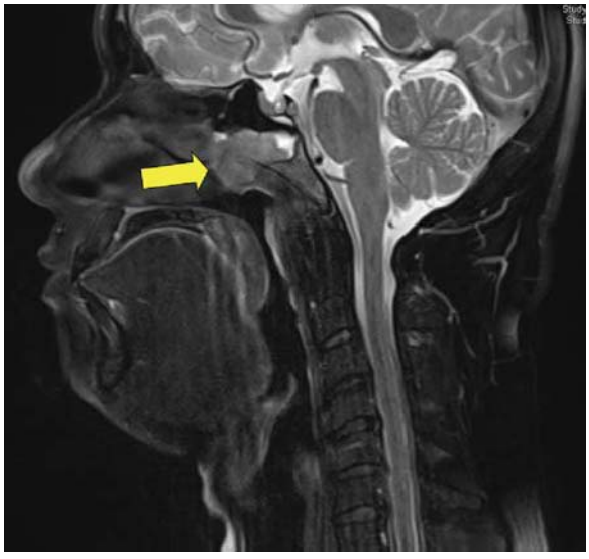

Figure 120.11 Sagittal T2-weighted MRI demonstrates NPC invading the sphenoid sinus (*arrow*).

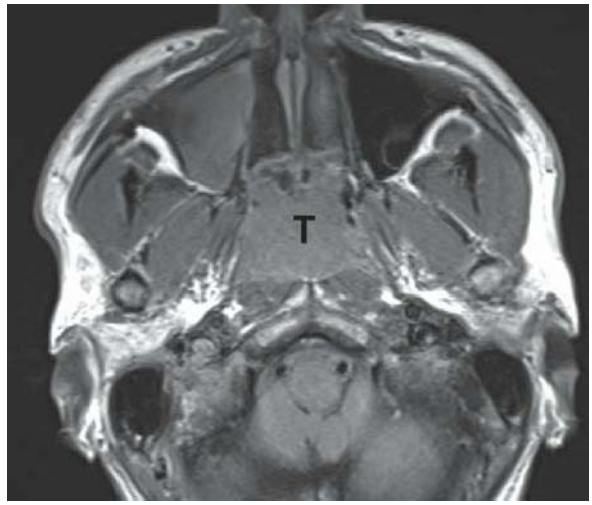

Figure 120.13 Axial unenhanced T1-weighted image shows a bulky tumor (T) filling the nasopharynx and extending into the nasal cavity bilaterally.

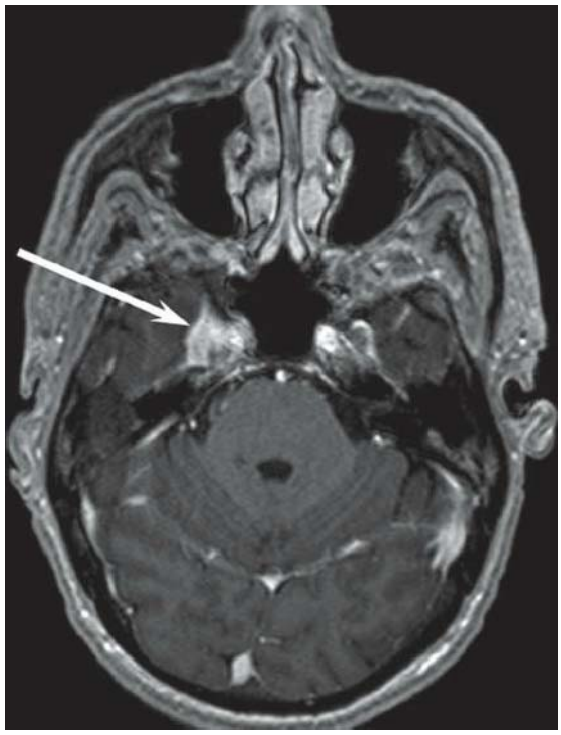

Figure 120.14 Axial T1-weighted MRI shows an enhancing mass (*arrow*) in the cavernous sinus and right middle cranial fossa, representing direct spread of NPC.

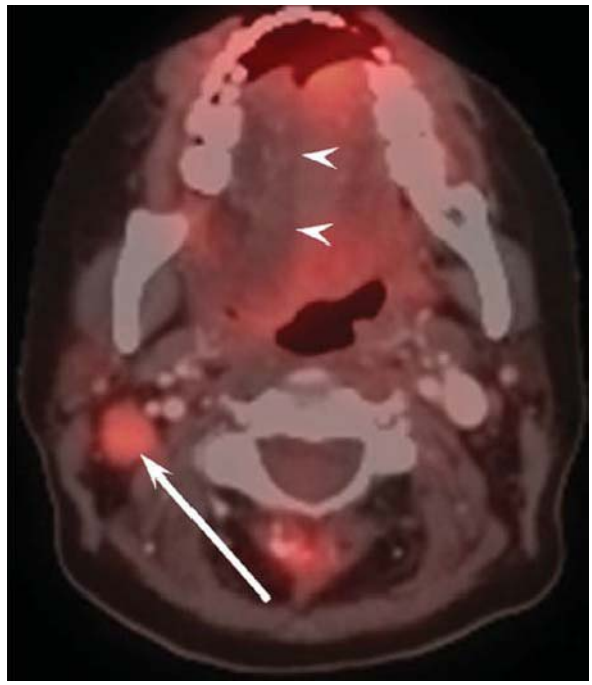

Figure 120.16 Combined PET-CT axial image shows an enlarged, FDG-avid Level II lymph node (*arrow*) representing metastatic NPC. The *arrowheads* show denervation atrophy of the tongue reflecting involvement of the hypoglossal nerve.

be more sensitive than cross-sectional imaging studies in detecting persistent and recurrent NPC (60), both at the primary site and in the neck. A recent systemic review showed that PET was better with dual-section and multisection helical CT (61).

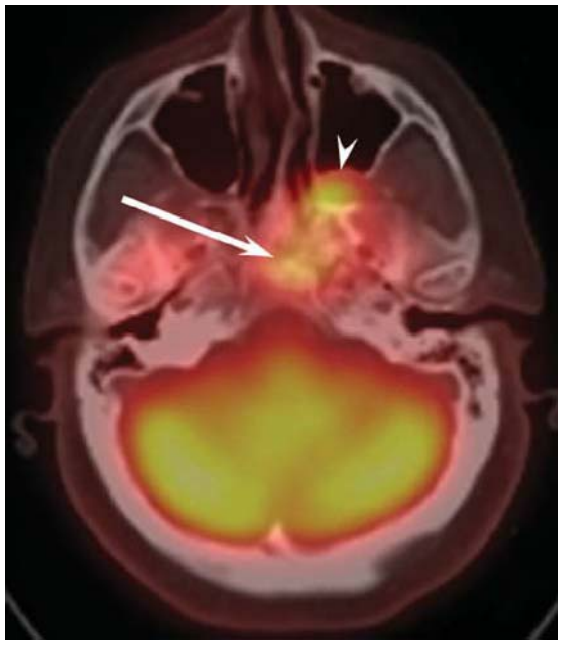

Figure 120.15 Combined PET-CT axial image shows increased activity in the middle skull base (*arrow*) and in the pterygopalatine fossa (*arrowhead*), demonstrating direct spread of primary NPC.

In summary, MRI is the preferred modality for local staging and detection of local recurrence. In patients with advanced disease, a PET/CT from the skull base to mid-thigh is useful to ascertain the extent of disease in the body.

ENDOSCOPIC EXAMINATION

The confirmation of the diagnosis of NPC requires a positive biopsy taken from the tumor in the nasopharynx. The nasopharynx can be adequately examined under topical anesthesia with endoscopes (Fig. 120.19). The rigid Hopkins telescopes, both 0° and 30°, give an excellent view of the nasopharynx on the side of insertion (Figs. 120.20 and 120.21). A 70° endoscope inserted behind the soft palate allows visualization of the roof of nasopharynx and both Eustachian tube openings (Fig. 120.22). These 3- or 4-mm-diameter rigid endoscopes do not have a suction or biopsy channel. Blood and mucus covering the tumor have to be removed by a separate suction catheter for a clear view of the pathology. Biopsy forceps should also be inserted alongside the endoscope for taking a biopsy of the tumor under direct vision.

The flexible endoscope allows thorough examination of the entire nasopharynx even when it is inserted through one nasal cavity. Its tip can be maneuvered behind the nasal septum to the opposite side. It has a suction channel and a biopsy forceps can be inserted through it to take a biopsy of the tumor under direct vision (Figs. 120.23

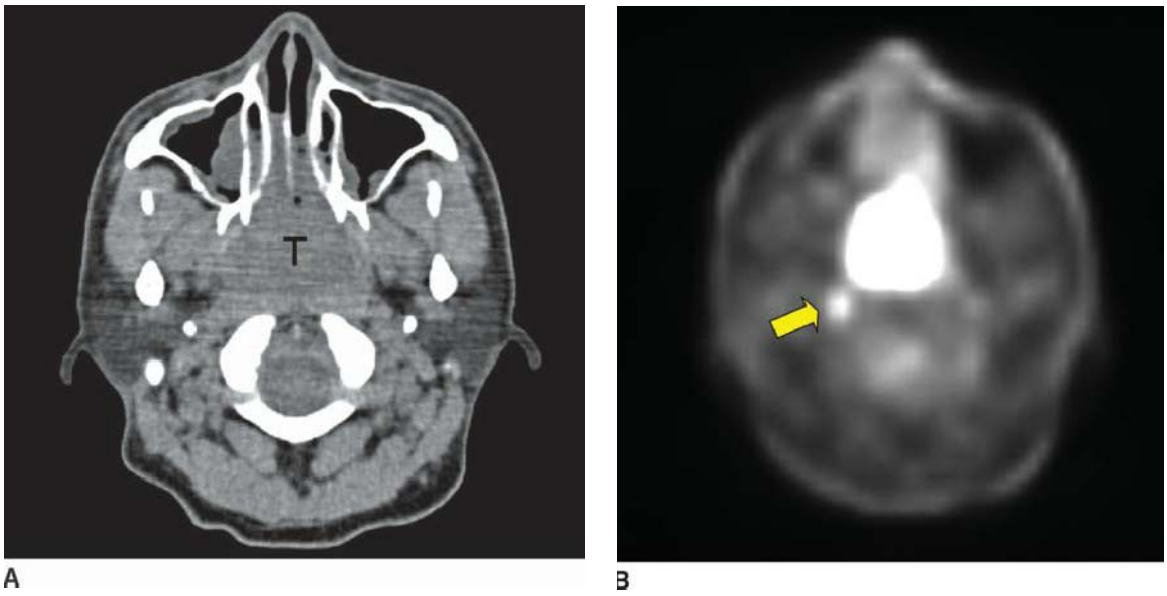

Figure 120.17 Axial CT (**A**) shows a large tumor in the nasopharynx, but the soft tissue in the nasal cavity and sinuses is equivocal for tumor. Corresponding PET image (**B**) shows the tumor is confined to the nasopharynx, and also identifies an unseen retropharyngeal node (*arrow*).

and 120.24). Despite all these advantages, the visual image gathered with the flexible endoscope is inferior to that of the rigid endoscope. The size of the biopsy forceps is also small thus the amount of tissue obtained might not be enough. Sometimes a larger biopsy forceps might have to be inserted by the side of the flexible endoscope to obtain more substantial amount of tissue for histologic examination.

STAGING

A clinical staging system for NPC is essential for treatment planning and evaluation of therapeutic outcome. Over the years, a few staging systems were used for NPC; the Union International Contre le Cancer (UICC) system and the American Joint Committee on Cancer Staging (AJCC) system are preferred in Europe and America, respectively, while Ho system (62) is frequently used in Asia.

Both the UICC and the AJCC systems assess tumor extent in the nasopharynx by considering the number of tumor-affected sites within the nasopharynx while the

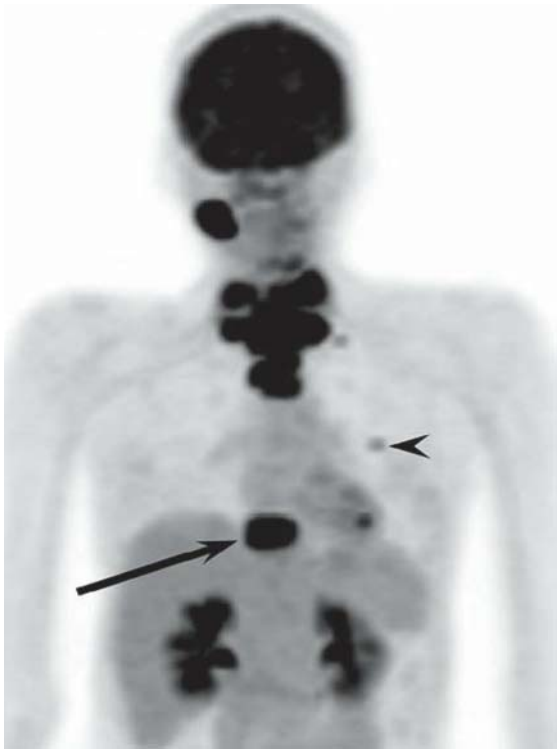

Figure 120.18 Frontal-projection MIP of a PET scan shows extensive NPC metastases in the neck and upper mediastinum, as well as unsuspected metastasis in the lower mediastinum (*arrow*) and the lung (*arrowhead*).

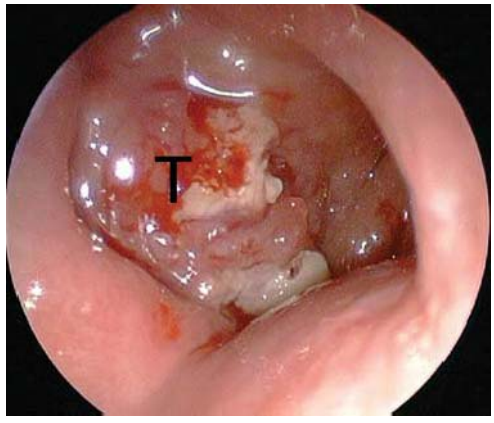

Figure 120.19 Rigid endoscope (0°) inserted through the right nasal cavity showing a fleshy tumor in the nasopharynx (T).

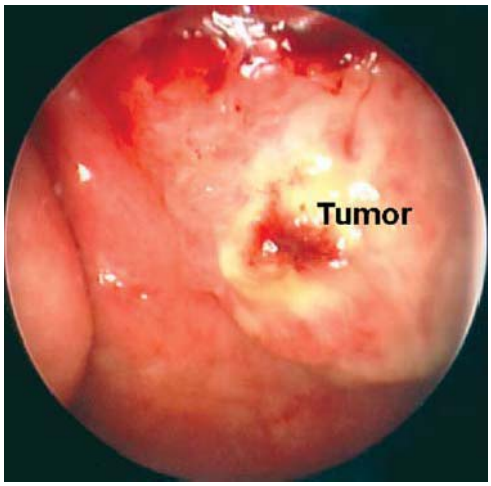

Figure 120.20 Rigid endoscope (0°) inserted through the right nasal cavity and tumor in the nasopharynx is identified (Tumor).

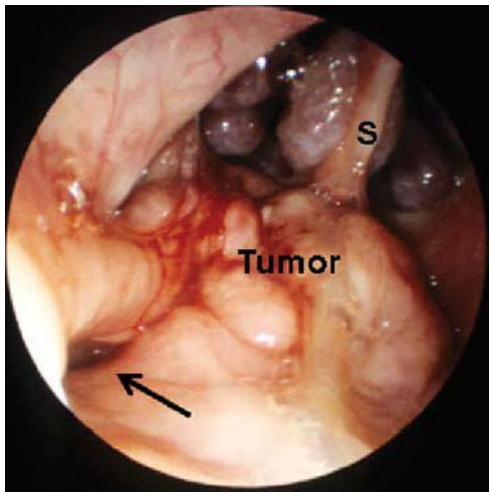

Figure 120.22 Rigid endoscope (70°) inserted through the oral cavity, inspecting the nasopharynx from below. Posterior edge of the nasal septum (S). Right Eustachian tube orifice (*arrow*) and nasopharyngeal tumor can be seen extending from the right lateral wall onto the roof of the nasopharynx (Tumor).

Ho system classifies all tumors confined to the nasopharynx as T1 disease. UICC and AJCC systems have unified since 1992. In the recent staging system of 2009, T1 stage included all tumors that confine to the nasopharynx or extend locally such as inferiorly to the oropharynx or anteriorly to the nasal cavity (63,64) (Table 120.1). On the other hand, lateral tumor extension to the parana-sopharyngeal space indicates more advanced disease. T2 stage includes tumor that has extended to the paranasopharyngeal space. The T3 disease covers tumors that have involved the skull base or the paranasal sinuses. T4 tumors are those that have extended to the infratemporal fossa, orbit, hypopharynx, and cranium, or have affected the cranial nerves.

The UICC/AJCC staging systems recognize the size of the cervical lymph node as an important factor. For other head and neck cancers, N1 is less than 3 cm in size and N2 is greater than 3 cm. The difference between N2 and N3 is a nodal size of 6 cm. The retropharyngeal nodes, which are the first-echelon nodes, are not taken into account by all staging systems. CT or MRI now detects these nodes (65).

These factors are all addressed in the nodal staging section of the recent UICC/AJCC for nasopharyngeal cancer staging system (Table 120.1). The measurement of 6 cm is the only factor for size. Laterality and site of involvement such as the retropharyngeal region and the supraclavicular fossa are other important factors in determining the N staging. Under the current system, N1 referred to unilateral nodal involvement less than 6 cm in diameter and not reaching the supraclavicular fossa. Bilateral retropharyngeal nodes as long as they are less than 6 cm are still N1. Bilateral cervical nodal disease that has not reached

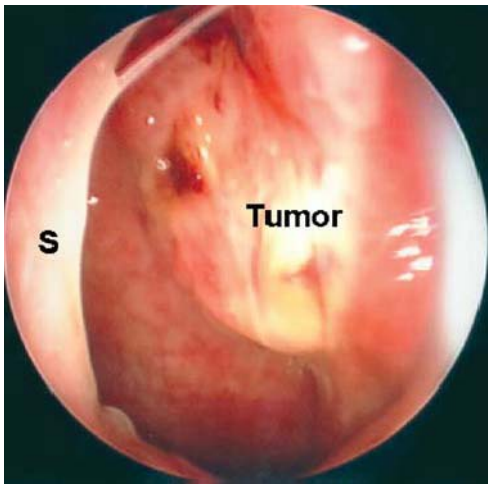

Figure 120.21 Rigid endoscope (30°) inserted through the left nasal cavity of the same patient and tumor in the nasopharynx identified (Tumor). The posterior edge of the septum is visible (S).

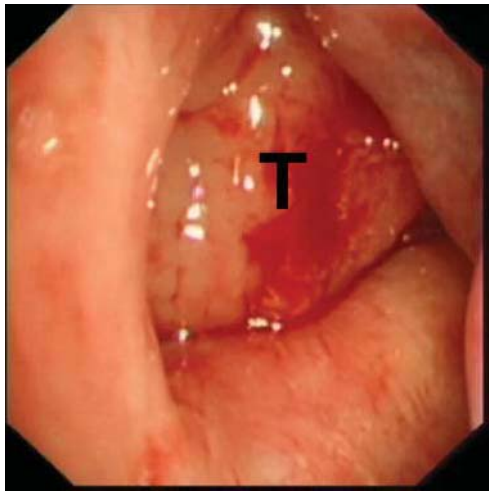

Figure 120.23 Flexible endoscope (videoendoscope) inserted through the left nasal cavity showing the tumor (T) on the right side.

Figure 120.24 Flexible endoscope (videoendoscope) inserted through the left nasal cavity a biopsy forceps (*arrow*) is inserted through the biopsy channel and guided to the tumor (T).

N3 designation, irrespective of size, number, and location is classified N2. Stage N3 disease referred to lymph nodes larger than 6 cm (N3a), or nodes that had extended to the supraclavicular fossa (N3b). For M-staging, M1 represents distant metastases, including any lymph node involvement below the level of the clavicle. The current unified staging system has enabled patients to be staged more precisely and simply; it is also considered as a better predictor of prognosis (66–68).

TREATMENT

Radiotherapy

In view of the location of the nasopharynx, lying in close proximity to important structures and the infiltrative nature of NPC, surgical resection of the primary tumor is challenging. NPC, however, is radiosensitive and thus RT has been the primary treatment modality for decades. RT though effective may also produce undesirable complications as the radiation might affect the structures around the nasopharynx. These structures include the brain stem, spinal cord, pituitary–hypothalamic axis, temporal lobes, eyes, middle and inner ears, and parotid glands. These structures limit the amount of radiation that can be delivered to the tumor. As NPCs tend to infiltrate and spread toward these dose-limiting organs, it is difficult to shield these structures without compromising the dose delivered to the primary tumor with conventional RT using two-dimensional treatment planning and custom block for shielding. Because of the high incidence of occult neck node involvement, the neck is usually included in the radiation field electively (69). A good locoregional control could be achieved and once there is a locoregional relapse there is an increased risk of developing distant metastases (70).

During the two-dimensional RT era, RT for NPC usually starts with large lateral opposing faciocervical fields that cover the primary tumor and the upper neck lymphatics in one volume, with matching lower anterior cervical field for lower neck lymphatics (71). In general, the radiation dose given to the primary tumor is in the range of 65 to 75 Gy and that to the involved neck nodes 65 to 70 Gy. For elective radiation of node-negative neck, the dose given is 50 to 60 Gy. This treatment has successfully controlled T1 and T2 tumors in between 75% to 90% of cases, and T3 and T4 tumors in 50% to 75% of cases (72,73). Nodal control is achieved in 90% of patients with N0 and N1 diseases, but the regional control rate drops to 70% for N2 and N3 cases (58).

Sometimes for T1 and T2 tumors, employing a booster dose using intracavitary brachytherapy has shown to improve tumor control by 16% (74). Although stereotactic radiosurgery has also been used for delivery of the booster dose (75), the hypofractionated treatment is associated with undesirable side effects and is probably better reserved for the treatment of persistent and recurrent disease (76).

The major limitations of two-dimensional planning for NPC can now be eliminated with three-dimensional conformal RT and IMRT (77,78). When the tumor extension was close to the dose-limiting organs, IMRT is distinctly useful as it further improves the dose differential between the tumor and the dose-limiting organs (79,80). IMRT is a complicated technique that allows the delivery of highly conformed dose distribution to the target and critical structures through optimization of intensity of multiple beams, that is, the beams are shaped so that high dose can be conformed to match the target while selective avoidance of dose to critical structures can be achieved at the same time. The advantages of IMRT include the ability to deliver highly conformal RT to irregular target, in particularly when the target volume wraps around critical structures such as brain stem and spinal cord. It also has the ability to treat primary and regional lymphatic in one volume thus eliminating the dose uncertainty problem at the junction between the primary tumor and neck lymphatic target volumes.

IMRT is ideal for treatment of NPC and has already achieved excellent local control rates for newly diagnosed NPC, with reported local control rate of 92% to 97% at 3 to 4 years (81,82). Apart from improvement of tumor control, IMRT also reduces the risk of late complications such as xerostomia in early stage disease. A prospective study has confirmed the recovery of salivary functions within 2 years (83). Satisfactory results were also achieved with IMRT for recurrent NPC, and the degree of short-term control was encouraging (84). The limitation of IMRT remains to be the precision of determining the junction of tumor and the adjacent normal structures and the accurate determination of this safety margin is crucial for an optimal treatment outcome.

TABLE 120.1 THE AMERICAN JOINT COMMITTEE ON CANCER STAGING

Primary tumor in nasopharynx (T)

T1—Tumor confined to the nasopharynx, or tumor extends to oropharynx and/or nasal cavity without parapharyngeal extension
T2—Tumor with parapharyngeal extension
T3—Tumor involves bony structures of skull base and/or paranasal sinuses
T4—Tumor with intracranial extension and/or involvement of cranial nerves, hypopharynx, orbit, or with extension to the infratemporal fossa/masticator space

Regional lymph nodes (N)

The distribution and the prognostic impact of regional lymph node spread from nasopharynx cancer, particularly of the undifferentiated type, are different from those of other head and neck mucosal cancers and justify the use of a different N classification scheme.
NX—Regional lymph nodes cannot be assessed
N0—No regional lymph node metastasis
N1—Unilateral metastasis in lymph node(s), 6 cm or less in greatest dimension, above the supraclavicular fossa, and/or unilateral or bilateral, retropharyngeal lymph nodes, 6 cm or less, in greatest dimension
N2—Bilateral metastasis in lymph node(s), 6 cm or less in greatest dimension, above the supraclavicular fossa
N3—Metastasis in a lymph node(s) >6 cm and/or to supraclavicular fossa
N3a—>6 cm in dimension
N3b—extension to the supraclavicular fossa

Distant metastasis (M)

M0—No distant metastasis
M1—Distant metastasis

Stage groups

Stage 0	T1s	N0	M0

Edge SB, Byrd DR, Compton CC, et al. *AJCC cancer staging hand book*, 7th ed. New York, NY: Springer, 2010:63–79.

Other attempts to enhance the results of RT included accelerated fractionation (85), accelerated hyperfractionation (86), combination of one or other of these treatments with chemotherapy (87,88).

Chemotherapy

For the management of NPC patients especially those with advanced locoregional disease, chemotherapy has been applied in combination with RT. The chemotherapy can be given before, during, or after radiation, and are named as neoadjuvant, concurrent, and adjuvant chemotherapy, respectively.

The Intergroup 1997 study first showed that employing chemotherapy together with radiation improved overall survival when compared to using RT alone (89). The Intergroup trial employed both concurrent and adjuvant chemotherapy in the study arm and reported an absolute improvement of survival of 31% at 3 years. This study included many patients with well-differentiated carcinoma and there were initially doubts whether it was applicable to NPC in the endemic areas. Subsequent randomized trials conducted in endemic regions have confirmed the benefits of concurrent chemoradiotherapy for locoregionally advanced NPC, although different regimens and schedule were being employed in these studies (90–93).

Four randomized phase III studies comparing neoadjuvant chemotherapy followed by RT versus RT alone in NPC have been reported (94–97). All these studies failed to demonstrate any survival benefits with addition of chemotherapy prior to RT. Two of these studies were recently updated and the data pooled for analysis,

and although significant improvement in disease-free survival in the chemotherapy arm was observed, overall survival was not improved (98). Two adjuvant chemotherapy phase III studies have been reported, and both showed no survival benefits (99,100). Both adjuvant chemotherapy trials had limitations since nonplatinum chemotherapy was used in one study and chemotherapy compliance was rather poor in the other study. These studies showed that induction chemotherapy alone has limited role in NPC, whereas the role of adjuvant chemotherapy remains undefined.

Another new approach being investigated currently is the combination of neoadjuvant chemotherapy and concurrent chemoradiotherapy for locoregional advanced NPC, since it may be easier to administer chemotherapy before than after concurrent chemotherapy with the added benefit of rapid tumor shrinkage prior to RT, and preliminary reports showed that excellent control can be achieved using this approach in advanced T stage tumors (101). Another study on neoadjuvant chemotherapy followed by concomitant chemoradiotherapy also reported excellent overall survival with acceptable toxicity (102). In view of the ototoxicity of cisplatin, other chemotherapeutic agents have been used. A study using cisplatin concurrently with RT, followed by adjuvant ifosfamide, 5-fluorouracil, and leucovorin in patients with stage IVb NPC has been reported. Although these patients have more advanced disease, the outcome of the treatment was comparable to other platinum-based adjuvant chemotherapy studies and the compliance rate was acceptable (103). Another study employed oxaliplatin instead of cisplatin as concurrent chemotherapy during RT, with favorable toxicity profile and superior outcome than RT alone (104).

In summary, current evidence indicates that concurrent chemoradiotherapy has a major role in advanced stage NPC. A recent meta-analysis that included eight trials with 1,753 patients showed an absolute survival benefit of 6% at 5 years from the addition of chemotherapy (from 56% to 62%) to RT in NPC, and the benefit was essentially observed when chemotherapy was administered concomitantly with RT (105). Based on current evidence, concurrent chemoradiotherapy should be given to all patients with nodal disease and/or T3–4 disease, whereas RT alone should be reserved for those with T1–2 N0 disease.

MANAGEMENT OF PERSISTENT OR RECURRENT DISEASE

Although concurrent chemoradiation is effective in the management of NPC, local or regional failure presenting as persistent or recurrent tumor still occurs. The incidence of local failure was around 8.3% (106) and they may present as residual or recurrent tumor, and the incidence of isolated failure in the neck in recent years was around 1.6% (107). To attain a high successful salvage rate, early detection and administration of the appropriate therapy is essential. Imaging studies such as CT and MRI at one time cannot give a definite diagnosis but on sequential imaging a progressive enlarging mass would suggest the presence of disease. PET scan has been reported to be superior to conventional imaging studies to provide the diagnosis of persistent or recurrent disease (108). The presence of malignancy can usually be confirmed with biopsy through endoscopic examination. Persistent or recurrent tumor in the neck node after chemoradiotherapy, however, is notoriously difficult to confirm, as in some lymph nodes only clusters of tumor cells were present. Fine needle aspiration cytology was diagnostic only in 50% of the time and frequently surgery has to be carried out for progressive enlarging cervical lymph node, either clinically or on sequential imaging.

Aggressive treatment for locally recurrent NPC is warranted as although survival after retreatment for extensive disease remains poor, it is still higher than that of those managed with supportive treatment only. Even when there were synchronous locoregional failures, aggressive treatment should be considered for selected patients (109).

Persistent or Recurrent Tumor in Neck Lymph Nodes

When the persistent or recurrent neck nodes are managed with another course of external RT, the reported overall 5-year survival rate was only 19.7% (110). Radical neck dissection performed as surgical salvage has reported to achieve a 5-year tumor control rate of 66% in the neck (111) and a 5-year disease progression free 44% (112). Pathologic studies have shown that for those persistent or recurrent tumors in the neck nodes, the disease involvement of the local tissue was extensive. Many lymph nodes appeared free of tumor macroscopically were identified to harbor malignant cells on histologic examination. Malignant cells could be seen to extend outside the capsule of the lymph nodes and lying close to the accessory nerve and internal jugular vein. Tumor clusters were also seen in the stern mastoid muscle and among other tissues in the neck (113). A radical neck dissection was considered essential for salvage treatment for the cervical nodal metastasis after RT in patients with NPC. A recent study showed that as the neck nodes in level I was infrequently involved, level I should be preserved in the neck dissection (114).

When tumor in the neck node extends beyond the confines of the lymph node, such as infiltrating the floor of the neck or the overlying skin, then brachytherapy should be applied to the tumor bed in addition to radical neck dissection (Figs. 120.25 and 120.26). With this adjuvant therapy, the 3-year actuarial control rate of neck disease

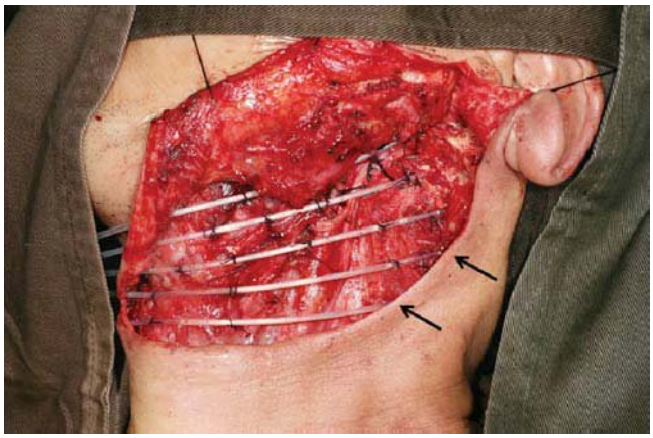

Figure 120.25 Following radical neck dissection for the extensive neck node, the overlying neck skin was also removed. Hollow nylon tubes (*arrows*) were placed in the tumor bed for postoperative brachytherapy.

was reported to be around 60% (115). This became similar to the local disease control rate when a radical neck dissection was carried out for less extensive neck disease.

Persistent or Recurrent Tumor in the Nasopharynx

Persistent or recurrent disease in the nasopharynx after the initial radical dose of radiation can still be managed with a second course of external RT with a larger radiation dose. The complications arising from the second dose of external RT affect significantly the quality of life of these patients. However, with the development of precision RT, such as IMRT, a second course of external RT could be given with sufficient efficacy and acceptable side effects. A salvage rate of 32% has been reported although the cumulative incidence of late post-reirradiation sequelae was 24%, with a treatment mortality of 1.8% (116). To alleviate the complications of reirradiation, alternative salvage measures have been introduced. These include stereotactic RT, brachytherapy, and surgical resection. These treatment options are applicable when the persistent or recurrent tumor is small and localized in the nasopharynx.

Figure 120.26 The neck skin defect was covered with a pectoralis major myocutaneous flap.

Stereotactic Radiotherapy

The local tumor control rate achieved with stereotactic RT for management of persistent or recurrent tumor was 72% at 2 years and 86% at 3 years (117). A recent study with 90 patients treated employing this approach for locally persistent and recurrent disease reported a 3-year local control rate of 83% (118). For small volume disease, using stereotactic RT with single fraction treatment achieved excellent result that appears to be comparable to gold grain implantation (119) and fractionated dose of stereotactic RT (120).

Brachytherapy

With brachytherapy, the radiation source is placed directly into the tumor. Thus, the radiation dose is highest at the source in the tumor, and this declines with increasing distance from the tumor. This allows the delivery of a high therapeutic radiation dose to the persistent or recurrent tumor in the nasopharynx while the surrounding tissue is irradiated with a much smaller dose. The brachytherapy radiation source also delivers radiation at a continuous rate, and this gives radiobiologic advantage over fractionated external radiation. Intracavitary brachytherapy has been used for NPCs both as a boost of the primary treatment and for persistent or recurrent disease (121). The radiation source was placed either in a tube or a mould and then inserted into the nasopharynx. Good local control has been reported with intracavitary brachytherapy (122). However, in view of the irregular contour of the primary tumor within the nasopharynx, it is difficult to apply the radiation source accurately to each part of the tumor to produce a tumoricidal effect. To circumvent this problem, radioactive interstitial implants have been used to treat small and localized persistent or recurrent tumor in the nasopharynx (123). The frequently used interstitial implant is radioactive gold grains (^{198}Au). They are implanted either transnasally or using the split-palate approach (124). The split-palate approach gives the surgeon a direct view of the tumor and enables the implantation of the desired number of gold grains permanently into the tumor with precision (Figs. 120.27 and 120.28). The surgical procedure is simple with limited morbidity (125). When gold grain implants were used to treat persistent and recurrent tumors after RT, the reported 5-year local tumor control rates were 87% and 63%, respectively, and the corresponding 5-year disease-free survival rates were 68% and 60%, respectively (126).

Nasopharyngectomy

When the persistent or recurrent tumor in the nasopharynx has extended to the paranasopharyngeal space or is too bulky for brachytherapy to be successful, then the

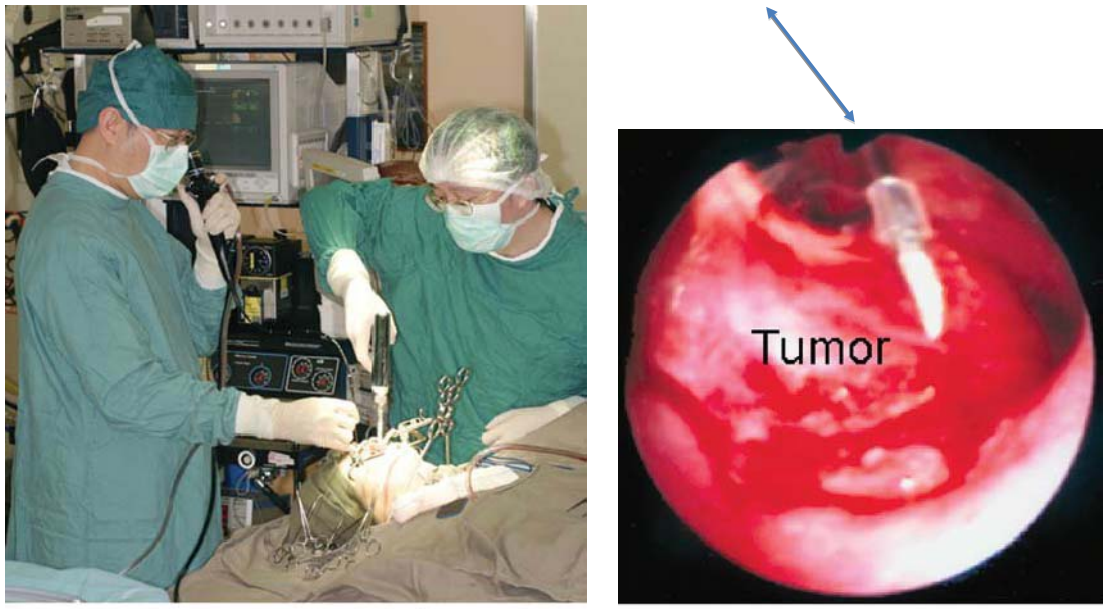

Figure 120.27 **A:** The surgeon (**left**), after splitting the palate, holds a flexible endoscope placed in the nasopharynx to provide illumination and guidance. The oncologist (**right**) uses the gold grain applicator to insert the radioactive grains directly into the tumor. **B**: endoscopic view showing the tip of the gold grain applicator (*arrow*) before inserting into the tumor (Tumor).

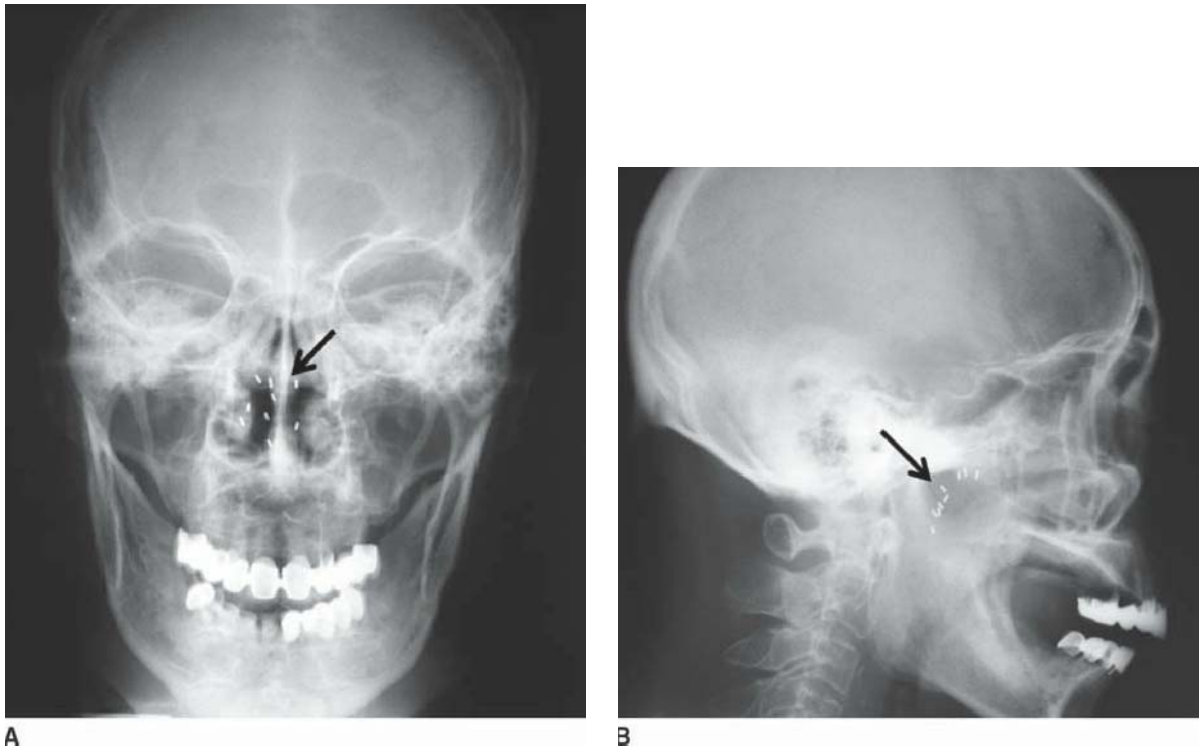

Figure 120.28 **A:** Frontal and (**B**) lateral conventional radiographs demonstrate gold grains (*arrows*) embedded in the nasopharynx.

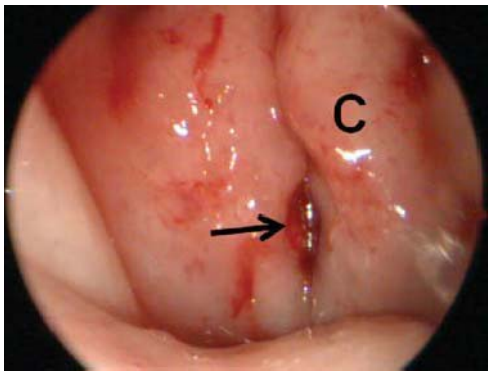

Figure 120.29 Endoscopic view showing a small recurrent tumor (*arrow*) situated medial to the medial crura of the left Eustachian tube (C).

next salvage option is surgery. Nasopharyngectomy is effective in the eradication of localized disease in selected patients.

Adequate resection of small but thick tumor located in the posterior wall of the nasopharynx could be achieved with endoscope inserted through the nasal and oral cavities (127–129) (Figs. 120.29 and 120.30). Microwave coagulation therapy has also been reported with success when applied transnasally (130). The rigid endoscopic instruments, however, limit the removal of tumor located over the lateral wall of the nasopharynx. These localized tumors not involving the paranasopharyngeal space, however, might be resected employing the versatile endowrists of the da Vinci Robot. The robotic arms and the three-dimensional camera could be inserted to the nasopharynx through a split-palate approach (131) (Fig. 120.31).

For more extensive disease in the nasopharynx, open approach resection is necessary. A successful surgical salvage depends on adequate tumor removal with a negative resection margin (132) and thus wide exposure of the tumor and its vicinity is essential. The anatomical location of the nasopharynx is in the central part of the head. It is difficult to expose the region adequately to carry out an oncologic resection. The brain and the spinal cord render

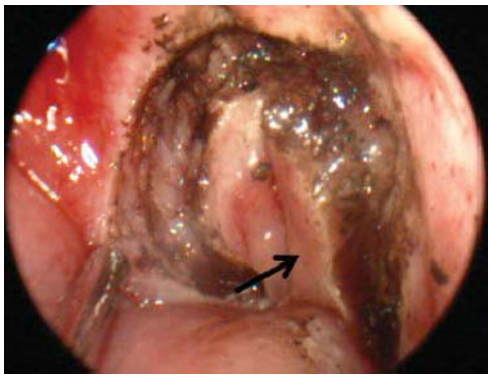

Figure 120.30 The tumor is resected with margin (*arrow*) employing diathermy under direct vision of the endoscope.

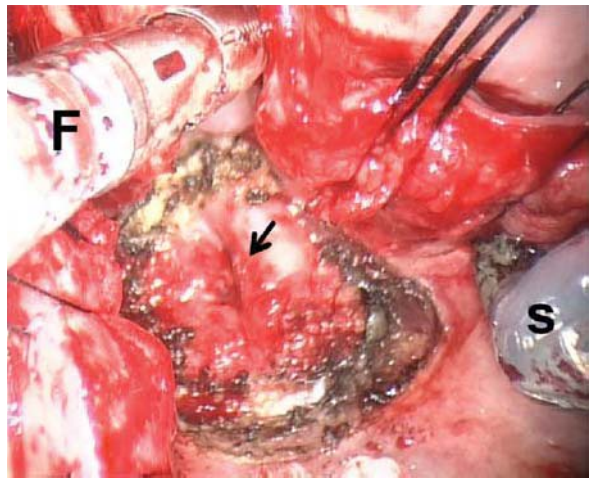

Figure 120.31 Through a split-palate approach, the endowrists of the da Vinci robot is employed to remove the tumor (*arrow*) under direct vision. Endowrist with grasping jaw (F) is shown on the left and the scissors with diathermy capabilities (S) on the right.

superior and posterior approaches not practical. The transantral and midfacial deglove procedures to reach the nasopharynx from the front do not provide adequate exposure of the whole nasopharynx. These anterior approaches, even with the down-fracture of the hard palate, only expose the posterior wall of the nasopharynx and not the lateral walls adequately. Despite these, satisfactory results of surgical salvage of recurrent tumor in the nasopharynx have been reported (133–136). The nasopharynx can be approached through the infratemporal fossa from the lateral aspect (137). It is applicable for lesions localized to the lateral wall. Recently, there was a report on 11 patients salvaged with this approach, resulting a 2-year disease-free survival rate of 72% (138). With this approach, however, it is difficult to remove adequately those tumors that have crossed the midline.

To remove tumor in nasopharynx from the inferior aspect, employing the transpalatal, transmaxillary, and transcervical approach is possible (139,140). It is useful for tumors located in central nasopharynx and not extending too far laterally.

To approach the nasopharynx anterolaterally with the maxillary antrum swung laterally provides adequate exposure of the tumor in nasopharynx and the paranasopharyngeal region (141). Following appropriate osteotomies, the maxilla bone attached to the anterior cheek flap can be swung laterally as one osteocutaneous complex (Fig. 120.32). This exposes the entire nasopharynx and the paranasopharyngeal space so that an oncologic surgical procedure can be carried out. The operative procedure is simple and similar to a maxillectomy (Figs. 120.33 to 120.35). It also provides good control of the internal carotid artery. The procedure has limited morbidity (142,143) and is the appropriate surgical salvage procedure for most residual or recurrent tumors in the nasopharynx (144). As all these patients had previously undergone

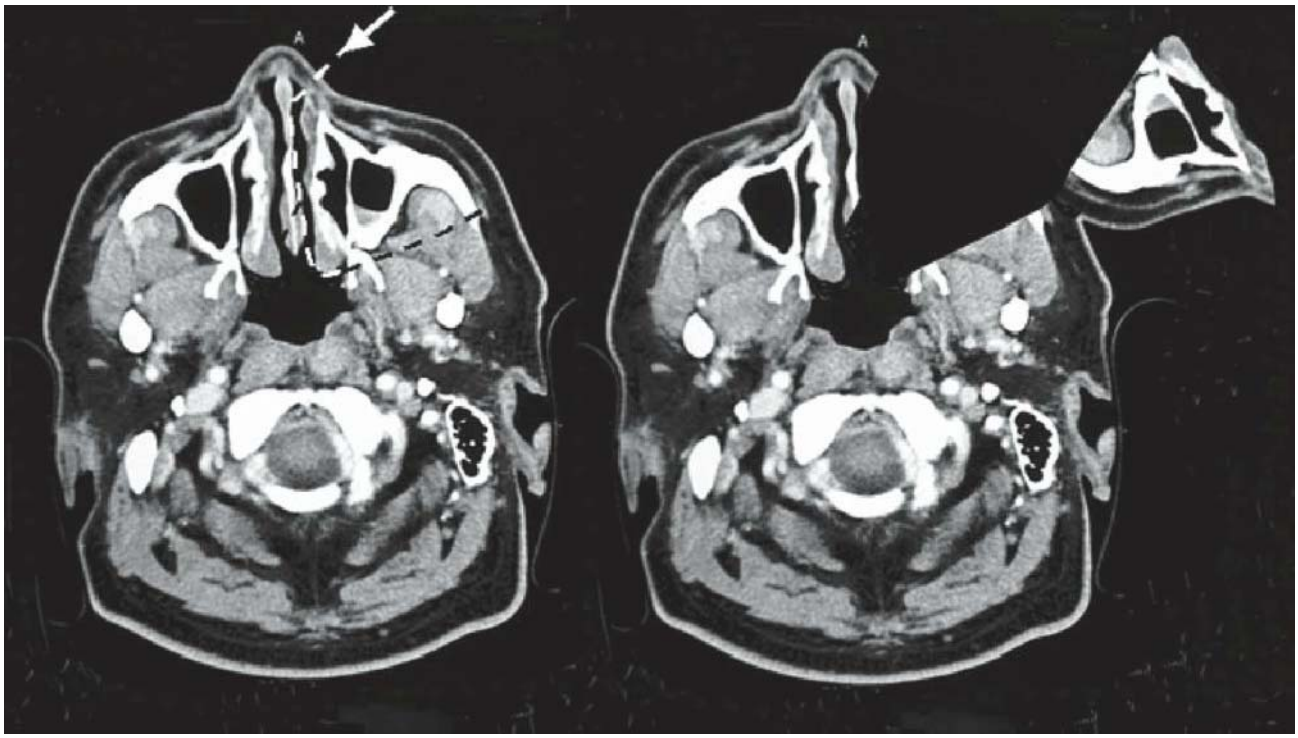

Figure 120.32 Schematic computed tomography. **Left**: Planned osteotomies of the maxilla and the posterior part of the nasal septum (*arrow* and *broken line*). **Right**: The maxilla is swung laterally while still attached to the cheek flap.

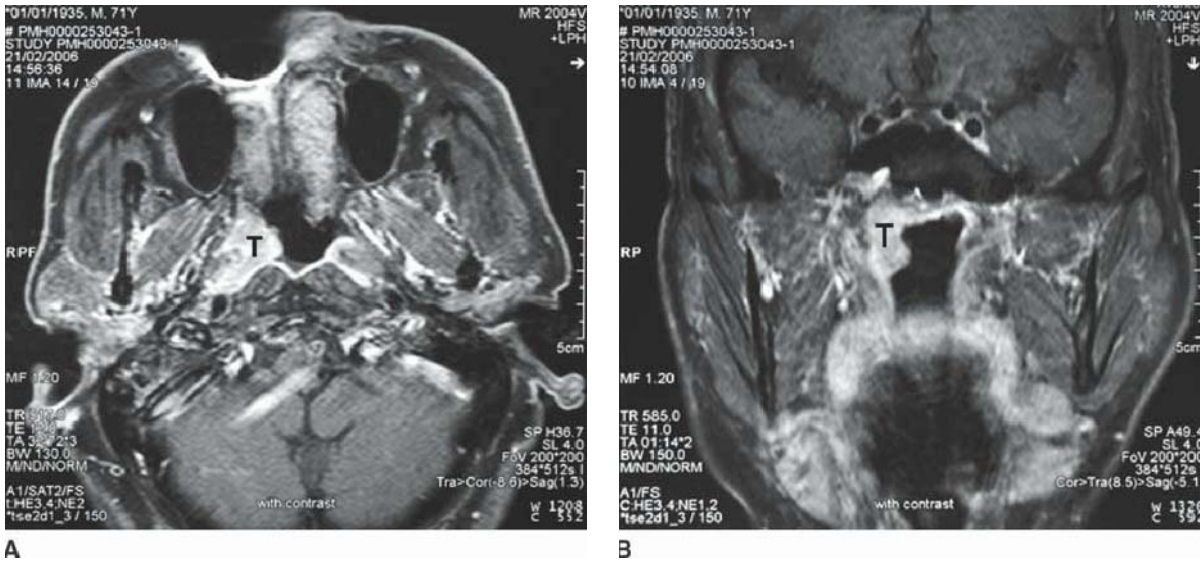

Figure 120.33 Recurrent NPC. **A:** Axial and (**B**) coronal fat-suppressed enhanced T1-weighted MR images show a bulky enhancing tumor (T) in the right nasopharynx. Bulky enhancement indicates recurrence, whereas infiltrative or linear enhancement may be related to treatment.

Figure 120.34 Facial incision marked on the patient with the MRI in Figure 120.33 for right maxillary swing approach to expose the nasopharynx for resection of recurrent NPC.

radical RT, complete wound healing might take some time and around 25% of patients developed trismus. In general, as long as the persistent or recurrent tumor can be resected with a clear margin, the long-term results have been satisfactory. Salvage nasopharyngectomy with this approach carried out for 246 selected patients showed a 5-year local control of disease of 74% and the 5-year disease-free survival was 56% (145).

External Radiotherapy, Chemotherapy, and Targeted Therapy

Reirradiation with external beam is the only option when the recurrence involves skull base. For these extensive recurrences, conformal RT such as IMRT is applicable. For 29 patients who had reirradiation with and without brachytherapy boost, the 5-year local control rate of 52% has been reported (146). In another study, for 31 patients, the 1-year locoregional control was 56% employing IMRT for reirradiation (147). With a shorter follow-up of 9 months, 100% local control has been reported following reirradiation with IMRT (148).

Induction chemotherapy has been employed to reduce the tumor bulk before reirradiation (149), or it was administered concurrent with reirradiation (150). Cisplatin-based agents combined with other agents give an overall response rate of 50% to 70%. Other drugs such as capecitabine (151,152), taxane (153,154), and gemcitabine (155,156) can be used either as a single agent or in combination with cisplatin. Oxaliplatin is also active in NPC and can be used in place of cisplatin (157).

There are only limited studies on the use of molecular targeted therapy in NPC. One study showed that addition of cetuximab to carboplatin in platinum-refractory disease resulted in a modest response rate of 11.7% and the median survival was 233 days (158). Studies using small molecular inhibitors such as gefitinib (159,160) and sunitinib (161) in recurrent and metastatic NPC failed to show any benefits. Currently there is no established role of molecular targeted therapy in the management of NPC, and treatment using such approach should not be routinely given outside the context of clinical trial.

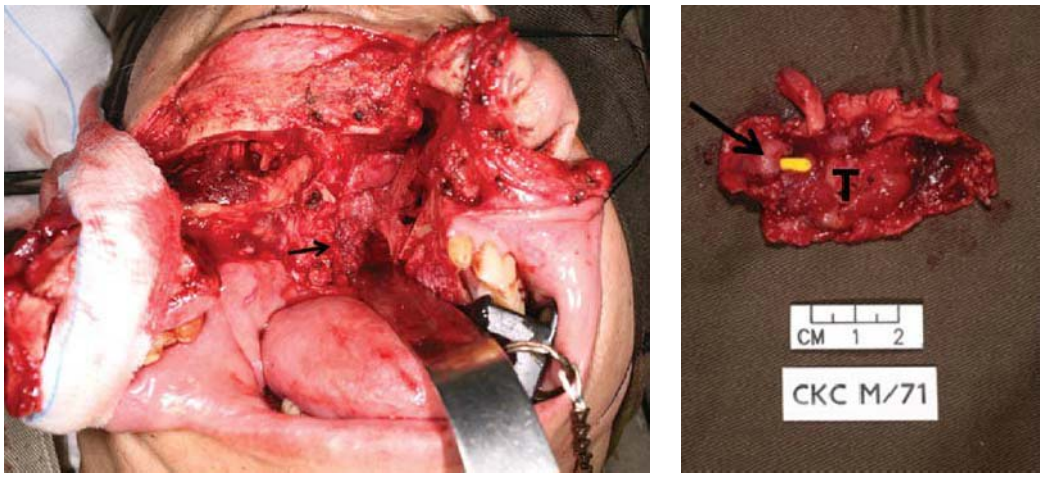

Figure 120.35 The same patient as in Figure 120.34, the right maxilla is swung laterally to expose the nasopharynx with recurrent tumor (*arrow*). Inset: Nasopharyngectomy specimen showing tumor (T). The Eustachian tube opening is marked with a yellow tube (*arrow*).

HIGHLIGHTS

- NPC is common among southern Chinese, and a combination of genetic, viral, and environmental factors contributes to the etiology.
- The diagnosis of NPC depends on the clinical features, serologic tests, and imaging features. The confirmation of the disease is through endoscopic examination and biopsy.
- The extent of the disease is determined by clinical examination, imaging studies, and endoscopic findings.
- The treatment of early stage NPC is by radiation alone while for advanced stage disease, concurrent chemoradiation gives the best outcome.
- The incidence of local/regional residual of recurrent disease after radiation/chemoradiation is around 10% and the outcome of salvage with further radiation, brachytherapy, and surgery depends on the extent of the disease.
- For salvage of localized lymph nodes confined to the neck, surgery with neck dissection gives satisfactory results.
- The choice of surgical approach for resection of recurrent NPC in the nasopharynx depends on the size, location, extent of disease, and condition of the patient. In general, the 5-year local tumor control rate following surgical salvage is around 74% and the 5-year disease-free survival rate is 56%.

121 Oropharyngeal Cancer

Anna M. Pou *Jonas T. Johnson*

Cancer of the oropharynx is relatively uncommon, accounting for fewer than 1% of all new cancers. Cancer data reported combine oral cavity sites with oropharyngeal sites. It has been estimated that over 39,000 cases of oral cavity and pharyngeal cancer will be diagnosed in the United States in 2010 (1). Approximately one-third of these will be expected to arise in the oropharynx. Its peak incidence is between the sixth and seventh decades of life; however, cases in the fifth and fourth decades of life are not uncommon. The disease has a distinct male predominance, but recent data show an increased incidence among women. Squamous cell carcinoma (SCC) and its variants account for more than 90% of malignant oropharyngeal lesions. Historically, the most important etiologic factor was the exposure to tobacco and alcohol; however, the majority of cases seen today are HPV associated (2). Treatment of this disease is complex, and a team including a head and neck surgeon, reconstructive surgeon, radiation oncologist, medical oncologist, prosthodontist, and speech and language pathologist offers the patient the best opportunity for disease control with management of treatment-related toxicities.

ANATOMY

The oropharynx is the midportion of the pharynx that connects the nasopharynx superiorly to the oral cavity anteriorly and to the hypopharynx inferiorly. It extends from an imaginary horizontal plane through the hard palate to another through the hyoid bone (Fig. 121.1). As it opens into the oral cavity, it is bounded by the circumvallate papillae, anterior tonsillar pillars, and the junction of the hard and soft palates. The posterior limit of the oropharynx is the posterior pharyngeal wall, which lies anterior to the prevertebral fascia. The lateral boundary includes the tonsillar fossae and pillars and the lateral pharyngeal walls. The superior limit is contiguous with the inferior boundary of the nasopharynx. Clinically, the oropharynx is divided into four subsites: base of tongue, soft palate, the palatine tonsillar fossa and pillars, and pharyngeal walls.

The pharyngeal walls are made of multiple layers, which include from surface to deep the mucosa, submucosa, pharyngobasilar fascia, constrictor muscles (superior and upper fibers of middle), and buccopharyngeal fascia. The superficial anatomy of the lateral walls includes the anterior tonsillar pillars (palatoglossus muscle); the palatine tonsillar tissue, which lies in the tonsillar fossae; posterior tonsillar pillars (palatopharyngeal muscle); and a small portion of lateral pharyngeal walls. The palatine tonsils, when present, often have an irregular surface filled with crypts, which are blind tubules of epithelium that invaginate deep within the lymphoid tissue of the tonsil.

The soft palate is a fibromuscular structure that projects posteriorly and downward into the oropharynx. It is composed of the palatine aponeurosis, which forms the skeleton and includes the tensor veli palatini, levator veli palatini, uvular, palatoglossus, and palatopharyngeal muscles.

The base of the tongue is the anterior wall of the oropharynx and extends from the circumvallate papillae back to the pharyngoepiglottic ligament and glossoepiglottic folds. The lingual tonsils lie superficial and lateral on either side and cause its mucosal surfaces to be irregular. The paired valleculae mark the transition of the base of the tongue into the epiglottis. This relationship explains why the submucosal spread of tumor from the base of the tongue may involve the supraglottic larynx or, conversely, laryngeal tumors may grow into the base of the tongue.

Most of the oropharynx is supplied with sensory and motor innervation through the glossopharyngeal (cranial nerve IX) and vagus (cranial nerve X) nerves. The hypoglossal nerve (cranial nerve XII) supplies motor innervation to the base of the tongue. The motor and most of the sensory innervation of the soft palate comes from the trigeminal nerve.

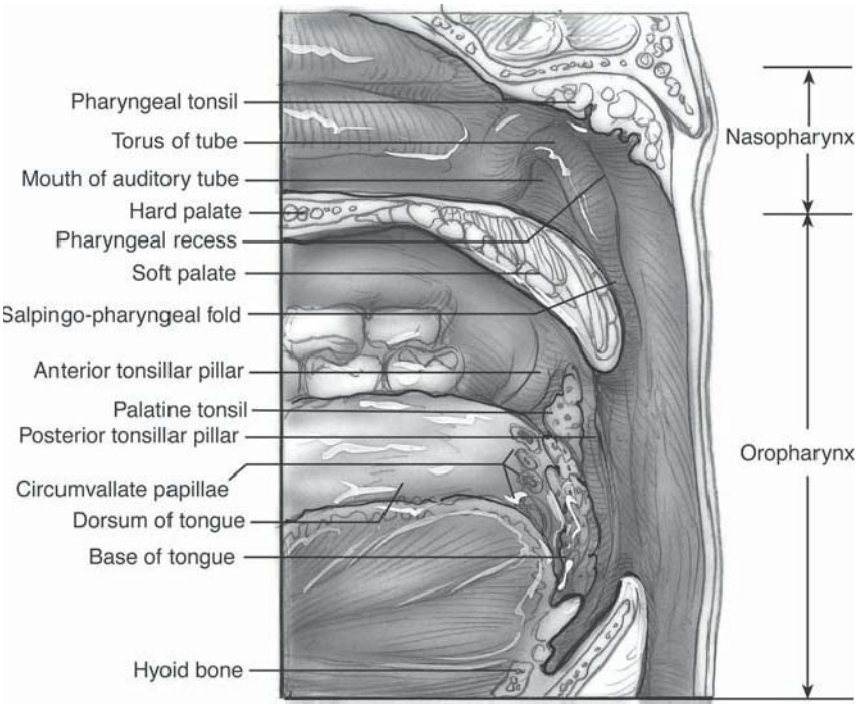

Figure 121.1 Surface anatomy of the oropharynx.

The oropharynx is abundantly supplied with blood from most branches of the external carotid artery, particularly the ascending pharyngeal. The lymphatic drainage is primarily to levels II and III, with midline structures such as the tongue base, soft palate, and posterior pharyngeal wall draining to both sides of the neck. The posterior pharyngeal wall, soft palate, and tonsillar region also drain to the retropharyngeal nodes, which in turn drain to the upper level II nodes.

The oropharynx is surrounded on three sides by potential fascial spaces. The retropharyngeal space is an area of loose connective tissue lying behind the pharynx between the buccopharyngeal fascia of the pharynx and the alar layer of the prevertebral fascia. The retropharyngeal space extends from the skull base to the superior mediastinum and communicates with the parapharyngeal space laterally. The parapharyngeal space is defined by fascial planes extending from the skull base to the greater cornu of the hyoid bone and lying lateral to the pharyngeal walls. It has the shape of an inverted pyramid, and its boundaries include the skull superiorly, pterygomandibular raphe anteriorly, prevertebral fascia posteriorly, and the pharynx medially. The lateral boundary is the most complex and is formed by the fascia overlying the medial pterygoid muscle, a portion of the mandible, deep lobe of the parotid, and the posterior belly of the digastric muscle. This fascia extends superiorly, incorporating the stylomandibular ligament, and fuses with the strong interpterygoid fascia to attach to the skull base in a line passing medial to the foramen ovale and spinosum. It also separates the parapharyngeal space from the infratemporal fossa and masticator space and places the trigeminal nerve within the latter (3). The parapharyngeal space can be further divided by a layer of fascia running from the tensor veli palatini muscle to the styloid and its related structures into two compartments. The prestyloid compartment contains fat, variable portions of the deep lobe of the parotid, and a small branch of the trigeminal nerve to the tensor veli palatini. The poststyloid compartment contains the carotid artery, jugular vein, cranial nerves IX to XII, sympathetic chain, and lymph nodes.

There are multiple aspects of oropharyngeal anatomy that are clinically important. The irregular surfaces of the tongue base and the tonsils make it difficult to identify small tumors. The vagus and glossopharyngeal nerves have tympanic and auricular branches (Jacobson and Arnold nerves), which cause the referred otalgia associated with tumors of this area. The retropharyngeal and parapharyngeal spaces also serve as potential routes for cancer spread. Surgical margins may be difficult to achieve in some patients because oropharyngeal structures lack natural boundaries. Tumors that involve the palate or tonsillar pillar may invade or encase bone of the mandible or maxilla. Involvement of the muscles of mastication results in pain and trismus. Base of tongue tumors may spread in all directions to involve larynx, palatine tonsil, or oral tongue.

PHYSIOLOGY

The oropharynx is essential for normal speech production, respiration, and deglutition. These highly coordinated functions require intact sensory and motor input and intact structures. A detailed understanding of these coordinated events is crucial. All treatment modalities may result in dysfunction.

Deglutition is the most complex of these functions and can be divided into four phases: (a) oral preparatory, (b)

oral, (c) pharyngeal, and (d) esophageal. The oropharynx plays an important role in the first three phases. The soft palate is pulled forward while the tongue base is slightly elevated during both oral phases to prevent food from spilling prematurely into the pharynx. The food bolus at the end of the oral phase is propelled between the tongue and palate, past the tongue base and faucial arches, triggering the pharyngeal phase. This phase culminates with the propulsion of the food bolus into the esophagus through the following events: (a) velopharyngeal closure, (b) elevation and closure of the larynx, (c) contraction of the pharyngeal muscles and retraction of the tongue base, and (d) opening of the cricopharyngeal region. The major driving force of the bolus through the pharyngeal phase is the pressure developed by the tongue base; pharyngeal contraction and peristalsis serve mostly to clear the residual material present at the end (4).

Extirpative surgery of the oropharynx may result in poor speech production, dysphagia, and aspiration. This may be a result of velopharyngeal incompetence, pharyngeal stenosis, inappropriate functioning of the tongue base tethering or volume reduction, decreased pharyngeal contraction, sensory denervation, and delayed triggering of the pharyngeal swallow because of decreased sensation. Avoidance of these undesirable sequelae may be mitigated with proper patient selection for surgery, appropriate reconstruction, and vigorous rehabilitation. Use of tissue sparing such as intensity-modulated radiation therapy (IMRT) radiation techniques and less toxic regimens may be appropriate in some cases. Evaluation of speech and swallowing should occur before, during, and after treatment to allow for the best outcomes and quality of life (5).

ETIOLOGY

SCC of the head and neck is known to arise from the accumulation of multiple genetic alterations to genes important to the regulation of cellular growth and death. These alterations, which may be inherited but are more often acquired from exposure to environmental agents, provide the cell with a selective growth advantage. The cells then undergo further selection, which eventually results in a clone that overcomes the normal growth controls and host defenses to establish the tumor (6).

Multiple environmental factors are associated with SCC of the oropharynx. Historically the most important was exposure to tobacco and alcohol. Heavy tobacco users have a 5- to 25-fold higher risk of developing head and neck cancer than nonsmokers (7). The effect of these agents is dose related, and concurrent exposure is synergistic, resulting in a risk that is greater than the sums of the risks of either one alone (8). The relative risk of developing cancer increases from 2.7 in those who smoke up to 10 cigarettes per day to 9 in those who smoke 1 pack per day. The relative risk also increases with an increase in alcohol consumption; the relative risk rises to 8.8 in those who consume 30 or more drinks per week compared to 1.2 in those who consume 1 to 4 drinks per week. The combination of smoking and drinking has a greater than additive effect as mentioned earlier; a person who has greater than a 40-pack-year history of smoking who consumes 5 alcoholic drinks per day has a relative risk of 40 (9,10).

Viruses have been shown to be a probable etiologic agent in development of SCC. The most extensively studied virus is the human papillomavirus (HPV) (11). In a study by Kerimer et al., a systematic review of 5,046 head and neck SCC specimens from 60 studies worldwide was performed to determine the worldwide prevalence and types of HPV in head and neck cancer (11). The overall prevalence of HPV was 25.9%: 35.6% in oropharyngeal SCC, 23.5% in oral cavity SCC, and 24.0% in laryngeal SCC. HPV 16 was the most common type detected: It accounted for 30.9% of oropharyngeal SCC, 16% of oral cavity SCC, and 16.6% of laryngeal SCC. HPV-positive tumors are more likely to originate in the oropharynx, to be poorly differentiated, have basaloid features, and present with a lower T stage than HPV-negative tumors. Prognosis and response to treatment are strongly associated with HPV status, and those who are positive appear to be more responsive to treatment and thus have a survival advantage (12).

Individuals with HPV-positive tumors have different risk factors than those who are HPV negative. HPV-positive SCC's were independently associated with sexual behavior and marijuana use but not with tobacco or alcohol use or poor oral hygiene. On the other hand, those tumors that were HPV negative were associated with heavy alcohol and tobacco use and poor oral hygiene, but not sexual behavior or marijuana use (13). D'Souza et al. (14) found that oral HPV infection is strongly associated with oropharyngeal SCC among those with or without established risk factors of alcohol and tobacco use. In addition, Mork et al. (15) found a 14-fold increase in risk of developing oropharyngeal SCC in those who are seropositive for PGY 16. Oropharyngeal tumors should be tested for HPV 16 status.

Dietary factors such as vitamin deficiency (Vitamin A, iron deficiency of Plummer-Vinson syndrome), poor nutrition, poor oral hygiene, syphilis, occupational exposure, and previous irradiation also have been implicated as etiologic agents; however, evidence is limited overshadowed by the evidence supporting the carcinogenic effects of tobacco and alcohol.

Immunosuppression due to heredity, transplantation, or human immunodeficiency virus (16,17) may accelerate the development of SCC, lymphoma, and other tumors of the oropharynx by impairing normal immune surveillance mechanisms.

HISTOPATHOLOGY

The oropharynx consists of different types of epithelium pending on the subsite. The oropharyngeal epithelium arises from stratified squamous epithelium and transitions

where the soft palate contacts the posterior pharyngeal wall (Passavant ridge) into ciliated respiratory epithelium of the nasopharynx.

Minor salivary glands can be found in the soft palate, tonsillar pillars, and lingual tonsils, and therefore, tumors of minor salivary gland origin can be found in these places. Lymphoepithelium can be found in the subsites that form Waldeyer ring (nasopharynx, palliative tonsils, and tongue base).

Premalignant lesions occur in the oropharynx; however, they are rarely recognized. Lesions are seen most commonly on the soft palate and anterior tonsillar pillars and include leukoplakia (white plaque lesion), erythroplakia (sharply demarcated red lesion), and lichen planus (white, lacy lesion). Diagnosis requires biopsy.

SCC (keratinizing and nonkeratinizing) and its variants account for more than 90% of malignant oropharyngeal lesions. The spindle cell variant is clinically and biologically similar to SCC, whereas others behave differently. Basaloid appearance of SCC may be an indication of HPV-positive status (12).

Verrucous carcinoma is a fungating, slow-growing tumor with well-differentiated keratinizing epithelium and rare cellular atypia or mitosis on histology. These tumors have "pushing" margins. They rarely metastasize and are considered a low-grade malignancy. Lymphoepitheliomas arise from Waldeyer ring. This tumor is nonkeratinizing and is similar in behavior to the undifferentiated type of nasopharyngeal carcinoma. These lesions usually occur in the tonsillar region of young adults that do not have typical risk factors. Lymphoma may occur in Waldeyer ring (usually non-Hodgkin lymphoma). Minor salivary gland tumors, mucosal melanomas, and sarcomas are other malignant lesions found in the oropharynx.

Minor salivary gland malignancies are relatively rare. The most common types include adenoid cystic carcinoma, mucoepidermoid carcinoma, and adenosquamous carcinoma. These tumors are treated with primary surgical excision and postoperative radiotherapy depending on high-risk features (perineural invasion, close or positive margins, nodal metastases, high-grade disease).

Some benign lesions, such as minor salivary gland tumors, pseudoepitheliomatous hyperplasia, necrotizing sialometaplasias, Crohn disease, papillomas, pyogenic granulomas, and median rhomboid glossitis, may clinically mimic malignant lesions. Biopsy is usually required to distinguish among these entities.

NATURAL HISTORY

Prolonged exposure of the upper aerodigestive surfaces to carcinogens results in molecular changes throughout the mucosa. With time, certain areas may undergo further change, giving rise to premalignant and malignant lesions. This concept of "field cancerization" or "condemned mucosa" applies to all mucosal head and neck cancers and results in the high rates of second primaries in patients with oropharyngeal cancer (18) (Table 121.1).

SCC usually starts on the surface. Invasion of vessels and thick fascia such as the prevertebral fascia or periosteum is uncommon until late stages, but perineural invasion may occur at any time. Bone involvement is also rare, occurring in only 17% of the lesions (19). Invasion into the parapharyngeal and retropharyngeal spaces allows easy spread to the skull base and neck with possible involvement of the internal carotid artery, cranial nerves IX through XII, and the sympathetic chain. Invasion of the masticator and infratemporal spaces results in trismus.

Lymphatic metastases at presentation are common because the oropharynx is richly supplied with lymphatics and the tumors are generally advanced (20) (Table 121.1). Tumors of the oropharynx may be remarkably asymptomatic. Symptoms of sore throat, otalgia, and dysphagia are commonly misinterpreted or overlooked. For many patients, the first acknowledged observation is the presence of a cervical metastasis.

Oropharyngeal cancer tends to metastasize early. The first echelon nodes are level II, III, or retropharyngeal. Metastasis may be altered by obstruction of the lymphatic channels caused by inflammation, previous surgery, radiation, or large metastatic deposits. Oropharyngeal cancers have a tendency to metastasize to both necks, especially if

TABLE 121.1 THE INCIDENCE OF NODAL DISEASE AT PRESENTATION, SECOND PRIMARIES, AND DISTANT METASTASIS

Site	Palpable Nodes at Presentation (%)	Second Primary (%)[a]	Distant Metastasis[b] (%)
Base of tongue	72	19	18
Tonsillar region	58	25	15
Soft palate	45	26	7.5
Posterior wall	52	29	11

[a]Incidence of synchronous and metachronous second primaries.
[b]Incidence of distant metastasis with control above the clavicles.

the lesion is midline. The rate of occult neck metastases in the clinically negative neck is estimated at greater than 20% for all lesions larger than T1.

Distant metastases are rare at presentation, occurring in 2% to 5% of patients, but with control of the disease above the clavicles, the incidence of overt distant metastasis increases (18,21) (Table 121.1). The most common sites affected by distant metastases are lung, liver, and bones.

DIAGNOSIS

History

A complete history, including a review of systems and past medical, social, and family history, is essential in planning the proper therapy. Patients with oropharyngeal cancer often have very subtle symptoms such as nonspecific sore throat or unilateral otalgia. Hemoptysis may occur but is relatively uncommon. Frequently the first time a patient presents is because of a neck mass. A history of tobacco use *is not* required to be suspicious. The prevalence of HPV-related cancer in patients who are younger nonsmokers has dramatically modified the profile. The physician must be alert to the asymptomatic patient who demonstrates a cervical cyst, which may be found to be a cystic metastasis (22).

Physical Examination

A complete physical and a thorough head and neck examination should be routinely performed on all patients. Systematic visualization of all the mucosal surfaces of the upper aerodigestive tract is essential due to the field cancerization phenomenon. This examination is greatly facilitated by the use of a fiberoptic nasopharyngolaryngoscope, especially in patients with trismus. The mandibular opening and cranial nerve function are also examined, with cranial nerve deficits indicating extension into the mandible, parapharyngeal, or masticator spaces. Palpation of the primary tumor is always performed in order to judge the extent of submucosal spread. All nodal levels of the neck are systematically evaluated, and size, location, and mobility of these nodes are documented. Dentition is also assessed because restoration or extraction may be required before initiation of treatment. The remainder of the physical exam is performed with emphasis on the cardiopulmonary and nutritional status of the patient.

Further Evaluation

The extent of the tumor, neck metastasis, distant metastasis, and the medical condition of the patient should be assessed completely before a treatment plan is devised or implemented (Table 121.2). In patients with biopsy-proven cancer, positron emission tomography (PET)/computed tomography (CT) has largely replaced other modalities in offering whole body evaluation, which can alert the treatment team to metastasis and synchronous cancers. In patients with cystic neck metastasis, PET scan can be helpful in detecting the occult primary tumor, which is usually found in the tonsils or base of tongue. Most oncologists employ PET/CT to evaluate patients with stage III/IV disease.

CT with iodine contrast and/or magnetic resonance imaging (MRI) with gadolinium may be employed during the diagnostic workup before a histologic diagnosis is established. A fine-cut CT may be needed for evaluating bony structures such as mandibular invasion. MRI is best at evaluating soft tissue involvement, such as the tongue base, parapharyngeal space, or prevertebral fascia.

Special tests:

a. Barium swallow is performed on patients with dysphagia. The barium study may alert the treatment team to a synchronous primary in the esophagus. Also, the movement of the posterior wall on the cervical spine observed during fluoroscopy is an indication that the prevertebral fascia is not involved by tumors of the posterior pharyngeal wall.
b. Angiography with the balloon test occlusion and cerebral blood flow evaluation should be considered if the tumor involves the carotid and resection is contemplated.
c. Speech and swallowing evaluation including a modified barium swallow. Patients should be evaluated before, during, and after treatment in order to achieve the best functional results (5,23).
d. Laboratory evaluation of oropharyngeal cancer patients includes a complete blood count, blood chemistry, liver function tests, and an electrocardiogram. Thyroid function and nutritional evaluation may be included in this.

TABLE 121.2 DIAGNOSIS OROPHARYNGEAL CANCER

1. History
   - Alcohol and tobacco abuse
   - Pain and dysphagia
2. Physical
   - Nodal enlargement
   - Trismus
   - Cranial nerve deficits
3. Biopsy of the primary lesion and fine-needle aspiration of enlarged nodes
4. Imaging studies
   - PET/CT—for Stages III and IV
   - Chest radiograph—if not evaluated by CT or PET/CT
   - CT scan/MRI—to evaluate bone and deep invasion
5. Laboratory studies
   - Complete blood count and chemistry
   - Liver function tests
   - ECG
6. Examination under anesthesia
   - Look for second primaries
   - Assessment of submucosal spread, mandibular invasion, and tumor fixation

Tissue diagnosis is obtained with fine-needle aspiration (FNA) of enlarged nodes and/or biopsy of the oropharyngeal lesion. This can usually be performed in the office or clinic, but biopsy under general anesthesia should be reserved for patients with trismus, tenuous airway, or lesions that are not accessible transorally. FNA may need to be performed with ultrasound guidance especially in patients with cystic masses in order to obtain sufficient epithelial cells to make a diagnosis (22).

Staging Endoscopy

Patients with epithelial primary tumors should undergo examination under anesthesia irrespective of the size of the tumor or the adequacy of the initial assessment. Complete visualization and palpation of the tumor greatly facilitate the assessment of submucosal spread and invasion of surrounding structures such as the prevertebral fascia and mandible, especially in patients with trismus. A thorough search for a synchronous second primary tumor, which occurs in approximately 8% of patients (15), is conducted via systematic examination of the upper aerodigestive tract and esophagus. Bronchoscopy is optional in patients with normal chest radiographs (16), but we usually perform a tracheobronchoscopy in patients who have not undergone a PET scan, because small lesions in the trachea or hilum are not readily seen on routine radiographs. Biopsies are performed at the end of the endoscopy to allow the examination to proceed unhindered by bleeding from the biopsy site. If lymphoma is suspected, the pathologist should be notified in advance, and an adequate sample of tissue is submitted fresh to allow for receptor typing. The teeth are evaluated and restored or extracted as needed at the end of the procedure. The findings of endoscopy and tumor mapping are then recorded and the patient is staged. Table 121.2 shows the tumor staging for the oropharynx. Many patients with oropharyngeal cancer present initially with an unknown primary with a cervical metastasis. Panendoscopy is crucial in these patients, and bilateral tonsillectomy and bilateral biopsies of the base of the tongue and nasopharynx are recommended if the primary tumor is not found. Recently authors have demonstrated the potential value of transoral tongue base resection in patients with occult HPV cervical metastasis (24). The neck staging and stage groupings are the same as other sites of the head and neck (Table 121.3).

TABLE 121.3 TUMOR (T) STAGING FOR THE OROPHARYNX

Stage	Description
Tx	Carcinoma *in situ*
T1	Tumor 2 cm or less in greatest dimension
T2	2–4 cm in greatest dimension
T3	>4 cm in greatest dimension
T4a	Tumor invades the larynx, deep/extrinsic muscles of the tongue, medial pterygoid, hard palate, or mandible
T4b	Tumor invades lateral pterygoid muscle, pterygoid plates, lateral nasopharynx, or skull base, or encases carotid artery

Greene FL, Page DL, Fleming ID, et al. *AJCC cancer staging manual*, 6th ed. New York: Springer, 2010.

TREATMENT

The treatment of oropharyngeal cancers, especially for patients with advanced tumors and those involving the base of the tongue, has evolved dramatically in the past decade. The initial shift away from primary surgery to "organ preservation" strategies employing CRT was reflective of the success of CRT in avoidance of laryngectomy in patients with laryngeal cancer. The community of head and neck oncologists seemed anxious to avoid the significant functional morbidity of open surgical approaches to the oropharynx. Unfortunately, the initial enthusiasm for nonoperative primary therapy has been tempered by the high rate of treatment related toxicity associated with CRT (25). These dilemmas are not resolved at the time of this writing. Recent advances in minimally invasive transoral surgery of the oropharynx offer the potential for enhanced functional results.

The treatment of oropharyngeal cancer is complex and requires a multidisciplinary team approach, which offers the patient the best opportunity for a comprehensive treatment plan. This team includes a head and neck surgeon, reconstructive surgeon, radiation oncologist, medical oncologist, dental oncologist, prosthodontist, and speech and language pathologist. The surgeon must consider an array of factors when deciding on the optimal treatment regimen for the individual patient. These include the type of treatment needed for the primary tumor and the neck, the modality best suited for functional preservation or restoration, the general medical condition of the patient, and, most importantly, the patient's preferences. The availability of facilities, expertise, and social support also play a role (Table 121.4). All patients should be counseled and aided in cessation of smoking and alcohol consumption at the time of diagnosis. While the relationship of HPV with these tumors is generally accepted, little is known about the potential of transmission at the time of diagnosis.

Squamous Cell Carcinoma

Surgery and radiation therapy, alone or combined, have been the mainstays of treatment for squamous cell oropharyngeal cancer, but the treatment paradigm regarding advanced disease has changed over the past several years. Early-stage oropharyngeal cancer can be successfully treated with radiotherapy (26), and concurrent chemoradiation is the standard of care for advanced cancers, both resectable and nonresectable (27). Further details of nonsurgical treatment are discussed in Chapters 110 and 111.

   b. Histologically positive nodes at multiple sites
   c. Perineural or vascular invasion
   d. Extracapsular nodal spread
2. N2
3. N3

Those patients with HPV-negative tumors and direct mandibular invasion may be better served with primary surgery. Similarly the availability of minimally invasive transoral resection techniques, either laser or robotic, offers the potential to cure patients with small tumors with surgery alone (28). Surgical resection also may afford the treatment team an opportunity to deintensify chemoradiation and further limit treatment related toxicity. The potential merits of this approach are being evaluated in many centers, but Level I evidence is not available at the time of this writing.

PET–CT is widely advocated at 12 weeks post-CRT to assess for residual disease. Intraoperative assessment with biopsies and/or neck dissection are performed if residual tumor persists.

Primary Tumor

Surgery and radiation alone are similar in controlling T1 and T2 oropharyngeal cancers. The high incidence of occult clinical metastatic deposits mandates the neck be treated electively with either modality in all patients except those with very small primary tumors. In patients who undergo primary surgery, the indications for postoperative radiotherapy (± chemotherapy) are listed in Table 121.5 (29,30). The decision to treat even the smallest oropharyngeal primary with surgery alone must be based upon favorable histologic findings. Stage T3 and T4 tumors can be controlled with surgery and postoperative radiation, but concurrent chemoradiation or hyperfractionated radiotherapy is now considered standard of care especially for patients who are HPV positive and for those in whom the morbidity from surgery is deemed too high to tolerate or in whom the regain of function is unlikely.

Neck

Almost all patients with oropharyngeal SCC require some treatment of the neck because of the high rate of clinically positive nodes and occult nodal metastasis at presentation. The choice of initial treatment modality (surgery or radiation) for the neck and retropharyngeal nodes is usually dictated by that used for the primary tumor. Stage N0 and N1 neck disease are effectively controlled with a single modality. Neck dissection has the added benefit of providing pathologic staging and may allow single modality surgery to be used for small primaries. The use of selective neck dissection in ruling out regional spread following transoral excision of the primary is not as reliable in oropharyngeal cancer as in oral cancer. This is due to the less predictable lymphatic pathways and the increased difficulty accessing the retropharyngeal nodes. For this reason, radiotherapy is often used even when the primary is treated surgically. Following combined chemoradiation surgery results in better regional control in stage N2 and N3 neck disease (31). Both necks should be treated when there is clinical disease in one side of the neck, and the lesion is midline or crosses the midline. The retropharyngeal lymph nodes (RPLNs) must always be considered in the neck treatment plan.

A recent study evaluated the pattern of cervical lymph node metastasis including RPLN metastasis in 76 patients presenting with SCC of the tonsil. 81.6% were stages III and IV. Sixteen patients were treated with surgery only. Seventy-one therapeutic and twenty-seven elective neck dissections were performed. Thirty-four patients underwent RPLN dissection. The rate of contralateral occult metastasis was 28.6%, and the rate of RPLN metastasis was 26.5%. The predictors of contralateral metastasis were stages T3–T4 disease, lesions close to the midline, and ipsilateral multilevel involvement. The predictors of RPLN metastasis were positive preoperative imaging, posterior pharyngeal wall invasion, more than N2 stage, contralateral nodal metastasis, or ipsilateral multilevel involvement. The authors recommend that an elective RPLN dissection be considered in patients with advanced T and N stage, particularly for tumors with posterior pharyngeal wall involvement (32). Although these authors did not discuss function, severe dysphagia can result due to disruption of the pharyngeal

plexus when dissecting RPLN's. In a previous study, Tauzin et al. (33) also found that RPLN metastasis was associated with advanced T and N stage. Tonsil was the primary site (82%) of those with RPLN metastasis. This is probably primarily reflective of the fact that tonsil cancers are far more common than posterior wall tumor. They also concluded that pretreatment PET/CT can be used as a single tool to aid in planning treatment of the neck in oropharyngeal tumors as their results were consistent with those reported in the literature. They suggest that pretreatment PET/CT may identify a subset of patients who can be treated with surgery only, negating the need for radiation therapy for treatment of the RPLN's in early-stage disease.

Nonsurgical Management

Nonsurgical management consists of radiotherapy with or without concurrent chemotherapy. Most chemotherapy regimens are based on platinum agents. The radiation course usually consists of delivering a dose of 60 to 70 Gy through an external-beam shrinking field to the primary lesion and necks over a 6- to 7-week period. Other strategies, such as brachytherapy, hyperfractionation, and electron boost to the neck, are used in some centers to enhance the effectiveness of radiation therapy in more advanced lesions. Radiation is typically delivered using IMRT (34,35). Patients treated nonsurgically should be evaluated using a posttreatment PET/CT to determine response at 8 to 12 weeks after completion of therapy. Patients who presented with N2 and N3 disease should undergo a neck dissection (36) if PET/CT-positive disease persists. If a complete clinical response is obtained, there are data to support a watchful waiting approach as this usually predicts a complete tumor control (37).

Surgery

Primary Tumor

Most oropharyngeal tumors are amenable to surgical excision; however, the best evidence suggests that CRT offers similar tumor control when compared to surgery and radiation. This is especially true for patients with advanced tumors because of poor disease control and the severe functional impairment associated with resection of these large tumors. This is true when tumor involves more than 1/2 of the tongue base extends to the oral tongue, or extends to the larynx. Extension into the parapharyngeal space, prevertebral fascia, or involvement of the carotid artery makes tumor control unlikely. Successful extirpation of oropharyngeal cancers hinges on good exposure and wide resection margins (1 to 2 cm), because these tumors have the propensity for submucosal spread; frozen-section clearance obtained of all the margins is needed. Patients with microscopically positive margins that are found intraoperatively or postoperatively after the permanent sections are examined should undergo 1-cm resection of the involved margin if possible and adjuvant radiation therapy. The use of robotics and transoral laser microsurgical resection is currently under investigation. The potential that minimally invasive resection can offer some patients single modality tumor control and de-intensification of adjuvant CRT, better functional recovery may result. This is the topic of ongoing clinical trials.

Surgical Approaches

Transoral

The transoral approach to the oropharynx involves resection of the tumor through the open mouth with no external incisions. Caution should be exercised before recommending this approach because it provides limited exposure. It may be indicated for small (T1), superficial, or exophytic cancers of the upper or anterior sites of the oropharynx, such as lesions of the soft palate, anterior tonsillar pillar, tonsil, and posterior wall. The surgeon must ensure that there is good visualization of not only the entire tumor but a 1- to 2-cm resection perimeter surrounding it on all sides, including the deep margin. Trismus, height of the mandible, and presence of teeth may further hinder visualization, making adequate resection almost impossible. Resections through this approach are quick and have minimal morbidity, but visualization of the posterior and deep resection margins tends to be very poor.

For tumors that are difficult to access, transoral microsurgical approaches using the CO_2 laser can be a valuable tool. Although tumors of the soft palate and tonsil may be removed with cautery, the laser is more precise. The CO_2 laser and microscope may be used to resect tumors that are otherwise difficult to access transorally including such as those involving the lateral and posterior pharyngeal walls, posterior tongue base, and vallecula. Good local control rates and functional results have been obtained. Steiner et al. (38) reported the use of transoral laser microsurgery for resection of tongue base tumors ($n = 48$) with 94% belonging to stages III and IVa. Forty-three patients underwent selective neck dissections and twenty-three patients underwent postoperative radiotherapy with or without chemotherapy. There was no local recurrence rate for T1 and T2 lesions but a 20% local recurrence rate for T3 and T4 tumors, with a 5-year disease-free survival rate of 73%. Function was preserved in the majority of patients. Laccourreye and colleagues reported a 5-year local control rate of 82% in patients with tonsillar cancer undergoing transoral laser microsurgery. The 5-year local control rate was 89% for T1 and T2 tumors and 63% with T3 lesions (39).

Transoral Robotic Surgery

The use of the robot has allowed the surgeon to manipulate the instruments and endoscopes simultaneously with improved dexterity by allowing more degrees of freedom (40). The advantages of transoral robotic surgery (TORS)

include improved optics, three-dimensional tumor visualization, and tremor filtration. Due to these advantages TORS is gaining popularity. In order to determine if the patient's anatomy is accessible to the use of any transoral approach, access should be evaluated and include evaluation of teeth/mandible, trismus, tori, tongue, size, and flexibility of the neck and tumor extent (28).

TORS has been used successfully for the resection of tongue base and tonsillar tumors (41,42). In a study by O'Malley et al., three patients with T1/T2 base of tongue tumors underwent successful TORS with clear margins and post-TORS neck dissection. One patient experienced a postoperative bleed, which was controlled with surgical intervention. All three patients were treated with adjuvant therapy. In another study, 27 patients with T1–3, N0–2 tumors were resected using TORS and underwent post-TORS neck dissection. Seventy-five percent of these tumors were T1–2. Thirty percent (8/27) required an additional unplanned operation and functional outcomes were good. TORS has also been shown to be a safe alternative to open salvage resection for selected tumors (43).

The oncologic benefit for TORS is still unclear. Many patients in the studies mentioned above required postoperative radiation therapy or chemoradiation therapy. Considering the fact that many patients with oropharyngeal tumors are treated successfully with primary radiation with or without chemotherapy, the additional benefit of surgery is unknown. Transoral approaches may be best suited for treatment of small primary tumors. For instance, patients with T1–2 N0–1 tumor may be considered for surgical therapy employed as a single modality. The potential to deintensify adjuvant therapies in advanced cancer may serve as a motive for surgical resection. Additional follow-up regarding oncologic and functional outcomes is needed to determine the utility of these novel approaches.

Open Procedures

The major open procedures were developed during a time when surgery was the primary mode of therapy for most patients. These procedures have been largely obsoleted as primary therapy because of the success of CRT and minimally invasive transoral surgical approaches. Open approaches may still be required in patients who are HPV negative and in very advanced cancer with bone involvement. Open approaches may be needed for salvage of CRT failures.

Mandibular Lingual Release

The mandibular lingual release or pull-through approach to the oropharynx is indicated for lesions confined mostly to the base of the tongue. The technique involves a standard apron flap elevated in the subplatysmal plane to the lower border of the mandible. Neck dissections are performed as needed. An incision is made through the lingual mucoperiosteum and the periosteum at the lower edge of the mandible (Fig. 121.2A). The anterior mandibular muscles are released with the periosteum from the inner mandibular table, delivering the tongue and floor of mouth into the neck. The lesion can then be resected with excellent direct visualization (Fig. 121.2B). This approach does not require

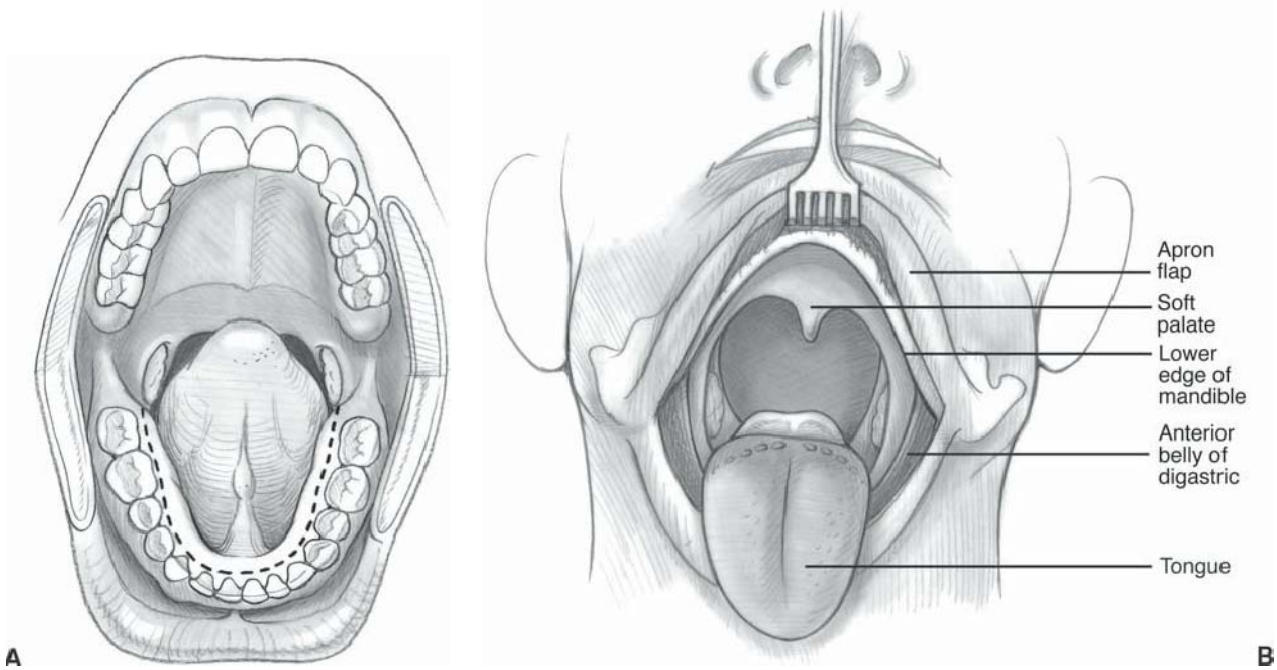

Figure 121.2 Mandibular lingual release. **A**: An incision is made through the lingual mucoperiosteum and the periosteum at the lower edge of the mandible. **B**: The anterior mandibular muscles are released with the periosteum from the inner mandibular table, delivering the tongue and floor of mouth into the neck.

mandibulotomy or a lower lip split, but it offers less access to the lateral pharynx and parapharyngeal spaces than the transmandibular approaches. The lingual arteries, lingual nerves, and hypoglossal nerves are also at risk for damage.

Transpharyngeal Approaches

Suprahyoid Pharyngotomy

The suprahyoid approach is useful for small tumors of the base of the tongue and pharyngeal walls. The pharynx is entered through the vallecula, and the resection is performed from the neck with preservation of the lingual arteries and the hypoglossal nerves (Fig. 121.3). The pharyngotomy also can be extended laterally and inferiorly along the thyroid ala to widen the exposure. This approach results in an excellent functional and cosmetic outcome, but the visualization of the superior margin in larger tumors is inadequate, and there is a risk of cutting into cancer if there is extensive involvement of the tongue base or vallecula. Following resection, the remaining base of tongue is sutured to the valleculae. The remainder of the pharyngotomy defect is then closed. This open technique places the lingual arteries, hypoglossal, and superior laryngeal nerves at risk.

Lateral Pharyngotomy

The lateral pharyngotomy may be used for small lesions of the base of the tongue and pharyngeal walls. The pharynx is entered posterior to the thyroid ala on the least affected side. The hypoglossal and superior laryngeal nerves are dissected and retracted superiorly and inferiorly. Once the pharynx has been entered, the larynx is retracted to the opposite side, providing a good view of the entire posterior pharyngeal wall, opposite lateral wall, and base of the tongue

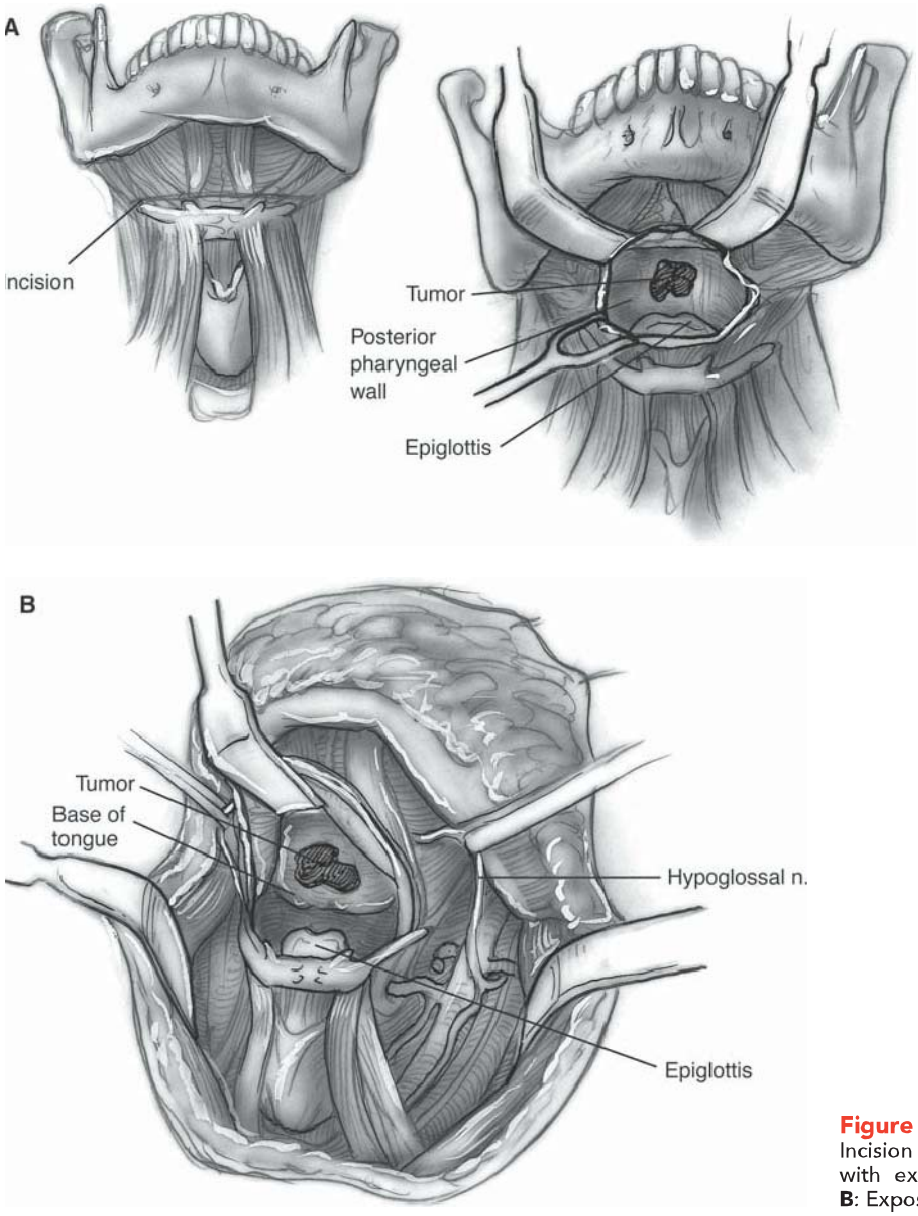

Figure 121.3 Suprahyoid pharyngotomy. **A**: Incision above the hyoid through the vallecula with exposure of the posterior pharyngeal wall. **B**: Exposure of the tongue base.

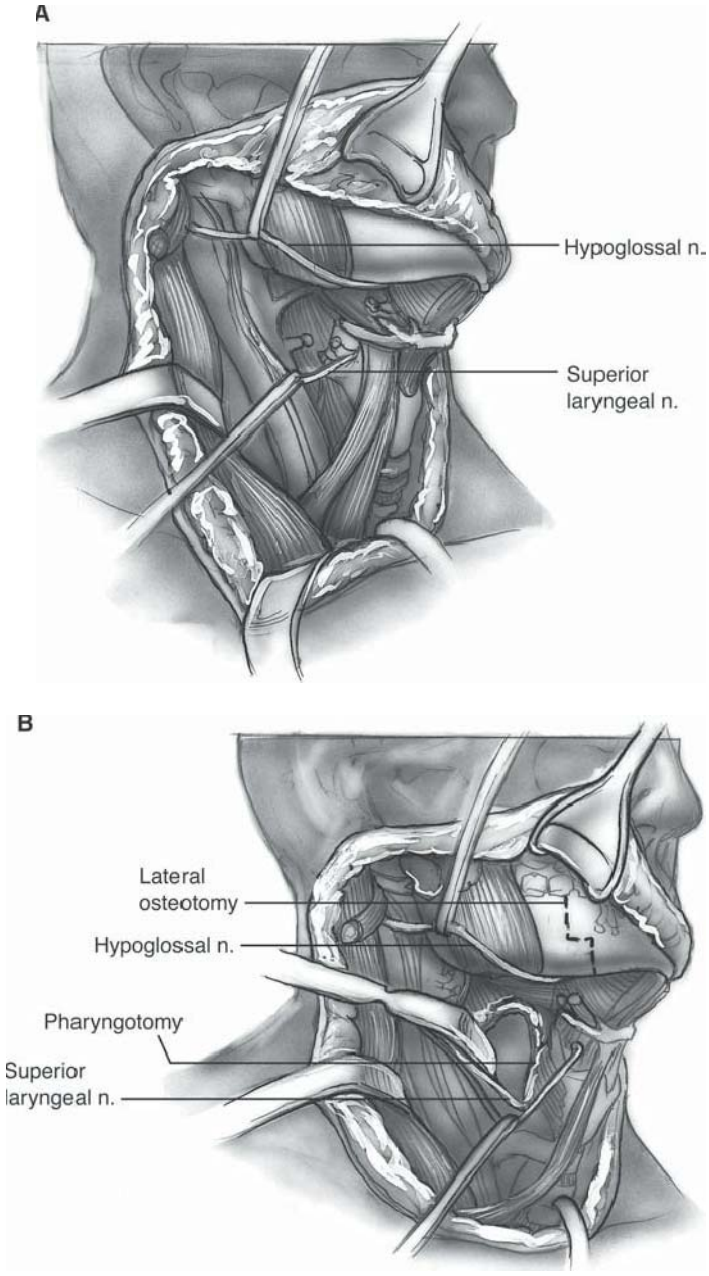

Figure 121.4 Lateral pharyngotomy. **A**: Retraction of the hypoglossal and superior laryngeal nerves. **B**: Exposure of the lower oropharynx and the hypopharynx. Further superior exposure is obtained with lateral mandibulotomy.

(Fig. 121.4A). Further superior exposure can be achieved by extending the pharyngotomy across the vallecula or by combining this approach with a lateral mandibulotomy (Fig. 121.4B). The disadvantages of this approach are the limited superior visualization and the risk of damage to the hypoglossal and superior laryngeal nerves. The lateral mandibulotomy also results in transection of the inferior alveolar nerve resulting in ipsilateral lower lip anesthesia.

Transmandibular

Midline Labiomandibular Glossotomy

The midline labiomandibular glossotomy is rarely used today. The approach involves splitting of the lip (44), gingiva, mandible, and anterior tongue in the midline. The incision can be carried through the base of the tongue down to the hyoid bone if wide exposure of the posterior wall is required (Fig. 121.5). Bleeding and neurologic deficits are minimal because the hypoglossal nerves and lingual arteries are usually not disrupted. However, the approach does not provide access to the parapharyngeal space or lateral oropharyngeal sites.

Mandibular Swing Approach

The mandibular swing approach provides wide exposure to the entire oropharynx and allows an en bloc resection of the cancer and the draining nodes. It can be used for resecting a variety of oropharyngeal cancers that do not involve the mandible, especially those that include multiple sites and the parapharyngeal space. The technique involves a

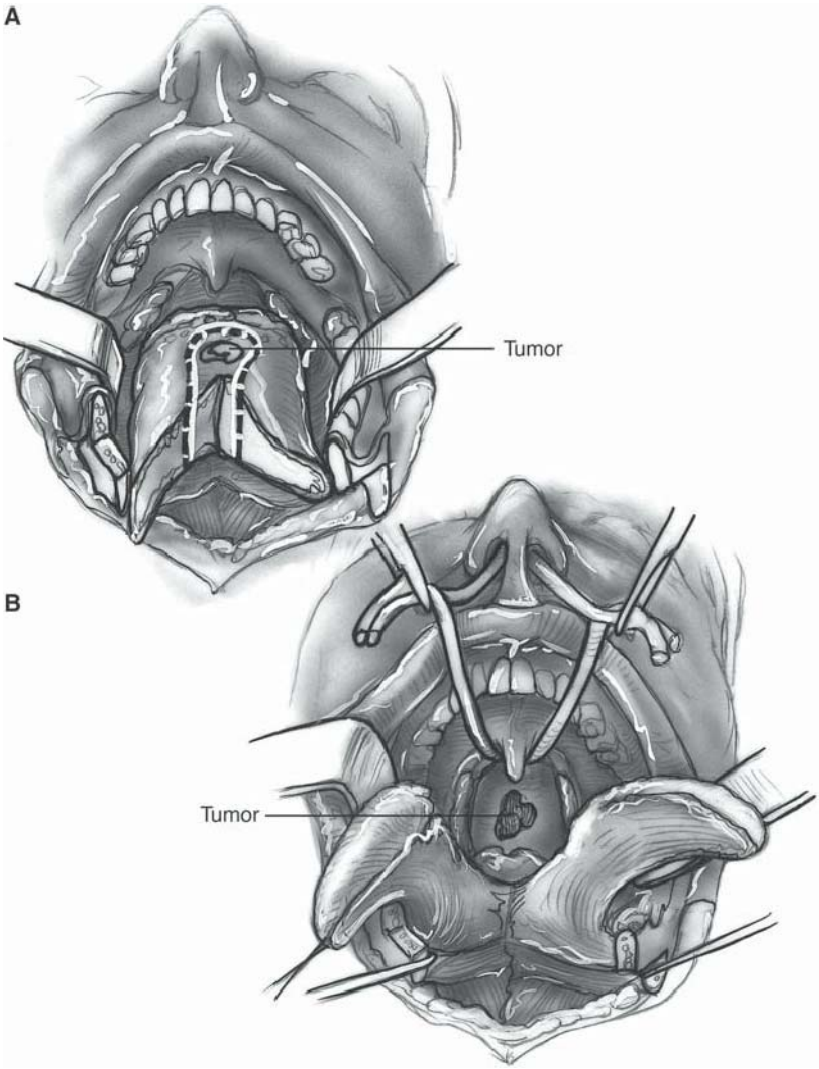

Figure 121.5 Midline labiomandibular glossotomy. **A**: The lip, mandible, and tongue are split in midline for a base of tongue lesion. **B**: Exposure of the posterior pharyngeal wall after division of the tongue base.

standard apron flap elevated in the subplatysmal plane to the lower border of the mandible. Neck dissections are performed as needed, identifying the carotid sheath structures and lingual and hypoglossal nerves in the process. The lip then is split. Visor flaps to preserve the continuity of the lip can be used but require division of both mental nerves and result in suboptimal posterior exposure. The osteotomy is performed anterior to the mental nerve on the ipsilateral side through the site of a missing or extracted tooth. Lateral osteotomies that are posterior to the mental foramen are not recommended because they result in the division of the inferior alveolar nerve and have more limited exposure. Prior to the mandibulotomy, compression plates are bent and screwed into place on either side of the planned cut. A full-thickness soft tissue cut then is made through the floor of the mouth and continued posteriorly to the anterior margin of resection, transecting the lingual nerve if needed. The mandibular segments and tongue are distracted, exposing the tumor and parapharyngeal space (Fig. 121.6). Closure of the soft tissue defect usually requires a flap, and the mandible is reapproximated using the previously bent compression plates. These plates are flashed prior to replacing them in the "clean" wound. The main disadvantage of using this approach is the potential sacrifice of the whole hemimandible if unsuspected mandibular involvement that is not amenable to a marginal resection is found after the mandibulotomy. This problem can be avoided in most cases by careful evaluation at endoscopy and review of the imaging modalities.

Mandibulectomy

Oropharyngeal composite resection with mandibulectomy is used in advanced cancers in which there is overt bony invasion or in situations in which mandibular invasion cannot be ruled out. Usually, the resection is preceded by a neck dissection, leaving the specimen attached to the inferior border of the angle of the mandible. The lip is divided and a cheek flap is developed by performing a full-thickness incision through the buccogingival sulcus. The uninvolved outer periosteum of the mandible may be left on the cheek flap. The anterior mandibular cut is performed well clear of the tumor (1 to 2 cm), preserving as much of the

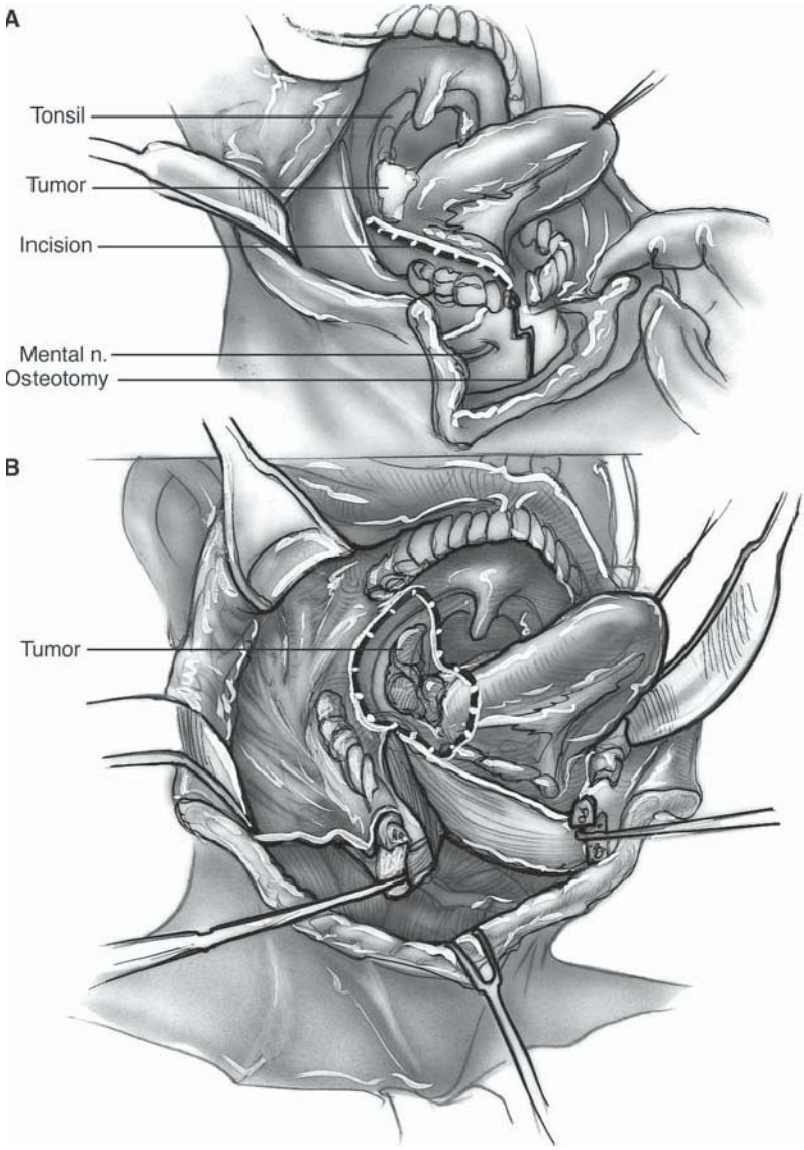

Figure 121.6 Mandibular swing approach. **A**: Osteotomy is placed anterior to the mental foramen. **B**: The full thickness of the floor of the mouth is incised. The mandibular segments are then retracted laterally, allowing good access to the oropharyngeal structures and parapharyngeal space.

mandibular body as possible, and frozen sections of the inferior alveolar nerve are obtained. However, the entire mental canal must be resected, placing the mandibular body osteotomy anterior to the mental foramen, if there is overt mandibular canal invasion or hypesthesia in the inferior alveolar distribution, or if the nerve is positive on frozen section, because there is no reliable method of assessing bony tumor extension intraoperatively. The cranial mandibular cuts are placed along the ramus, but resection of the coronoid process and the condyle may be required with extensive tumors. The mandible then is retracted laterally, and the remaining tumor cuts are performed (Fig. 121.7). The main disadvantage of this approach is the resultant functional and cosmetic deficits, especially if the defect is closed primarily. Reconstruction using free tissue transfer (osteocutaneous flap) is ideal. However, reconstruction of the soft tissue defect takes precedence over reconstruction of the lateral mandibular defect if both soft tissue and bone cannot be reconstructed. However, in order to rehabilitate mastication, bony reconstruction with dental implants is necessary. Mandibulectomy and mandibulotomy approaches compare favorably (45) for tumor control.

RECONSTRUCTION

The reconstruction of oropharyngeal cancer defects has been revolutionized in the past two decades by the development of pedicled regional myocutaneous flaps and free tissue transfer. The objective of modern reconstruction is to restore the integrity of the oropharynx and its essential functions of deglutition, respiration, and speech production.

Successful reconstruction requires the surgeon to have a detailed knowledge of the various reconstructive techniques and an understanding of their limitations. A variety of techniques have been described over the years, but none has achieved the ideal reconstruction of replacing the resected structure with tissue that matches its form and function. The reconstructive capabilities at present are limited to

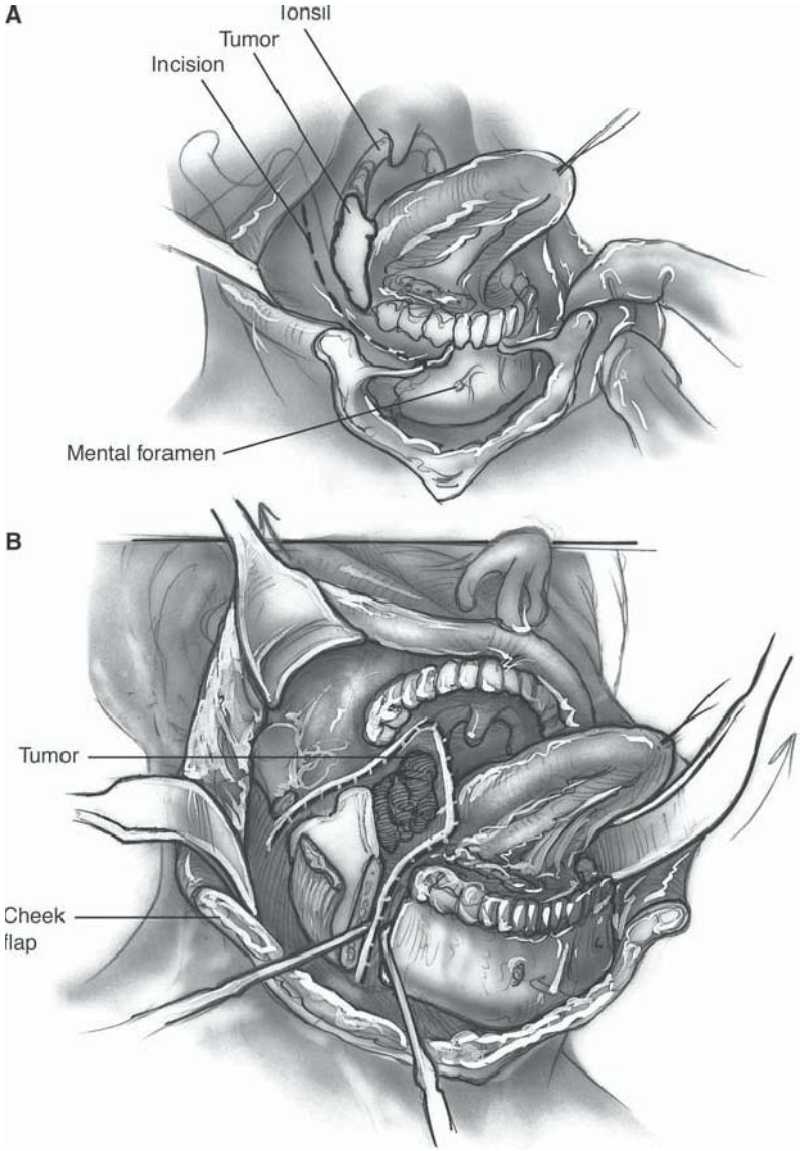

Figure 121.7 Mandibulectomy. **A**: A cheek flap is developed through a full-thickness incision of the gingivobuccal sulcus, exposing the mandible. **B**: The mandibular cuts are made well clear of the tumor and anterior to the mental foramen if the mandibular canal or inferior alveolar nerve is involved with tumor. The mandible is then retracted laterally and the soft tissue cuts are performed.

restoration of integrity, bulk, and sensation, but the complex motor functions of the oropharynx cannot be duplicated.

The use of local flaps has decreased significantly in the past two decades as a result of the limited amount of tissue they provide and their inferior functional results when compared with regional flaps and free tissue transfer. The regional flaps reliably provide abundant well-vascularized tissue that can be used for single-stage reconstruction, they are easy to harvest, and they do not require microvascular expertise. Their disadvantages include the limited superior reach, bulk, and the significant rate of marginal necrosis of the distal skin, especially with pectoralis major flaps. They also can rarely be tailored to reconstruct a defect that involves multiple sites. The free microvascular flaps overcome most deficiencies of the regional flaps and have the added advantage of sensory or motor reinnervation. The use of free tissue transfer along with conservative approaches to the mandible significantly decreases morbidity and length of hospitalization and results in improved function at a cost comparable with regional myocutaneous flaps (46–48). The main disadvantages of free microvascular flaps that have prevented them from wide acceptance by head and neck surgeons are the prolongation of operative time and the need for special expertise. A free skin graft is also often a very viable method (48).

The other component essential for successful reconstruction is an intimate understanding of the ablated tissue's functional and cosmetic capacities. The tongue base is the structure most important to the function of the oropharynx, because it is responsible for pharyngeal closure during the oral phase and is the main driving force of the bolus through the pharyngeal phase (5). Optimal functional restoration requires the presence of at least one intact hypoglossal nerve and lingual artery to allow for mobility and survival of the remaining tongue. The reconstruction must restore some of the bulk, the glossopharyngeal fold, and ensure continued mobility of this organ (49,50). The pharyngeal walls help generate the pressure needed for appropriate movement of

the food bolus and clear material remaining in the pharynx after a swallow. The remaining pharynx and the tongue can easily compensate for these functions after partial resection (51); therefore, a reconstruction that maintains the integrity of the pharynx and function of the base of the tongue is required. The soft palate is the most important component of the velopharyngeal mechanism, which also includes the lateral and posterior pharyngeal walls. Restoration of the soft palate's complex dynamic fibromuscular structure is not possible, but good velopharyngeal function is obtained if the reconstruction allows for the closure of the nasopharynx with swallowing and an opening of no more than 20 mm^2 during speech (52). Defects that involve multiple sites provide a considerable challenge, and elaborate techniques often are required to achieve the reconstructive objectives because of the different requirements of each site. Patients with extensive defects involving most of the oropharyngeal walls or tongue base may require laryngeal manipulation (suturing the thyroid ala anteriorly and superiorly to the mandible) to prevent chronic aspiration. Despite reconstruction, function may be suboptimal.

Soft Tissue Reconstruction

Choosing the appropriate reconstruction requires an individualized treatment plan based on careful consideration of all pertinent tumor-, defect-, and patient-related factors. Generally, the least complex method that restores function and form is selected. Sensory reinnervation of the flaps is preferred whenever feasible, because pharyngeal function may benefit from such a reconstruction. Small defects of the pharyngeal walls up to 3 cm in largest dimension and those less than one-third the volume of the tongue base can be closed primarily, reconstructed using a split-thickness skin graft, or left to granulate if the defect does not communicate with the neck. There are minimal functional deficits with these small defects. Larger lesions require some form of reconstruction, because primary closure results in poor function due to tongue tethering or pharyngeal stenosis. Free fasciocutaneous flaps are well suited for these reconstructions, especially when the defect involves multiple sites, such as the pharyngeal wall, soft palate, and tongue base. The thin and pliable nature of these flaps is ideal for pharyngeal wall reconstruction, and bulk for the tongue base may be obtained by deepithelializing and burying part of the flap (50) (Fig. 121.8). Adequate reconstruction with myocutaneous regional flaps is achieved when the defect is mostly base of tongue, but these flaps tend to be too bulky for pharyngeal wall or soft palate reconstruction, especially when mandibular continuity is maintained. In these situations, regional myofascial flaps are better suited because of the decreased bulk. It is important to remember, however, that only vascularized fat maintains its bulk, and following atrophy of these myofascial flaps, there may be insufficient bulk to sustain good results.

Small tumors of the soft palate that can be removed with partial-thickness resection and preservation of the posterior mucosa may be left to granulate with excellent functional results. Full-thickness defects are best reconstructed with fasciocutaneous flaps that are folded onto themselves and sutured to the remaining nasal and oral aspects of the soft palate (Fig. 121.8). Surgical adhesions are fashioned between the neopalate and the posterior pharyngeal wall to narrow the adynamic reconstructed segment of the velopharyngeal complex when the defect involves more than half the soft palate. Alternatively, a combination of fasciocutaneous flaps and pharyngeal flaps also can be used (53,54). These reconstructions result in immediate and excellent function in most cases and may be further augmented with a prosthesis if needed after the radiation mucositis resolves. The use of prosthetics only is also an option, with good

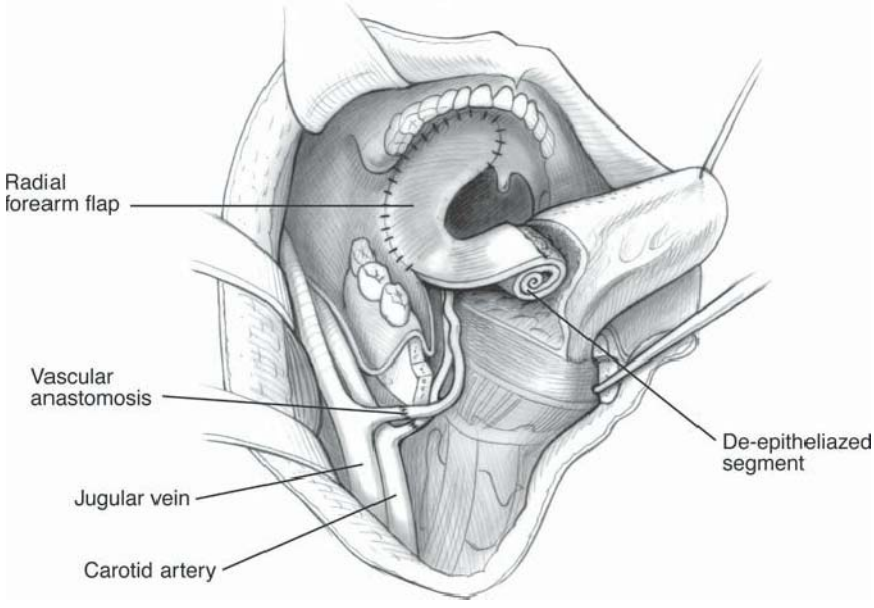

Figure 121.8 Reconstruction of the pharyngeal wall and tongue base with radial forearm fasciocutaneous flap. The distal flap is deepithelialized and rolled on itself to replace tongue base volume. The proximal flap is folded onto itself and sutured to the remaining nasal and oral aspects of the soft palate.

results obtained when the defect involves the total palate, movement of the residual velopharyngeal complex exists, and the patient has good supporting tissue to anchor the palatal device properly (49). The main disadvantage of prosthetics is the potential delay in function because definitive obturation cannot be performed until postoperative healing is complete and the acute radiation changes resolve. Also, foods can become trapped on the nasal side of the prosthesis with foul-smelling debris in the mouth.

Mandibular Reconstruction

Oropharyngeal cancers rarely invade the mandible, and with the use of mandibular preservation techniques, segmental resections are infrequent. Controversy exists regarding reconstruction of the lateral mandible; however, to achieve the best aesthetic and functional results, this defect should be reconstructed. Lateral mandibular defects can be reconstructed with bone containing free flaps, but newer generation reconstruction plates with soft tissue reconstruction have been shown to be an alternative for some patients (55).

COMPLICATIONS

Complications related to the management of oropharyngeal cancer patients are the same as those of any head and neck cancer patient and are listed in Table 121.6. Surgical complications are more likely in patients previously treated with radiotherapy or chemoradiation. Radiotherapy complications can be reduced by using IMRT, but caution is advised as altered patterns of local recurrence have been reported in patients treated with IMRT (56).

     - Malocclusion and TMJ dysfunction

TABLE 121.7 EMERGENCY CARE

1. Airway obstruction
2. Bleeding
3. Free tissue transfer vascular compromise

EMERGENCIES

The most urgent problems that arise in oropharyngeal cancer patients are airway obstruction, bleeding, and free flap vascular compromise after reconstruction (Table 121.7). Airway obstruction is usually due to large exophytic tumors or edema from treatment. Imminent obstruction should be managed with a tracheotomy in the operating room with an anesthesiologist experienced in fiberoptic intubation. Bleeding from the tumor is usually controlled with selective cautery or embolization, but surgery with ligation of the carotid artery or its branches may be required in extreme situations. Bleeding from the carotid artery system itself (due to fistula or other wound complications) is life threatening, and hemorrhage can be controlled with embolization, endovascular stenting, or, as a last resort, carotid artery ligation. When free tissue transfer is used to reconstruct the surgical defect, any signs of arterial or venous compromise require immediate exploration of the vessels in an attempt to salvage the failing flap.

FOLLOW-UP

Oropharyngeal cancer patients require close observation initially to detect recurrences and lifelong follow-up after to identify second primaries. A general follow-up schedule after completion of treatment is provided in Table 121.8 (25). Chest radiographs, liver enzymes,

TABLE 121.8 FOLLOW-UP SCHEDULE AFTER COMPLETION OF TREATMENT

Years Posttreatment	Follow-Up
1st	1–3 mo
2nd	2–4 mo
3rd	3–6 mo
4th and 5th	4–6 mo
After 5th	Every 12 mo

and thyroid-stimulating hormone levels are obtained as indicated. Many centers now use a schema of serial PET/CT evaluation beginning 2 to 3 months after completion of therapy. Concurrent use of chest x-ray and CT seems wasteful. Recurrence after a normal post treatment PET/CT is unusual.

PROGNOSIS

Table 121.9 shows the expected actuarial 5-year survival of patients with oropharyngeal cancers (57). As previously mentioned, for selected groups, better results have been reported. Patients with early-stage cancer die of unrelated diseases or second primary tumors, because they are usually cured of their index tumor, whereas patients who have advanced disease often die of locoregional recurrence or distant metastasis. Patients with advanced disease treated with surgery and postoperative radiotherapy can be expected to have approximately a 50% 3-year survival and greater than 70% local control rate (58). The results are very similar with concurrent chemoradiation (59). HPV-positive cancers are more effectively controlled. HPV-positive patients with tobacco exposure represent an intermediate risk population. Clinical trials are seeking to optimize results while reducing toxicities.

NEW AND DEVELOPING TREATMENTS

The continued discovery of more active chemotherapeutic and biologic agents such as the monoclonal antibody inhibitor and tyrosine kinase inhibitors offers hope for the future. Refinement of diagnostic and reconstructive techniques offers improved cure rates and better function for oropharyngeal cancer patients. PET/CT scan has allowed detection of occult metastatic disease and persistent disease following nonsurgical therapy and may help in the future to guide the extent of surgery and the role of adjuvant therapy (59). Lymphoscintigraphy and sentinel node mapping and biopsy for oral cancer are now being studied in a multicenter cooperative group trial in the United States. Preliminary experience also suggests that it may be feasible in oropharyngeal carcinomas (60). Properly conducted quality of life studies with larger patient numbers will help predict functional outcomes for different treatments and help determine which patients would be better served with a nonsurgical approach (49,54,61).

TABLE 121.9 THE 5-YEAR SURVIVAL OF OROPHARYNGEAL CANCER PATIENTS BY STAGE

Stage	5-Year Survival (%)
1	67
2	46
3	31
4	32

HIGHLIGHTS

- Cancer of the oropharynx is relatively uncommon; however, the incidence is rising primarily attributable to HPV-related tumor.
- SCC and its variants account for 90% of primary malignant oropharyngeal lesions, whereas lymphomas, minor salivary gland tumors, melanomas, and sarcomas make up the rest.
- The concept of "field cancerization" or "condemned mucosa" applies to all mucosal head and neck cancers and is the reason for the high rate of second primaries in oropharyngeal cancer patients.
- The complete visualization and palpation of the tumor under general anesthesia greatly facilitate the assessment of submucosal spread, invasion of surrounding structures such as the prevertebral fascia and mandible, and identification of second primary tumors.
- Almost all patients with oropharyngeal squamous cell cancers require some treatment of the neck because of the high rate of clinically positive nodes and occult nodal metastasis at presentation.
- N0 and N1 are usually adequately treated with a single modality, whereas a combined modality results in better regional control in N2 and N3 neck disease. Treatment often includes both necks and retropharyngeal nodes. Sentinel node mapping remains investigational.
- Successful extirpation of oropharyngeal cancers hinges on good exposure and wide resection margins because these tumors have the propensity for submucosal spread. Mandibular sparing procedures are used whenever possible.
- The appropriate reconstruction requires an individualized treatment plan based on careful consideration of all pertinent tumor-, defect-, and patient-related factors. Generally, the least complex method that restores function and form is selected. If good function cannot be maintained with surgery, a nonsurgical approach should be considered.
- Oropharyngeal cancer patients require close observation initially to detect recurrences and lifelong follow-up afterward to identify second primary tumors. Patients with early-stage cancer die of unrelated diseases or second primary tumors, whereas those with advanced disease die of locoregional recurrence or distal metastasis.
- HPV 16 is an independent risk factor for oropharyngeal carcinoma. HPV-positive tumors respond better to treatment and appear to have a survival benefit.

Hypopharyngeal and Cervical Esophageal Carcinoma

122

Mihir Kiran Bhayani *Randal S. Weber*

Hypopharyngeal and cervical esophageal malignancies are rare upper aerodigestive tract cancers that create a treatment challenge for head and neck surgeons. Although the hypopharynx and cervical esophagus are two separate subsites, the management of carcinoma in this area is, for the most part, similar. These tumors are characterized by multicentricity, submucosal spread, and early lymphatic metastasis. Patients typically present with advanced-stage disease and severe malnutrition that requires a multidisciplinary approach to their care. This multidisciplinary team must consist of the head and neck surgeon, radiation oncologist, medical oncologist, plastic surgeon, speech pathologist, and nutritionist to help guide the treatment to not only remove the disease but to maintain as much of the patient's baseline function from before the tumor arose.

Despite these efforts from multiple fronts, the overall prognosis of patients with these tumors is poor. Advancements in surgical technique have been expanded to transoral techniques that may minimize the morbidity from major resections. Sequential chemotherapy and innovations with radiation techniques as part of clinical trials have resulted in larynx preservation without compromising survival (1–3). Together, these improvements result in improved function without compromising disease-free intervals. Enhanced microsurgical techniques with a diverse range of reconstructive flaps have created many options for surgical approaches in the primary and salvage setting. Thus, the development of a sound approach to patients with these tumors must include a thorough understanding of the anatomy, pathology, and clinical signs when preparing the most appropriate treatment.

ANATOMY

The hypopharynx begins at the level of the hyoid bone where it borders the oropharynx superiorly and funnels inferiorly to the cervical esophagus at the level of the inferior cricoid cartilage (Fig. 122.1). Three subsites make up the hypopharynx: the pyriform sinuses laterally, the postcricoid area anteriorly, and the pharyngeal wall posteriorly (Fig. 122.2). The paired pyriform sinuses lie in the form of inverted pyramids that begin at the pharyngoepiglottic folds superiorly and the apex blending into the cervical esophagus at its inferior extent. The postcricoid area represents the mucosa overlying the posterior portion of the cricoid ring. It extends from the arytenoid cartilage to the inferior border of the cricoid cartilage. The proximity of the pyriform sinuses and the postcricoid area to the larynx can lead to direct invasion of tumors of these regions into the paraglottic space and laryngeal skeleton. The posterior pharyngeal wall is the portion of the hypopharynx overlying the vertebrae. Tumors of this area can directly invade the potential retropharyngeal space, paraspinous muscles, and prevertebral fascia, making complete resection extremely difficult.

The lining of the hypopharynx is stratified squamous epithelium that overlies a submucosal loose areolar tissue layer, followed by a muscular layer made up of the posterior cricoarytenoid muscles anteriorly and the middle/inferior pharyngeal constrictors posteriorly and laterally. These structures are enclosed by the buccopharyngeal fascia. The muscular layer is notable because tumor extension from the posterior cricoid mucosa can invade into the posterior cricoarytenoid muscles causing vocal cord fixation, and the inferior constrictor muscles blend into the cricopharyngeus muscle inferiorly where the potential area weakness, Killian triangle, is located. Although this region is noted for the site of pharyngeal diverticula, tumor extension to the prevertebral space is also possible.

The vascular supply of the hypopharynx comes from the external carotid system and includes branches of the superior thyroid artery and ascending pharyngeal and lingual arteries. Venous drainage mirrors the arterial system in addition to the prevertebral venous plexus.

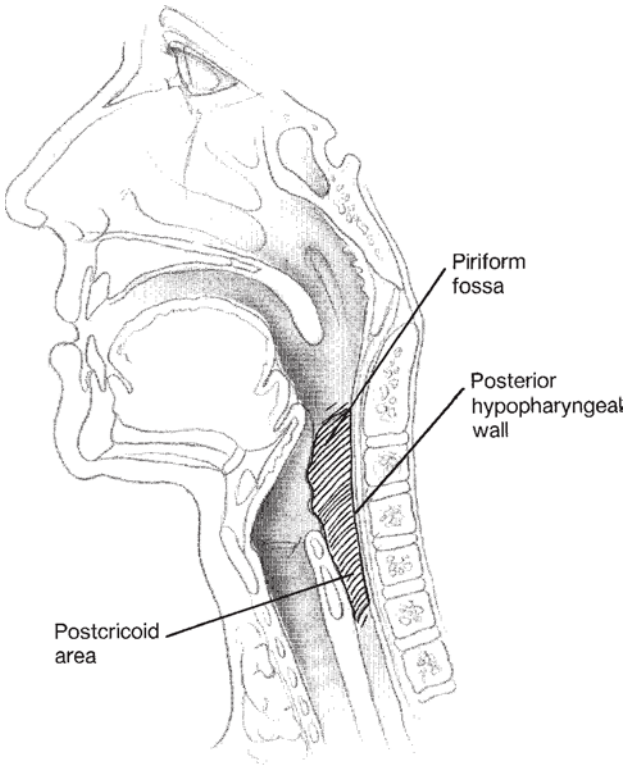

Figure 122.1 The hypopharyngeal region extends from a point at the superior edge of the body of the hyoid bone down to the inferior aspect of the cricoid cartilage; it is composed of the piriform fossa, the posterior hypopharyngeal wall, and the postcricoid area.

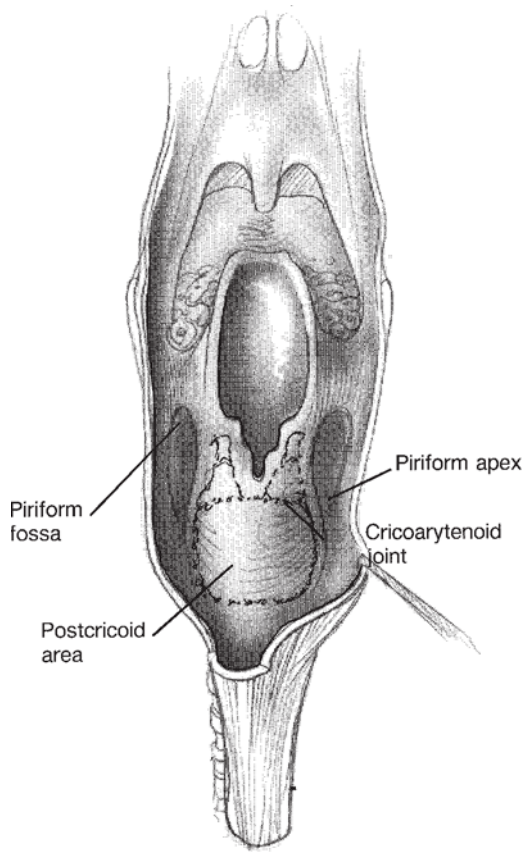

Figure 122.2 The piriform apex is at the junction between the inferior aspect of the piriform fossa and the postcricoid region. It marks the location of the cricoarytenoid joint.

Sensory innervation to the hypopharynx is derived from branches of the glossopharyngeal and vagus nerves via the pharyngeal plexus and the internal branch of the superior laryngeal nerve. The latter nerve pierces the thyrohyoid membrane and joins with the vagus nerve where fibers coalesce with branches of Arnold nerve to the external auditory canal. This connection can result in the referred otalgia seen in many patients with hypopharyngeal pathology. Motor innervation to the pharyngeal constrictors comes from the pharyngeal plexus, while the posterior cricoarytenoid muscles are innervated by the recurrent laryngeal nerve.

The hypopharynx has an extensive network of lymphatics. Drainage can occur laterally to the jugulodigastric nodes (Fig. 122.3). The second drainage pathway is posterior to the retropharyngeal nodes and can extend as high as the skull base in the nodes of Rouviere. Inferiorly, nodal metastases can occur in the paratracheal and paraesophageal nodes (4). Bilateral drainage is common, especially for lesions located in the medial pyriform and posterior pharyngeal wall.

The cervical esophagus begins at the inferior extent of the hypopharynx and extends to the thoracic inlet. It can vary in length depending on the length and angle of the neck. The lining of the cervical esophagus is stratified squamous epithelium that covers a submucosal layer that is rich in lymphatic vessels. The muscular layer contains the bilayered esophageal muscles, with an internal circular layer and external longitudinal layer. The serosa is a continuation of the buccopharyngeal fascia. Arterial supply to this region comes from the inferior thyroid circulation off the thyrocervical trunk, and venous drainage occurs via the inferior thyroid veins. Innervation is derived from the recurrent laryngeal nerve and sympathetic chain. Lymphatic drainage occurs in the paraesophageal and paratracheal nodes, which can then spread to the superior mediastinum or lateral cervical nodes.

EPIDEMIOLOGY

In the United States and Canada, two large studies of national cancer registries have shed light on the presence of hypopharynx carcinoma in the population. In a review of the National Cancer Data Base (NCDB), a hospital-based cancer registry that covers the entire United States, hypopharyngeal carcinomas account for approximately 3% to 4% of all head and neck cancers, which account for approximately 3% of all cancers (5,6). Of note, this report also showed that the percentage of hypopharyngeal carcinoma cases decreased nearly 30% from 2000 to 2004 compared to the 1990 to 1994 (5). This number has been attributed to the decrease in cigarette smoking among

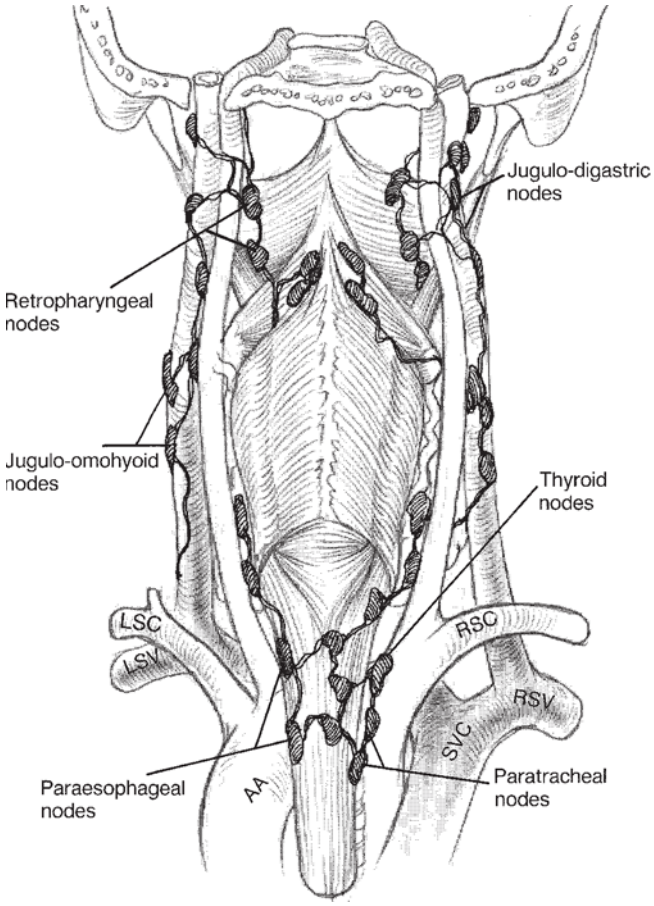

Figure 122.3 The primary lymph node drainage of the hypopharynx. Cancers of the superior hypopharynx metastasize to the jugulodigastric and retropharyngeal nodes, whereas those of the inferior hypopharynx, including the piriform apex, metastasize to the jugulo-omohyoid, paraesophageal, paratracheal, and thyroid lymph nodes. AA, aortic arch; LSC, left subclavian artery; LSV, left subclavian vein; RSC, right subclavian artery; RSV, right subclavian vein; SVC, superior vena cava.

Americans (7). A previous review of the NCDB revealed that 77% of patients with hypopharynx carcinoma present with stage III or IV disease (8). Of note, the survival in the most recent update of the NCDB showed hypopharynx carcinoma to have the worst survival of any primary head and neck mucosal surface malignancy, with a 5-year overall survival around 35% (5).

A review of the data pooled from multiple Canadian cancer registries from 1990 to 1999 revealed that hypopharynx cancer is 5% of all head and neck cancers (9). In Canada, this represents an incidence of approximately 0.8 new cases per 100,000 persons/year. Peak incidence was seen in the sixth and seventh decades of life with 80% of cases being male. Similar to the NCDB data, 74% of patients presented with advanced-stage disease, and survival was 35% at 5 years.

Cervical esophageal carcinoma is difficult to assess, as they are very rare and many times mislabeled as thoracic esophageal carcinoma or hypopharyngeal carcinoma as the tumors grow. They have been reported to account for between 2% and 10% of all esophageal carcinomas (10). In 2010, esophageal carcinoma represented 5% of all digestive system cancers, estimated at 16,640 new cases with 14,500 deaths, thus explaining the paucity of data with cervical esophageal carcinoma (6).

ETIOLOGY

Tobacco smoking and alcohol are well-established risk factors for upper aerodigestive tract tumors. In a recent study reviewing smoking in Europeans, the association with active tobacco smoking was strongest for cancer risk of hypopharynx compared to the oral cavity, oropharynx, and esophagus (11). Alcohol intake appears to be more common in patients with hypopharyngeal cancer when compared with laryngeal cancer and is considered an independent risk factor in the development of hypopharyngeal carcinoma when controlled for smoking (12). Daily consumption of alcohol has been found to increase the risk of hypopharyngeal carcinoma by 2.2 (13). The mechanism of carcinogenesis by alcohol is unclear. Many believe it has a direct carcinogenic effect on the hypopharyngeal mucosa, potentiates tobacco, or is related to the poor nutritional status in alcoholics that contributes to the development of hypopharyngeal carcinoma (14). The use of smokeless tobacco products has also been implicated as a cause of hypopharynx cancer increasing the risk by 4.6 in a study from India (13).

Another causative factor for hypopharyngeal carcinoma that is specifically associated with the postcricoid mucosa is Plummer-Vinson syndrome. This syndrome is characterized by dysphagia, iron deficiency anemia, and hypopharyngeal webs. Chronic irritation of the webs is thought to be the causative factor in the progression to carcinoma.

DIAGNOSIS

Patient Evaluation

Most patients with hypopharyngeal and cervical esophageal carcinoma present at an advanced stage with a multitude of presenting symptoms. A review of the Canadian Cancer Registry found that the most common symptoms in patients presenting with hypopharyngeal carcinoma were dysphagia (53%), hoarseness (39%), neck mass (37%), weight loss (36%), sore throat (34%), and otalgia (30%) (9). Airway distress and voice changes can be seen in advanced tumors by direct invasion into the larynx. Progressive dysphagia for liquids and solids points to larger primary tumors. Chronic throat clearing and globus sensation may initially be diagnosed as reflux disease, but in cases that are refractory to medical therapy, hypopharyngeal or esophageal carcinoma should be ruled out. Unilateral otalgia with a normal otologic exam should lead to full evaluation of the upper aerodigestive tract.

After evaluation of presenting symptoms, a comprehensive medical history includes information regarding smoking and alcohol use. A prior history of iron deficiency anemia in middle-aged women points to Plummer-Vinson syndrome. Pulmonary and cardiac history is assessed in planning for future treatment. A review of systems can elicit significant weight loss and malnutrition (Table 122.1)

Physical Exam

The general status of the patient is the initial observation during the physical examination of patients with hypopharyngeal or cervical esophageal carcinoma. With chronic alcoholism, patients typically have nutritional deficiencies and weight loss. Patients may appear thin and dehydrated and have poor hygiene.

TABLE 122.1 DIAGNOSIS HYPOPHARYNGEAL CANCER

History
- Treated for pharyngitis
- Tobacco and ethanol abuse
- Weight loss
- Dehydration
- Odynophagia
- Dysphagia
- Hoarseness
- Dyspnea
- Otalgia
- Neck mass
- Airway obstruction
- Support group status

Physical
- Weight loss or cachexia
- Decreased skin turgor
- Hyporesonant voice
- Hoarseness
- Stridor
- Status of dentition
- Indirect examination with mirror
- Flexible fiberoptic laryngoscopy
- Full neck examination

Radiology
- Chest radiograph
- Barium swallow
- CT or MRI of the neck

Laboratory
- Complete chemistries
- Staging endoscopy and biopsy
- Control of airway
- Complete paralysis
- Gross characteristics of tumor
- Three-dimensional relationships of tumor
- Biopsy
- Determination of inferior border
- Esophagoscopy
- Bronchoscopy, if warranted

CT, computed tomography; MRI, magnetic resonance imaging.

The head and neck examination begins with evaluation of the facial skin, which can have decreased turgor and increased pallor. Examination of the oral cavity includes a dental evaluation since most patients will require radiation therapy. Poor dentition is also an indicator of malnutrition and hypovitaminosis. The oral cavity and oropharynx also needs to be evaluated for second primary malignancies.

Evaluation of the hypopharynx and larynx can be done using indirect mirror exam, if possible. If secretions or patient comfort does not allow full mirror exam, then endoscopic evaluation is performed. Appearance of the larynx must rule out obstructing mass, direct tumor invasion, or vocal cord paralysis. Evaluation of the hypopharynx should include assessment of any ulceration or mass lesion present in the pyriform fossae, pharyngeal wall, or postcricoid area. The pyriform fossae are best seen when the patient performs a puffed cheek maneuver. Evaluation of the cervical esophagus is limited in the office setting and should be reserved for a flexible or rigid evaluation under sedation.

Palpation of the neck to evaluate for clinically apparent nodes is a necessity. Hypopharyngeal and cervical esophageal carcinomas have a high rate of cervical metastasis; therefore, a thorough evaluation of the neck is mandatory.

Imaging

The goal of imaging in patients with hypopharyngeal and cervical esophageal carcinoma is to evaluate the extent of the primary disease and presence of regional or distant metastasis. Since hypopharyngeal and cervical esophageal carcinoma are characterized by submucosal spread of disease, the ideal imaging modality should facilitate identification of the full extent to the primary. Computed tomography (CT) of the neck with IV contrast is the imaging modality of choice to assess the primary disease by most practitioners. Magnetic resonance imaging (MRI) is an alternative to CT and can provide greater soft tissue delineation; however, the patient with an obstructing hypopharyngeal and cervical esophageal carcinoma may find it difficult to lay supine for extended period due to aspiration risk. CT has been historically used to detect cartilage invasion, but multiple studies have found MRI to be equivalent compared to CT in detecting neoplastic cartilage invasion (15). A study from Switzerland investigated the accuracy of MRI and CT in a cohort of 44 patients undergoing surgical resection of their hypopharyngeal cancer. The authors found that MRI was more sensitive than CT in detecting neoplastic invasion of the laryngeal cartilage, but CT was more specific. Overall accuracy of both modalities was equivalent (MRI, 78% and CT, 75%) (16). Due to practical reasons and patient comfort, though, CT is the preferred modality for many practitioners.

In evaluating for regional disease, contrast-enhanced CT has been the imaging modality of choice since the primary site is also covered. Distant disease can be evaluated using multiple imaging modalities. Many patients with

early-stage disease may have a chest radiograph as the only screening radiograph. With higher nodal stage, the risk of distant metastasis increases. Therefore, chest CT is the preferred imaging modality (17,18). A study from Toronto found that higher stage hypopharynx primary disease (T3–4/N2–3) has five times the increased risk of having either synchronous second primary or distant metastasis, and they recommend chest CT in all patients with advanced-stage hypopharynx primary tumors (19). Another imaging modality used to investigate distant metastasis or synchronous second primary tumor is 18-fluorodeoxyglucose positron-emission tomography (FDG-PET). PET scans can be fused with CT scans for improved evaluation of the anatomic location of FDG avid lesions. It has been found superior to chest radiograph and chest CT in many studies (20–22). The advantage of PET–CT is whole body scanning for distant metastasis at the time of diagnosis. However, further studies need to be performed to evaluate the cost-effectiveness of PET–CT over traditional chest CT and bone scanning for screening of distant metastasis in patients with hypopharynx and cervical esophageal cancer.

Nutritional Evaluation

Standard laboratory evaluation should be performed on all patients who present with hypopharyngeal and cervical esophageal cancer at the initial visit. Blood counts, electrolytes, thyroid stimulating hormone, vitamin, iron, prealbumin, transferrin, and albumin levels are appropriate initial tests that are completed. In severely malnourished patients, a referral to a dietician and placement of a feeding tube are appropriate. Prior to placement of feeding tube, one must consider the reconstructive method to be carried out since location of the tube in either the stomach or jejunum can affect reconstructive options.

PATHOLOGY

Squamous cell carcinoma is the most common histology seen in the hypopharyngeal and cervical esophageal cancer, representing over 95% of cases (9). Three variants are commonly seen in the hypopharynx. The first is basaloid squamous cell carcinoma, which has a more aggressive course. Lymphoepithelial carcinomas are similar in nature to nasopharyngeal carcinoma. Adenosquamous carcinoma is the third variant with a similar aggressive course to basaloid squamous cell carcinoma. The remaining 5% of histologies consist of adenocarcinomas, thought to arise from ectopic gastric mucosa, lymphomas, and sarcomas (8).

Patterns of Spread

A distinguishing feature of hypopharyngeal and cervical esophageal carcinomas is submucosal extension of the tumors. An understanding of the patterns of spread of tumors begins with the site of origin. Most hypopharynx cancers are located in the pyriform sinuses, followed by the posterior pharyngeal wall, and then the postcricoid mucosa (Table 122.2) (23). Submucosal extension is more common in the inferior hypopharynx and cervical esophagus, thought to be caused by the rich submucosal lymphatic network seen at the pharyngoesophageal junction. Satellite lesions are also a characteristic of these tumors; however, it is difficult to determine if these tumors are separate primary tumors or metastatic lesions. The presence of submucosal extension, especially in the inferior hypopharynx and cervical esophagus, must be taken into account when assessing margins during surgical resection. It has generally been recommended that 3-cm margins be taken in the cervical esophagus and inferior hypopharynx, 2 cm laterally and 1.5 cm along the superior margin.

TABLE 122.2 HYPOPHARYNGEAL CANCER: STAGING (EASTERN VIRGINIA MEDICAL SCHOOL EXPERIENCE)

		Stage			
Location	No. (%)	I	II	III	IV
Piriform fossa	63 (64)	11	10	24	18
Posterior wall	30 (30)	5	15	8	2
Postcricoid	4 (4)	—	—	3	1

Eastern Virginia Medical School experience of 97 previously untreated patients, 1972 to 1985.

Tumors of the pyriform fossae can spread laterally to the thyroid cartilage and soft tissues of the neck. Medial extension of these tumors will involve the larynx and the paraglottic space (Fig. 122.4). Postcricoid tumors tend to grow circumferentially. Inferior extension via submucosal spread involves the cervical esophagus. Anterior extension spreads to the cricoarytenoid joint and posterior cricoarytenoid muscles causing vocal cord immobility (Fig. 122.5). Advanced cases of hypopharyngeal carcinoma can present with direct invasion into the thyroid gland (24).

Lymph node metastases are common in hypopharyngeal carcinoma with 64% to 90% of patients presenting with nodal disease and bilateral disease seen in 8% to 16% of cases (9,25,26). Regional metastasis occurs in levels II to IV, with rare involvement of levels I and V (25,27). Invasion of the pyriform apex (20%), postcricoid mucosa (57%), and subglottis is associated with metastasis in the paratracheal and paraesophageal nodes (4,28,29). Mediastinal nodal involvement is noted in 73% to 80% of T4 hypopharynx cancers and 33% to 62% of cervical esophageal carcinomas of all stages (30,31). Forty-three percent of cervical esophageal carcinomas are noted to have paratracheal and paraesophageal nodal disease (29). Retropharyngeal nodal disease is seen in 20% to 50% of patients with hypopharyngeal and cervical esophageal cancers (32–34). The significant percentage of nodal metastasis in hypopharyngeal and cervical esophageal percentage

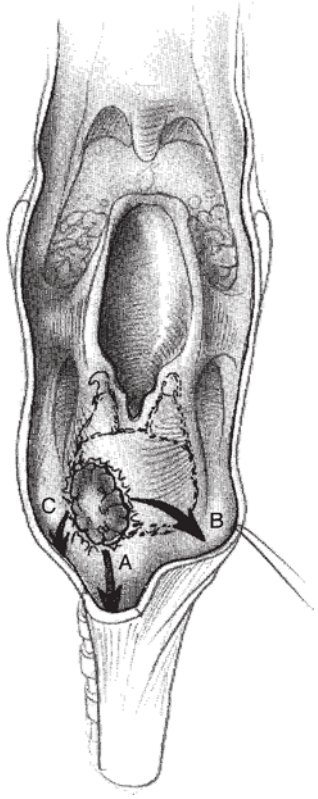

Figure 122.4 Lymph node and submucosal spread of piriform fossa cancer. Submucosal spread inferiorly (*A*) can involve the piriform apex and then metastases to the paratracheal, paraesophageal, thyroid, and jugulo-omohyoid nodes (*B*). Medial extension (*C*) involves the arytenoid and perilaryngeal compartments.

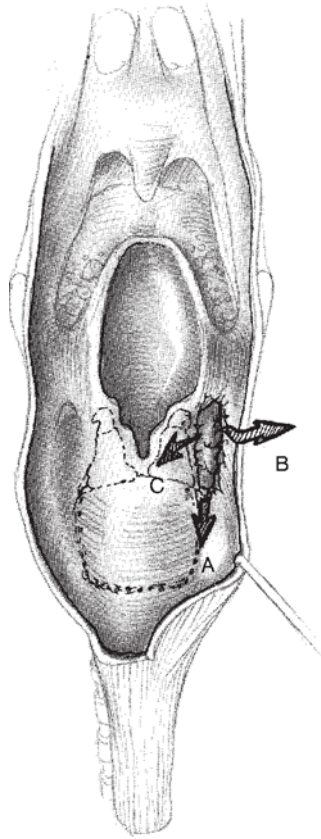

Figure 122.5 Lymph node and submucosal spread of postcricoid cancer. Submucosal spread inferiorly (*A*) can be extensive, and these lesions frequently metastasize to the paratracheal, thyroid, and paraesophageal nodes (*B*,*C*).

requires treatment of the nodal basins that are specific to each subsite of these regions.

Staging

The seventh edition of the American Joint Committee on Cancer Staging Manual has similar TNM staging compared to the sixth edition manual. This staging system facilitates the study of prognostic variables as related to the volume of local, regional, and distant disease. T4 tumors are divided into T4a (resectable; advanced local disease) and T4b (low likelihood of resection free margins; very advanced local disease). This has led to stratification of stage IV disease into IVA (moderately advanced local/regional disease), IVB (very advanced local/regional disease), and IVC (distant metastatic disease). The TNM staging for the hypopharynx is as follows:

TX: Primary tumor cannot be assessed.
T0: No evidence of primary tumor
Tis: Carcinoma *in situ*
T1: Tumor limited to one subsite and ≤2 cm in greatest dimension
T2: Tumor invades more than one subsite of the hypopharynx or adjacent site, or measures greater than 2 cm but not ≤4 cm in greatest dimension without larynx fixation.
T3: Tumor greater than 4 cm in greatest dimension or with fixation of the hemilarynx
T4a: Tumor invades thyroid/cricoids cartilage, hyoid bone, thyroid gland, esophagus, or central compartment soft tissue.
T4b: Tumor invades prevertebral fascia, encases carotid artery, or involves mediastinal structure.
NX: Regional lymph nodes cannot be assessed.
N0: No regional lymph node metastasis
N1: Metastasis in a single ipsilateral lymph node less than 3 cm in greatest dimension
N2a: Metastasis in a single ipsilateral lymph node ≥3 cm but less than 6 cm in greatest dimension
N2b: Metastasis in multiple ipsilateral lymph nodes, all less than 6 cm in greatest dimension
N2c: Metastasis in bilateral lymph nodes, all less than 6 cm in greatest dimension
N3: Metastasis in lymph node is ≥6 cm in greatest dimension
MX: Distant metastasis cannot be assessed.
M0: No distant metastasis
M1: Distant metastasis

The TNM staging system for the cervical esophagus is different from the hypopharynx. T stage is based on tumor depth of invasion, and N stage is based on the number of nodes present. The staging system has been updated since the sixth edition and is as follows:

TX: Primary tumor cannot be assessed.
T0: No evidence of primary tumor
Tis: Carcinoma *in situ*
T1: Tumor invades lamina propria or submucosa.
T2: Tumor invades muscularis propria.
T3: Tumor invades adventitia.
T4: Tumor invades adjacent structures (hypopharynx, thyroid gland, carotid sheath).
T4a: Resectable disease
T4b: Unresectable disease
NX: Regional lymph nodes cannot be assessed.
N0: No regional nodal metastasis
N1: Regional lymph node metastasis 1 to 2 nodes
N2: Regional lymph node metastasis in 3 to 6
N3: Regional lymph node metastasis in greater than 7 nodes
MX: Distant metastasis cannot be assessed
M0: No distant metastasis
M1: Distant metastasis

Molecular Staging

Hypopharyngeal and cervical esophageal cancers have distinct clinical behavior compared to other head and neck cancers; however, no specific molecular markers have paralleled this behavior. One study found an association between the stem cell markers, Oct4 and Sox2, and hypopharyngeal cancer progression, but the authors in this study did not compare their results to other head and neck sites (35). The recent interest in human papillomavirus (HPV) in head and neck carcinoma has not translated to hypopharyngeal carcinoma. A study from M.D. Anderson Cancer Center revealed the presence of HPV correlated with poor prognosis in hypopharyngeal carcinoma (36). Another study from Belgium identified no difference in survival between HPV-positive and HPV-negative hypopharyngeal carcinomas despite the presence of HPV in 74% of patients (37). This may represent the molecular heterogeneity within hypopharyngeal carcinoma that makes HPV status irrelevant, but future study is warranted.

PROGNOSIS

Overall survival for patients with hypopharyngeal cancer who receive no treatment is dismal, with a 1-year survival of 10%. Conversely, those who seek treatment have 1-year overall survival of 48% (9). Five-year overall survival for advanced-stage cancer ranges from 18% to 47%, while early-stage cancers have much improved survival ranging from 64% to 78% (Table 122.3) (23,38). The improvements in treatment protocols are reflected in the change in 5-year disease-specific survival rates for hypopharyngeal cancer patients. Between 1980 and 1985, 5-year disease-specific survival was 4.2%, and between 1990 and 1999, the 5-year disease-specific survival increased to 35% (8,9).

Lymph node status affects survival in hypopharyngeal carcinoma (Table 122.4) (23). A review of 132 patients treated with surgery and radiation revealed patients with N0 or N1 disease had 5-year survival of 54%, which drops to 20% in those with N2 or greater disease (39).

Prognostic information for cervical esophageal carcinoma is limited because most analyses are combined with all esophageal carcinomas. A large study from Hong Kong outlined the treatment of 124 patients with cervical esophageal carcinoma. They found that the primary surgery group had 2-year overall survival of 38% with median survival of 20 months and the chemoradiation-treated group had 2-year overall survival of 48% with median survival of 24 months, although the differences were not statistically significant (40). Five-year survival was noted to be 33% in a Japanese series of 84 patients with cervical esophageal

carcinoma treated with surgery and radiation (41). Another review of 32 patients with cervical esophageal carcinoma treated with primary surgery found a 5-year disease-free survival of 33% in higher stage tumors and 47% in early-stage tumors (10).

MANAGEMENT

Since the majority of patients present with advanced-stage disease, multimodality therapy is required, which would consist of surgery, radiation, and chemotherapy. Presentation at a multidisciplinary conference is a necessity to reach a consensus opinion on the management of patients; however, patients should be treated according to evidence-based guidelines or entered into an institutional review board approved protocol (42). In lieu of a therapeutic trial, treatment should comply with treatment guidelines put forth by the National Comprehensive Cancer Network (43). Functional rehabilitation, facilitated by speech pathology and dental and nutrition services in addition to the treating oncologists, is required as part of the recovery process. Typically, early-stage tumors are treated with surgery or definitive radiation. Advanced-stage disease requires combination therapy with two to three modalities. The following sections outline surgical (open and minimally invasive) and nonsurgical treatments for hypopharyngeal and cervical esophageal carcinoma. When considering treatment options, it is vital for the practitioner not to compromise oncologic outcome for preservation of organ function or application of unproven technology.

Surgery of the Hypopharynx

Preoperative Considerations

Patients who present with hypopharyngeal carcinoma typically are malnourished and have multiple comorbidities. These issues must be addressed and managed as much as possible prior to undertaking surgical resection to ensure optimal outcomes. Nutritional deficits can be identified with preoperative evaluation of weight loss and laboratory testing to assess the degree of malnutrition (e.g., anemia, low serum prealbumin and transferrin). A dietician can assist with improving diet, or recommendation can be made for temporary feeding tube. Respiratory status must also be optimized, especially if the patient is undergoing partial laryngeal resection.

Early-Stage Pyriform Sinus Cancer

Surgical approaches to early-stage pyriform sinus cancers can result in preservation of the larynx that involves the medial or lateral walls of the pyriform sinus that does not extend to the pyriform sinus apex or postcricoid mucosa. Selection for patients with early-stage tumor resections must also take into account the predilection for submucosal extension in hypopharyngeal tumors.

One approach to resection of these early-stage tumors in the superior pyriform fossae is a partial laryngopharyngectomy (Figs. 122.6 to 122.8). This procedure involves resection of the involved pyriform sinus with a partial laryngectomy. Tumor visualization is via a transhyoid or lateral pharyngotomy. Entry into the pharynx is through the contralateral side. With the tumor in full view, a mucosal incision is carried along the posterior pharyngeal wall to the involved side maintaining an adequate 1- to 1.5-cm margin. The contralateral aryepiglottic fold is incised and extended inferiorly into the laryngeal ventricle and anteriorly to the anterior commissure (Fig. 122.9).

Next, attention is directed to interarytenoid space with a vertical incision carried to the superior border of the cricoid cartilage. This incision is then directed laterally to the ipsilateral cricoarytenoid joint, orienting the incision superiorly and anteriorly across the vocal process. The cut is then directed anteriorly across the ipsilateral ventricle to the anterior commissure, joining it with the contralateral cuts. The specimen is now centered on the tumor,

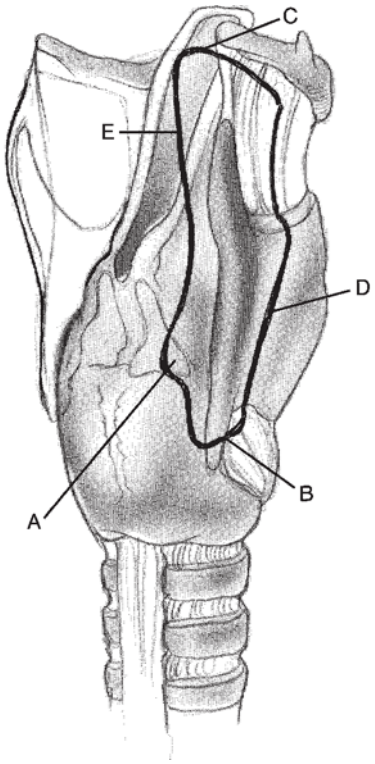

Figure 122.6 External surgical anatomic projections of the piriform fossa. The piriform apex (*A*) is just above the cricothyroid articulation at the inferior cornu (*B*). The superior border is at the inferior margin of the hyoid bone (*C*). The anterior border is at the junction of the anterior and posterior halves of the thyroid cartilage (*D*). The posterior edge of the thyroid cartilage marks the posterior border of the piriform fossa (*E*).

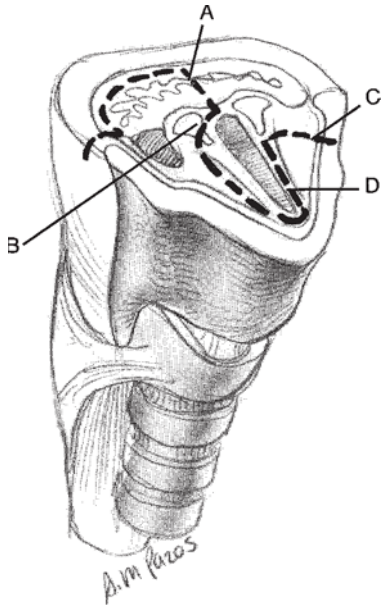

Figure 122.7 Partial laryngopharyngectomy (PLP) for cancer of the superior piriform fossa. The key elements of the PLP involve an interarytenoid incision (*A*) that extends across the vocal process (*B*) on the ipsilateral side and an incision in the aryepiglottic fold (*C*) and ventricle (*D*), similar to that used for supraglottic laryngectomy on the contralateral side.

which is resected with adequate margins. Frozen sections should be used to evaluate mucosal and soft tissue margins. Reconstruction of the laryngopharyngeal defect is accomplished by suturing of the vocal cord remnant to the posterior–superior cricoid cartilage, and the tongue base is sutured to the thyroid cartilage perichondrium. Reinforcement of the pharyngeal closure can be accomplished with the remaining strap muscles or a sternocleidomastoid flap (Figs. 122.10 and 122.11). A cricopharyngeal myotomy is performed, and either a nasogastric feeding tube or gastrostomy tube is placed. The airway is secured temporarily with a tracheostomy.

This procedure was studied by Makeieff et al. (44) in 87 patients with early-stage tumors. He found a 5-year overall survival of 60% in his cohort of T1 and T2 tumors with a local recurrence rate of 19.9%. Ninety-three percent of patients resumed normal oral diet after a median duration of nasogastric tube alimentation for 20 days. Another recent series reviewing 48 patients with selected T1 and T2 tumors of the pyriform fossae found a 5-year local control rate of 98% and 5-year actuarial survival of 47% (45). All patients in this series returned to normal diet after 1 month. In both of these series, postoperative radiotherapy was used in 90% of the patients.

Another approach to larger tumors of the pyriform fossae is the supracricoid hemilaryngectomy. Invasion of the pyriform apex, postcricoid mucosa, and posterior pharyngeal wall and vocal cord immobility are relative contraindications to this procedure. The efficacy of this procedure was studied in France with a cohort of 147 patients who received induction chemotherapy followed by surgery (46). Half of the patients went on to receive adjuvant radiotherapy. He found a 5-year local control rate of 90%, including 63% for T4a tumors. Lesions invading the pyriform sinus apex and posterior pharyngeal wall were associated with increased rate of recurrence. Normal deglutition was observed in 64.6% after 1 month and 92% after 1 year. Only 1.5% of the patients in the cohort required completion laryngectomy. In the United States, this procedure has gained little acceptance.

Currently, most of these early-stage tumors are treated with definitive radiotherapy with or without chemotherapy. In addition, endoscopic laser or transoral robotic techniques have replaced these open partial laryngeal procedures. These points will be discussed in other sections.

Advanced-Stage Pyriform Sinus Cancer

In T3 and T4 tumors of the pyriform sinus, treatment centers on surgery and adjuvant radiation. Conservation surgery may be possible, but local control is poor (47). Therefore, surgical resection involves total laryngectomy with partial or total pharyngectomy. The surgeon must take into account the propensity for submucosal spread when addressing margins. Varying amounts of cervical esophagus or thoracic esophagus must be resected based on size of the primary tumor. In one study from Australia, 180

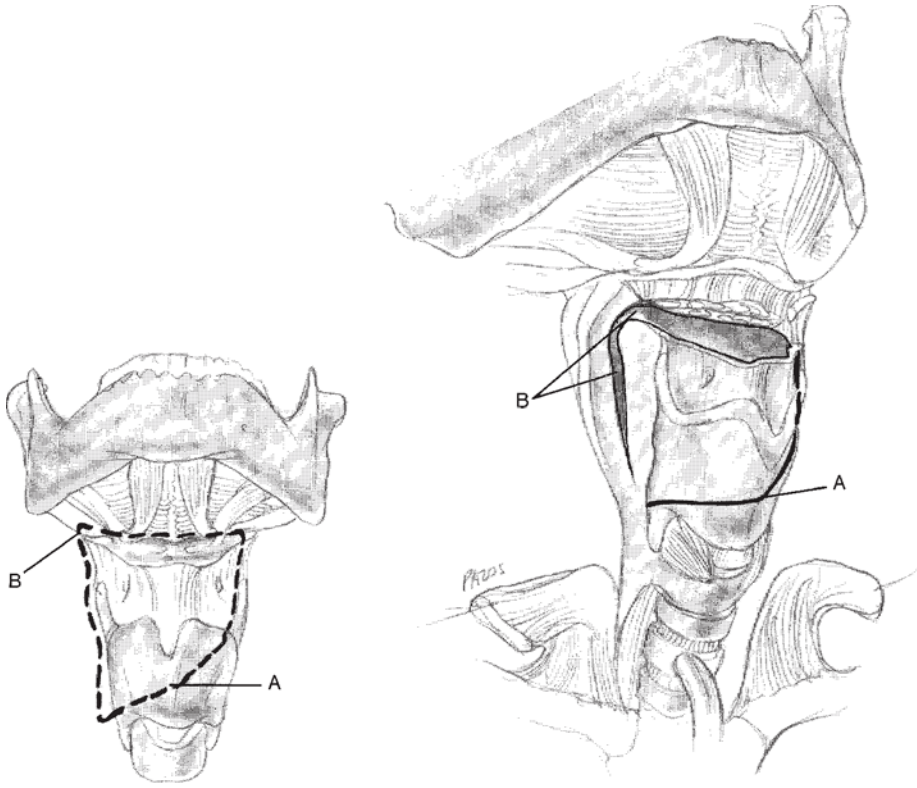

Figure 122.8 Partial laryngopharyngectomy for cancer of the superior piriform fossa. The cartilage cuts begin at a point above the anterior commissure (*A*) and extend laterally and inferiorly on the ipsilateral side and laterally and superiorly on the contralateral side. The pharynx is entered through a combination of suprahyoid and lateral pharyngotomy incisions (*B*).

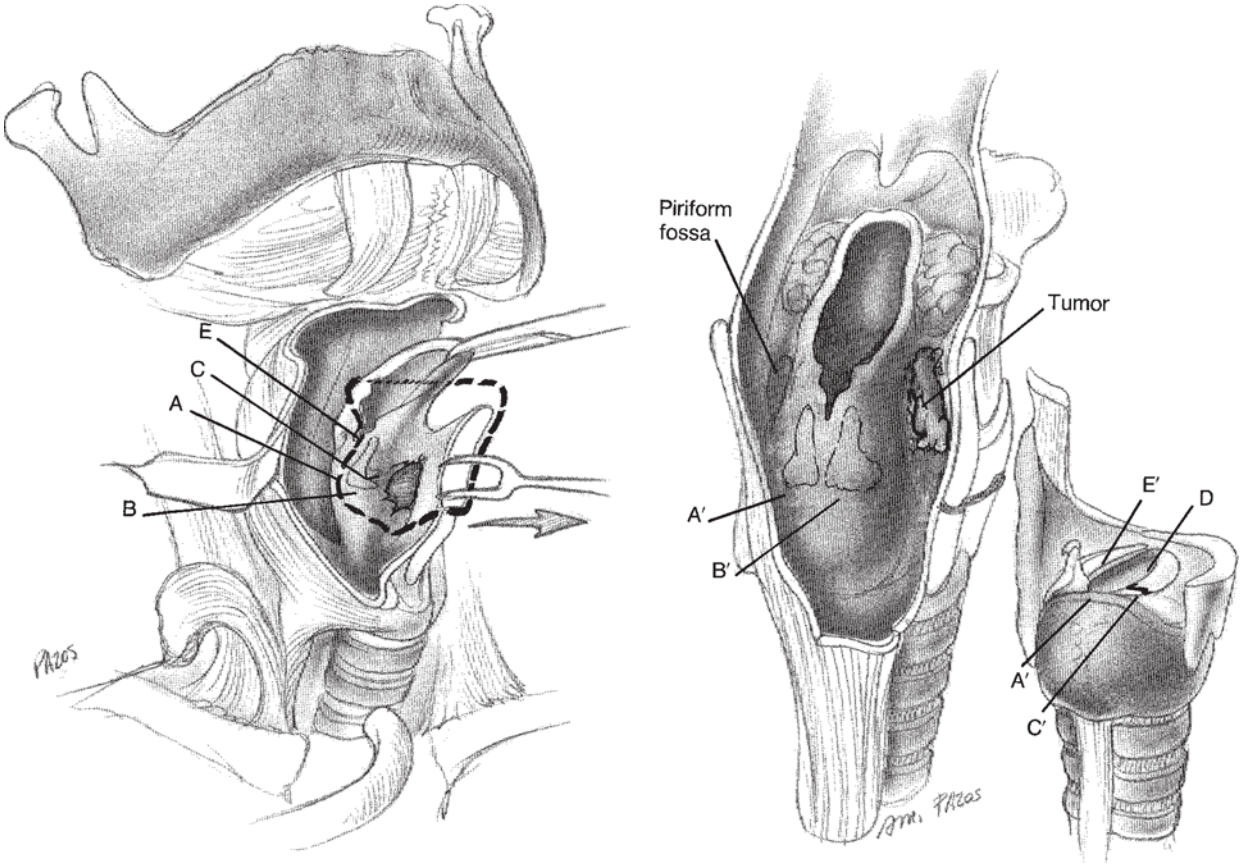

Figure 122.9 Partial laryngopharyngectomy for cancer of the superior piriform fossa. The interarytenoid incision (*A*) is carried down to the cricoid cartilage through the cricoarytenoid joint (*B*), across the vocal process (*C*), and anteriorly through the ventricle (*D*). The contralateral aryepiglottic fold and ventricular incisions (*E*) also extend forward to the anterior commissure.

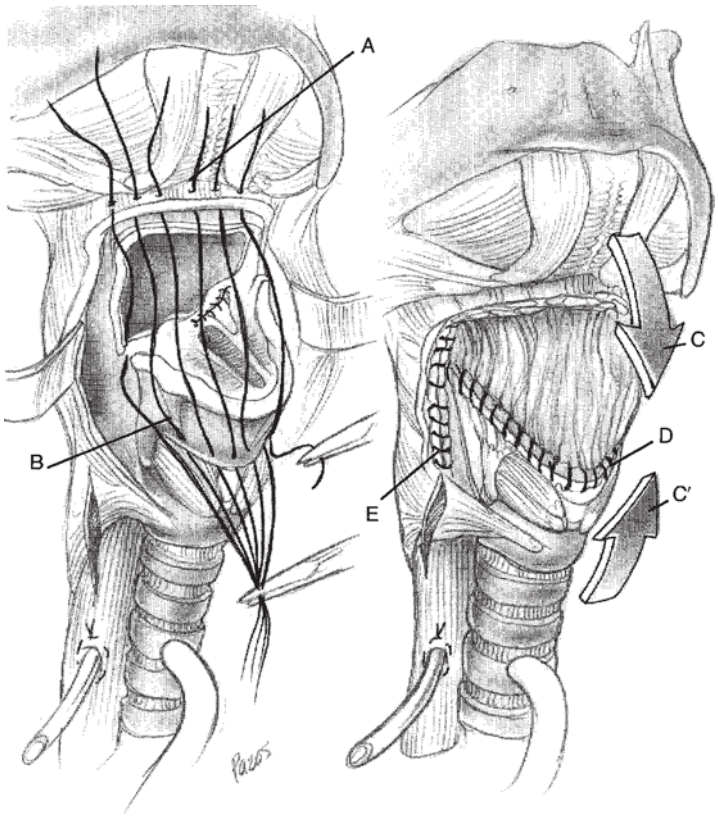

Figure 122.10 Partial laryngopharyngectomy for cancer of the superior piriform fossa. A watertight closure of the pharyngotomy is accomplished with a combination of sutures from the tongue base (*A*) to the thyroid perichondrium (*B*). Head flexion allows tongue base and laryngeal relaxation (*C*) with closure of the horizontal segment of the pharyngotomy (*D*). The lateral pharyngotomy is sutured vertically (*E*).

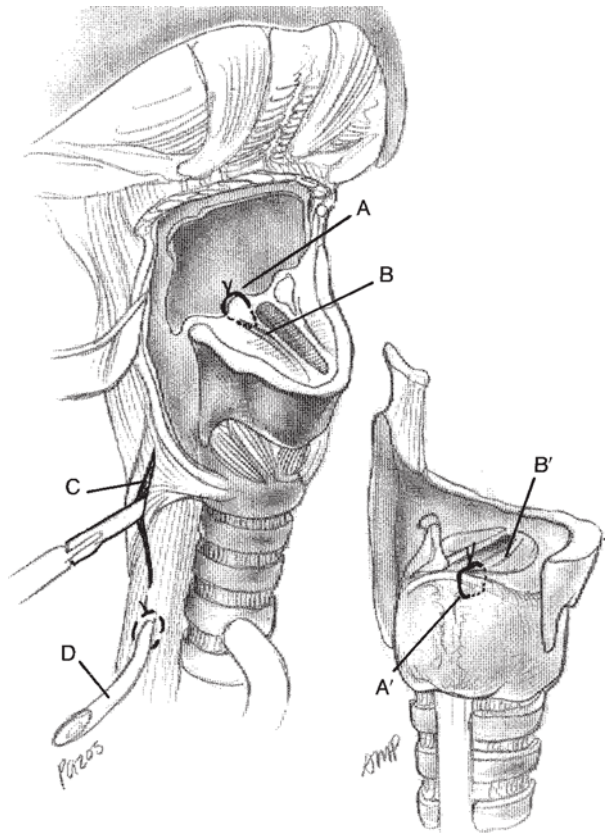

Figure 122.11 Partial laryngopharyngectomy for cancer of the superior piriform fossa. The vocal cord retention suture (*A*) is placed through the lateral aspect of the vocal process remnant, through the cricoid cartilage, and then tied down to bring the cord (*B*) to the midline. A cricopharyngeal myotomy (*C*) is performed, and a feeding esophagostomy tube (*D*) placed.

patients had total laryngopharyngectomy followed by postoperative radiation treatment (48). Local/regional control rate was 82% with 5-year survival of 52%. These results illustrate the aggressive nature of these tumors. Organ preservation protocols are a valid alternative to total laryngopharyngectomy and will be discussed subsequently.

Posterior Hypopharyngeal Wall Cancer

These lesions are typically localized and exophytic, allowing for wide excision and reconstruction. Advanced-stage tumors are typically fixed to the prevertebral fascia and not amenable to surgery. The approach requires either a lateral pharyngotomy or transhyoid pharyngotomy (Fig. 122.12). Once the vallecula has been entered, the incision is extended along the hyoid bone on either side ensuring the superior laryngeal neurovascular bundles are hypoglossal nerves that are protected. The hyoid and larynx can be retracted inferiorly to provide excellent exposure of the pharyngeal wall (Fig. 122.13). Resection of the tumor should involve the prevertebral musculature if the prevertebral fascia is involved. In this setting, local control is poor with surgery alone. Retropharyngeal node dissection should be performed as well. If these nodes are not dissected, then adjuvant radiotherapy must cover the retropharyngeal nodal basin. One problem with surgery is the denervation of the pharyngeal plexus, which can result in significant dysphagia and aspiration in larger tumor resections.

Reconstruction of a small posterior pharyngeal wall defect can be achieved with a split-thickness skin graft

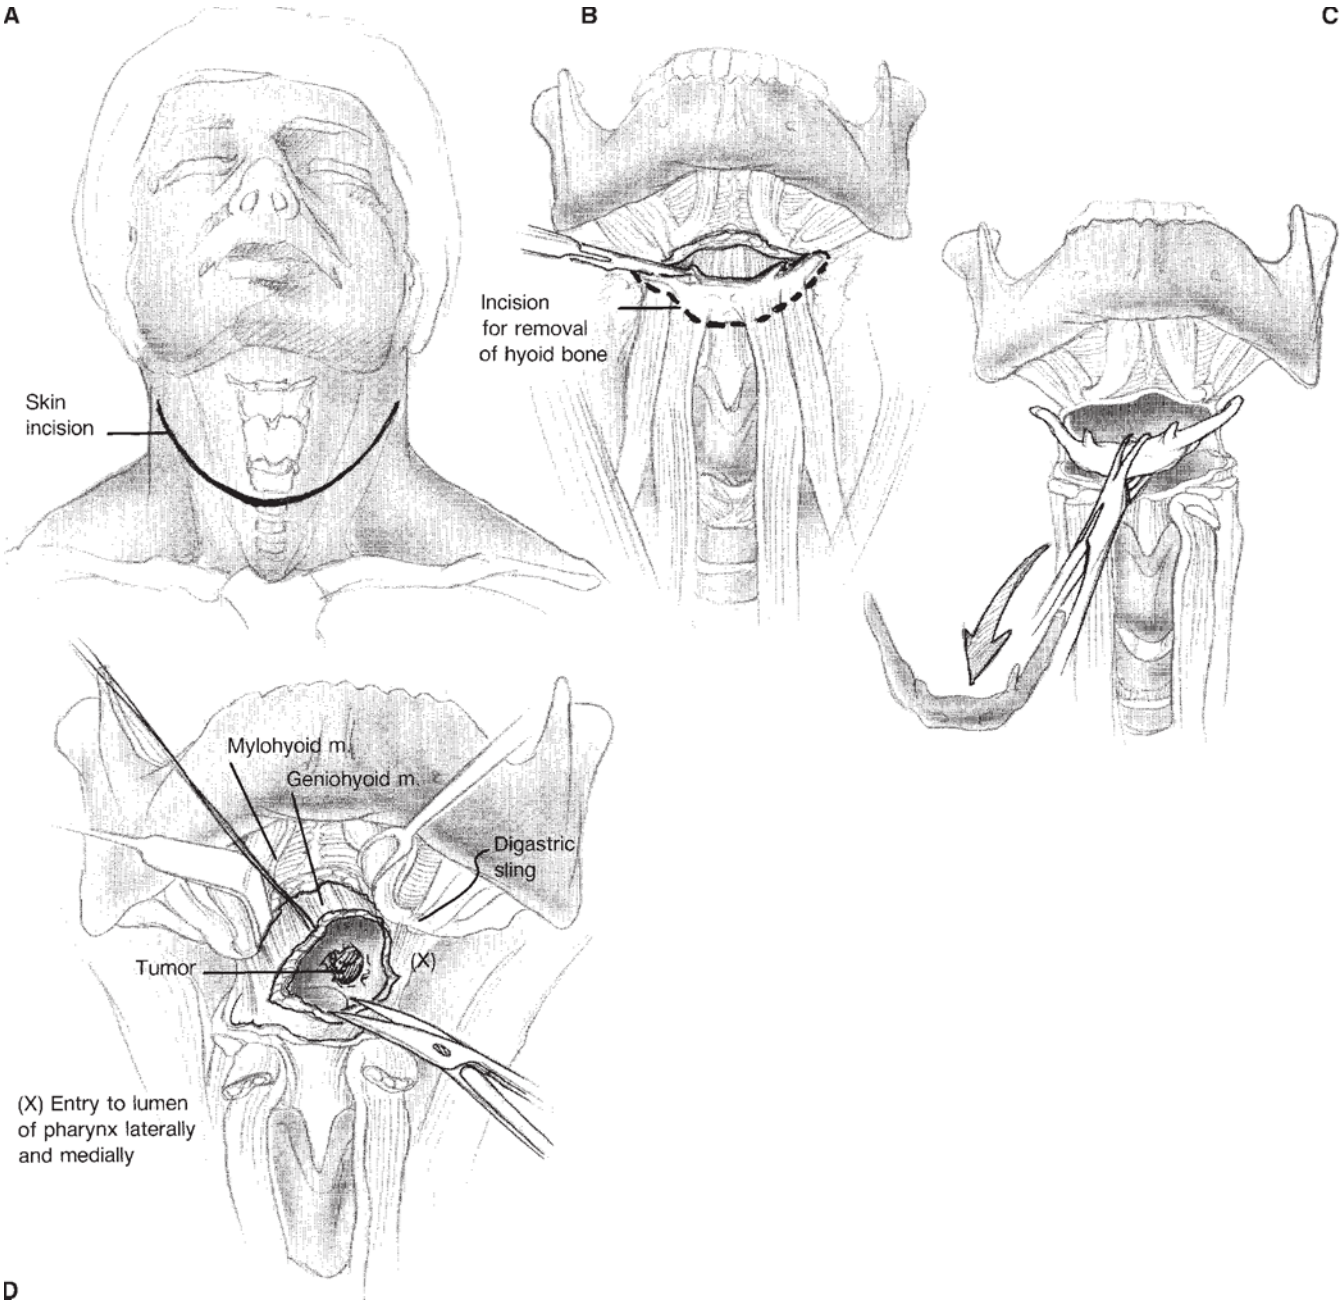

Figure 122.12 Suprahyoid pharyngotomy for posterior hypopharyngeal cancer. The initial incision **(A** and **B)** extends along the superior border of the hyoid for its entire length. The hyoid then is removed **(C)** to facilitate completion of the pharyngotomy **(D)**.

(Fig. 122.14). A bolster is placed over the graft and can be removed transorally in 5 days. If the resection involves removal of the lateral wall of the pyriform sinus, the defect size will not support a skin graft alone (Figs. 122.15 and 122.16). In this situation, a pectoral myocutaneous flap, platysma myocutaneous flap, or free fasciocutaneous flap (e.g., radial forearm or anterolateral thigh) can repair this defect. A local alternative can be achieved with bilateral advancement of the prevertebral muscles with a skin graft (Figs. 122.17 and 122.18). Reconstruction of posterior hypopharyngeal wall defects is fraught with significant morbidity (49,50). For example, a series from Memorial Sloan-Kettering reported a 67% complication rate after surgery, and only 33% of the patients in the series resumed a full oral diet (49).

If surgery is considered for posterior pharyngeal wall tumors, the surgeon must understand that resection will likely involve the pharyngeal plexus and patients may experience significant swallowing dysfunction as well as the high complication rate associated with the reconstruction. Definitive radiation is an alternative therapy to achieve good local control with adequate function posttreatment, and the retropharyngeal lymph nodes will be treated.

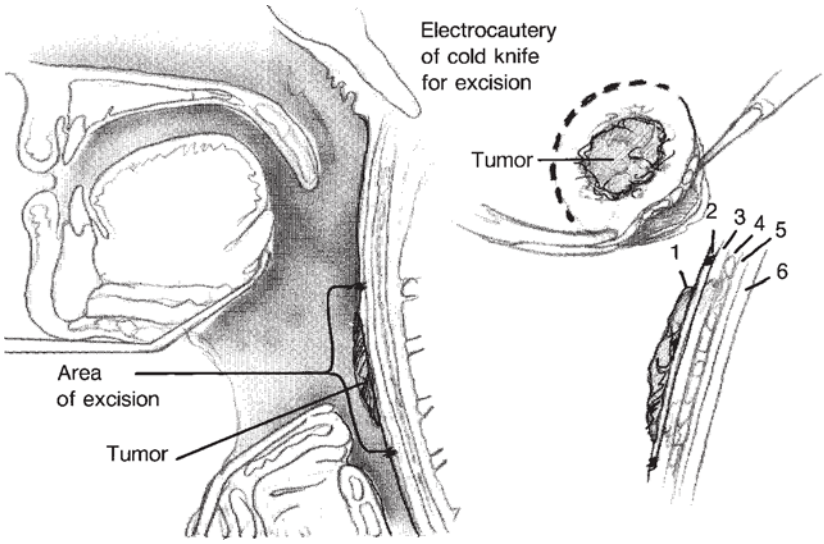

Figure 122.13 Suprahyoid pharyngotomy for posterior hypopharyngeal cancer. After the hyoid is removed and the pharyngotomy completed, superior and inferior retraction provides excellent exposure for wide excision of the cancer. *1*, tumor; *2*, mucosa; *3*, constrictor; *4*, longus colli; *5*, retropharyngeal space; *6*, prevertebral fascia.

Postcricoid Cancer

Tumors of the postcricoid region typically do not present until reaching an advanced stage. The lesions have invaded the cricoid cartilage and posterior cricoarytenoid muscles. Inferior extension into the cervical esophagus is common. Therefore, surgery should involve total laryngopharyngectomy and cervical esophagectomy with postoperative radiation therapy. Again, organ preservation approaches can be presented to patients who do not desire total laryngectomy.

Minimally Invasive Approaches

Transoral laser surgery was initially developed for laryngeal carcinoma in head and neck cancers, but its use has been translated to the hypopharynx. Multiple case series have been published detailing the personal experiences of individual surgeons. All stages have been evaluated for transoral laser surgery. Local control rates have been reported between 90% and 95% in early-stage tumors and 47% and 69% in advanced-stage tumors (51–53). The purported advantages of transoral laser surgery compared to open functional surgery are avoidance of tracheotomy in most cases, a feeding tube is not required in many cases, and the hospital stay is shorter. Moreover, endoscopic laser surgery, in contrast to open surgery, better spares the pharyngeal sensory innervation, thus improving the capability of protecting the airway during swallowing (52).

Transoral robotic surgery is a new technique that is gaining popularity in some centers. Its application in oropharyngeal carcinoma has been well documented (54). However, only small series have included hypopharyngeal cancers, with the largest personal series being 10 patients with T1 or T2 tumors (55,56). Feasibility of surgery has been limited to the posterior pharyngeal wall and lateral pyriform sinus due to restricted space that safely allows the robotic arms to perform the resection.

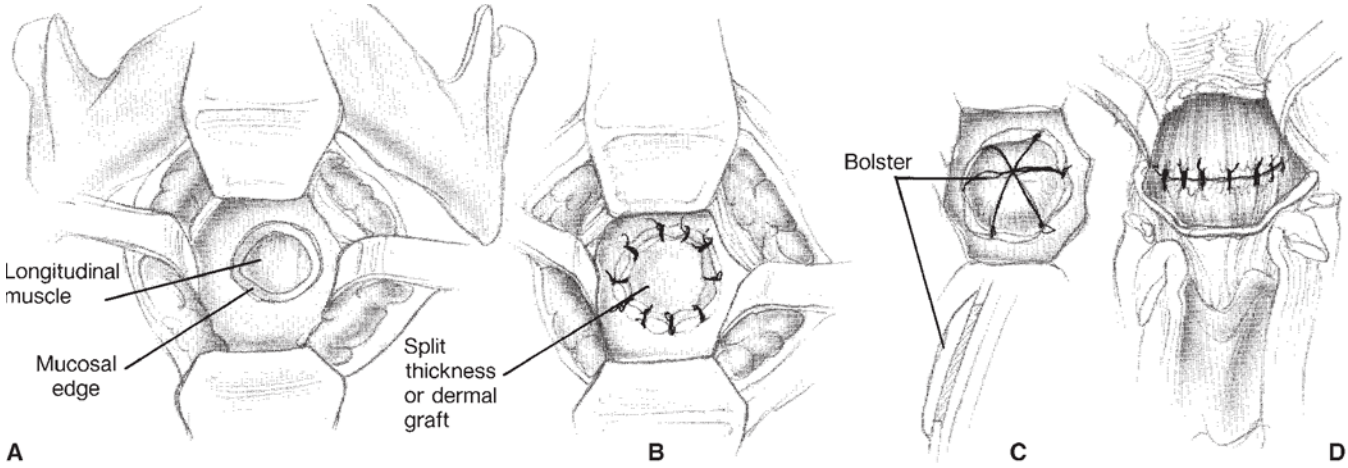

Figure 122.14 Suprahyoid pharyngotomy for posterior hypopharyngeal cancer. The incision is usually carried down to the prevertebral fascia **(A)**, which acts as the surgical plane for excision. The defect then is covered with a split-thickness or dermal skin graft **(B)**. This is held in place with a bolster **(C)** of nylon sheeting stuffed with cotton balls. The pharyngotomy is closed in layers, avoiding suture ligation of the hypoglossal and superior laryngeal nerves **(D)**.

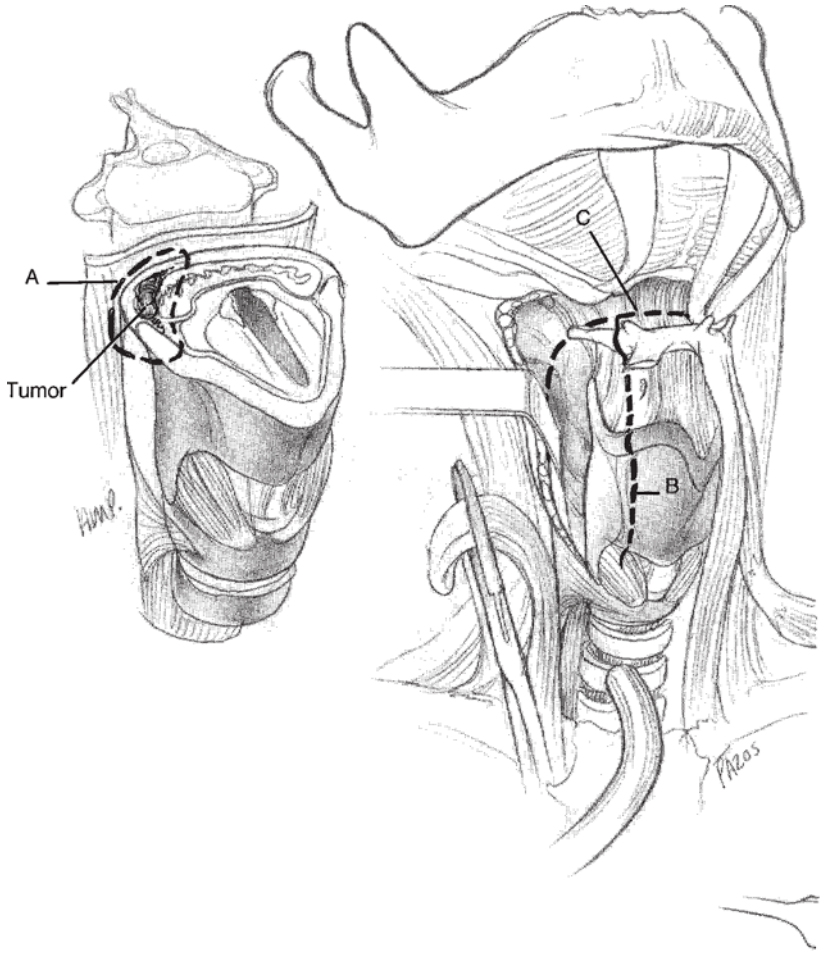

Figure 122.15 Combined suprahyoid and lateral pharyngotomy for posterolateral hypopharyngeal cancer. These cancers (*A*) are approached by excising the posterior third of the thyroid cartilage and combining the anterolateral pharyngotomy incision (*B*) with the suprahyoid incision (*C*).

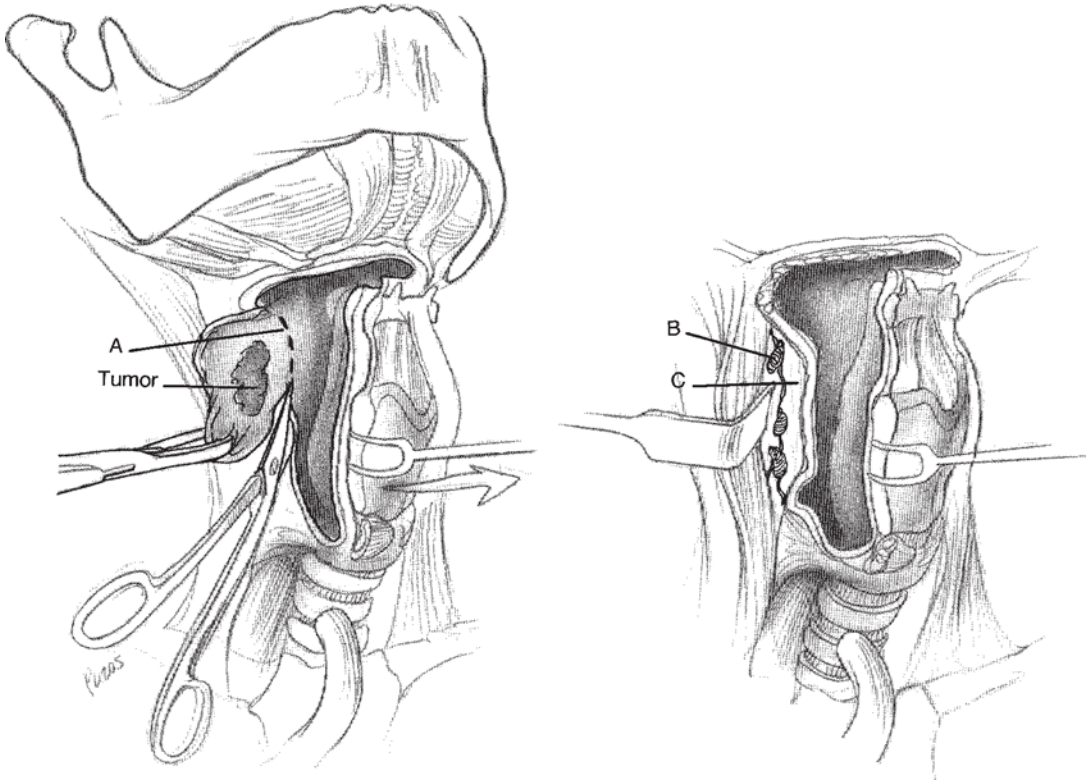

Figure 122.16 Combined suprahyoid and lateral pharyngotomy for posterolateral hypopharyngeal cancer. The final incision (*A*) is made under direct vision. The cervical sympathetic ganglion (*B*) should be preserved if it is not involved with the cancer. Reconstruction can be accomplished by using a portion of the prevertebral muscle (*C*) as a backing for a skin graft.

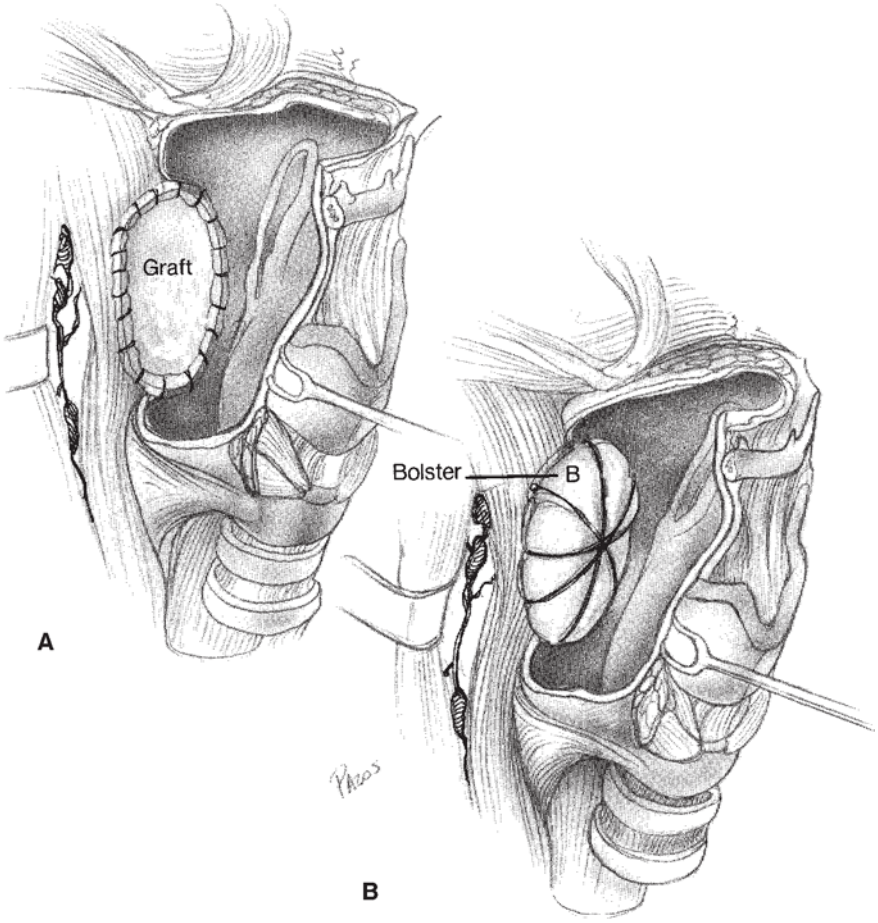

Figure 122.17 Combined suprahyoid and lateral pharyngotomy for posterolateral hypopharyngeal cancer. The split-thickness or dermal skin graft is sutured to the prevertebral muscle (*A*) and held in place with a nylon mesh and cotton-ball bolster (*B*).

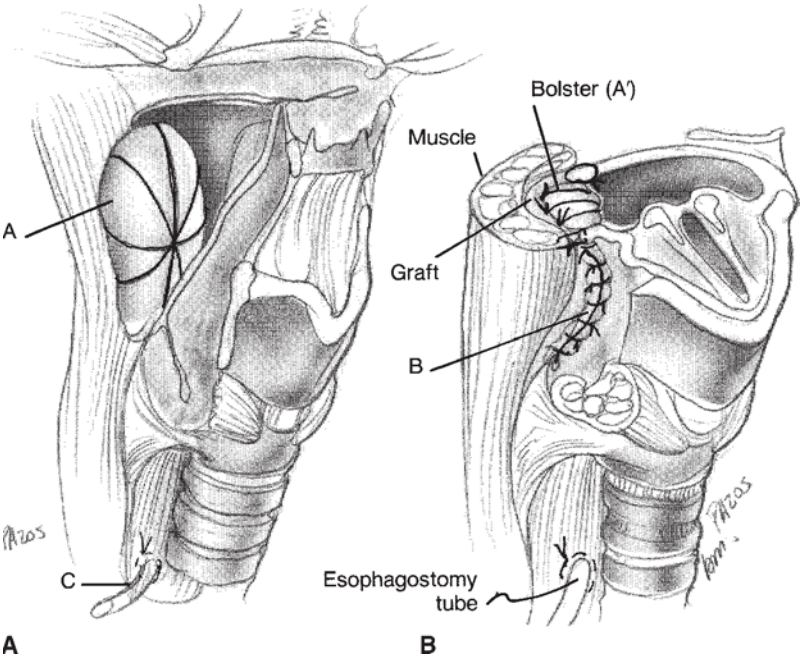

Figure 122.18 Combined suprahyoid and lateral pharyngotomy for posterolateral hypopharyngeal cancer. After the steps illustrated in Figures 122.15 and 122.16 the prevertebral muscle is mobilized as a bipedicled flap for medial rotation of the skin graft–bolster combination (*A*). The bolster is sutured in place with long sutures from the graft. A watertight closure of the pharyngotomy (*B*) is then accomplished, and a feeding esophagostomy is placed.

SURGERY OF THE CERVICAL ESOPHAGUS

Tumors of the cervical esophagus typically present at an advanced stage; therefore, a limited local surgery is rare. Because the proximal cervical esophagus is adjacent to the larynx, total laryngopharyngectomy with cervical esophagectomy is often the indicated procedure, both to obtain an adequate upper surgical margin and to avoid postoperative aspiration. In instances where the tumor extends inferiorly into the thoracic esophagus, total esophagectomy is required. Tumors that do not invade into the hypopharynx or larynx may be amenable to larynx-preserving cervical esophagectomy with adequate functional and oncologic outcomes (10).

MANAGEMENT OF THE NECK

Nodal metastasis is common in hypopharyngeal and cervical esophageal carcinoma. Therefore, nodal basins must be addressed by either surgery or radiation. Lymph node metastases are common in hypopharyngeal carcinoma with 64% to 90% of patients presenting with nodal disease and bilateral disease seen in 8% to 16% of cases (9,25,26). Ipsilateral neck dissection is adequate for early-stage tumors of the lateral pyriform sinus. However, tumors approaching the midline require bilateral dissection. For the hypopharynx, nodal dissection should involve the levels II, III, and IV. Elective dissection of the paratracheal and paraesophageal nodes is unclear at this time. A high rate of paratracheal nodal metastasis is seen in advanced-stage disease and tumors involving the postcricoid mucosa (57%) (28,31,57); therefore, paratracheal dissection is indicated in advanced hypopharyngeal carcinoma. Bilateral paratracheal dissection and total thyroidectomy are indicated in midline lesions or lesions involving the cervical esophagus (57). Mediastinal dissection is advocated in T4 hypopharynx tumors because of nodal metastasis rate that approaches up to 40% (30,31).

The cervical esophagus has a propensity to metastasize to bilateral paratracheal and paraesophageal basins (29). Therefore, elective bilateral central compartment dissection is advocated in cervical esophageal carcinoma. Mediastinal dissection is also recommended due to high rate of mediastinal nodal metastasis (30,31).

Retropharyngeal nodal disease is seen in 20% to 50% of patients with hypopharyngeal and cervical esophageal cancers (32–34). These data suggest the importance of treating the retropharyngeal nodes with surgery or radiation. Gross retropharyngeal nodal disease that is noted with preoperative imaging should be removed at the time of surgery. Radiation can be used in the adjuvant setting or in the elective setting when there is no apparent retropharyngeal nodal disease.

RECONSTRUCTION

Small defects of the hypopharynx are amenable to reconstruction via a split-thickness and local advancement flaps. It is best to avoid primary closure of a mucosal remnant less than 2 cm because of concerns for stricture. These larger defects are better suited for reconstruction with pedicled myocutaneous flaps, such as the pectoral myocutaneous or deltopectoral flap. The pedicled flaps are reliable with minimal complications (58). Free tissue transfer with a radial forearm flap or anterolateral thigh (ALT) flap is another option in the reconstruction of these defects with acceptable functional results (59). Bulky flaps should be avoided in cases of laryngeal preservation, as this may interfere with swallowing and cause intractable aspiration.

Total pharyngeal defects are best reconstructed with free tissue flaps. Tubed fasciocutaneous flaps from the radial forearm and ALT or free enteral grafts are the common choices by the reconstructive surgeons. The ALT flap has good versatility with only a 5% stricture rate reported in one study (60). Another review from Korea found 92% of patients undergoing reconstruction with a tubed free fasciocutaneous flap returned to normal oral diet, and only 6% experienced stricture (61). Enteric flaps have the advantages of tissue pliability, tubed shape, ease of contouring, intrinsic peristalsis, and the ability to secrete mucus. However, it has been observed that many patients have inferior vocal quality that is described as "wet" due to the increased mucus secretion (62). In addition, jejunal grafts can be harvested with laparoscopic techniques, thus, avoiding a laparotomy incision (63).

Surgery of the cervical esophagus many times requires resection of the entire esophagus posing a challenge in the reconstruction. Tubed fasciocutaneous flaps are not an option in these cases due to length of the defect. Colon interposition is an option in the reconstruction of the esophagus because it does not involve microvascular anastomosis (Fig. 122.19). However, postoperative infection is common with devastating consequences; therefore, this technique is only used when other options are not available.

Gastric transposition has several advantages in the reconstruction with a robust blood supply and creation of a single pharyngeal anastomosis. Blunt dissection from the abdomen and posterior mediastinum can mobilize the stomach. In addition, mobilization of the duodenum allows the stomach to be pulled up to the level of the nasopharynx (Fig. 122.20). Complications of this procedure commonly involve fluid collections within the pleural space causing pneumo/hemothorax. This complication can be resolved with a thoracostomy tube. Mortality of this procedure is approximately 5% to 15% (64,65).

The jejunal graft is an excellent option in reconstruction of the cervical esophagus as described above. In cases where total esophagectomy is required, additional length can be obtained by "supercharging" the jejunum with a distal pedicle supplying the enteric anastomotic end (66). The stomach

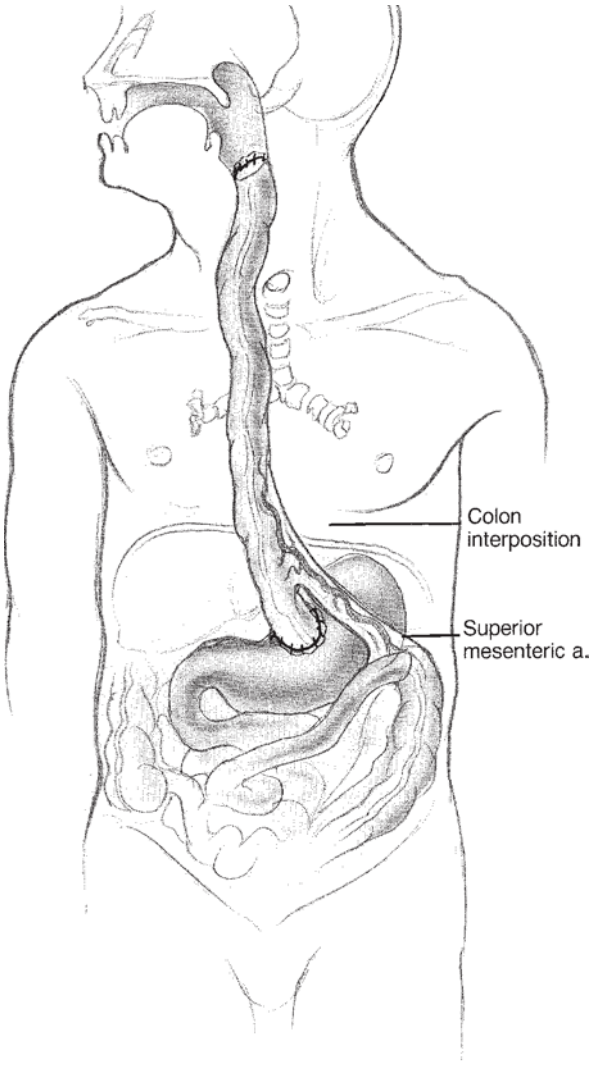

Figure 122.19 Colon interposition allows one-stage reconstruction or bypass of the entire esophagus. A high incidence of septic complications is associated with this procedure.

remains *in situ* and serves as a reservoir, thus avoiding reflux seen in the gastric pull-up. Another advantage of this surgery is it requires one microvascular anastomosis in the neck with acceptable operative morbidity. In fact, 90% of the patients are able to return to normal oral diet.

Many reconstructive options exist for the closure of hypopharyngeal and cervical esophageal defects. It is imperative that the reconstructive surgeon plays a role in the multidisciplinary team. However, oncologic safety must not be compromised for a specific reconstructive method.

NONSURGICAL THERAPIES FOR HYPOPHARYNGEAL AND CERVICAL ESOPHAGEAL CARCINOMA

Primary radiation is the treatment of choice in many early-stage hypopharyngeal carcinomas. Disease-specific survival and local control rates are similar to published surgical series of similar stage cases with acceptable morbidity (67,68). Advanced-stage tumors typically are treated with surgery followed by postoperative radiation. Local control rates in this situation range between 76% and 79% (69).

Although chemotherapy is not used as a definitive treatment in hypopharyngeal carcinoma, its use in the neoadjuvant or concomitant role has proven beneficial in many patients. A meta-analysis of over 87 trials using chemotherapy in head and neck cancers between 1965 and 2000 revealed an absolute survival benefit of 4.5% (70). The use of concurrent chemotherapy had a more pronounced survival benefit at 6.5%. Therefore, the addition of chemotherapy to protocols in the treatment of hypopharyngeal carcinoma may improve survival. Although induction chemotherapy did not show a survival benefit in these studies, more recent studies have shown the addition of taxanes (docetaxel) to the previous platinum-based regimen (cisplatin and 5-fluorouracil) provides a significant survival benefit over the platinum-based regimen alone (1).

The addition of chemotherapy in the postoperative radiation setting has been studied by two cooperative trials, RTOG 95-01 and EORTC 22391 (71,72). These two trials compared the addition of chemotherapy to postoperative radiation to conventional postoperative radiation alone in patients with high-risk head and neck cancer (defined as extranodal spread, multiple positive nodes, and positive surgical margins). Hypopharynx carcinomas constituted 20% of the European Organization for Research and Treatment of Cancer (EORTC) group, 12% of the Radiation Therapy Oncology Group (RTOG) radiation arm, and 7% of the RTOG concurrent chemoradiation arm. Both trials showed improved local and regional control in the chemotherapy arms with an increase in control rate of 10% and 11% in RTOG and EORTC trials, respectively. Only the EORTC found a significant survival benefit in the chemotherapy arm (13% difference at 2 years). Therefore, the conclusions of these two studies are addition of chemotherapy in high-risk head and neck cancer will improve local and regional control and survival.

The results of the Veterans Affairs Laryngeal Cancer Study and the RTOG have encouraged treatment regimens using chemotherapy and radiation therapy to preserve the larynx (73,74). The use of chemotherapy as part of induction or concurrent treatment has resulted in improved local/regional control rates and decreased distant metastasis. These results have not compromised survival rates when compared to surgery and adjuvant radiation. However, these studies looked at patients with larynx cancers alone without any hypopharyngeal carcinomas.

The promising results of the VA trial led to consideration for organ preservation protocols in the treatment of hypopharyngeal carcinoma. The first such study was a retrospective review from M.D. Anderson Cancer Center comparing induction chemotherapy and radiation therapy to surgery in patients with laryngeal and hypopharyngeal

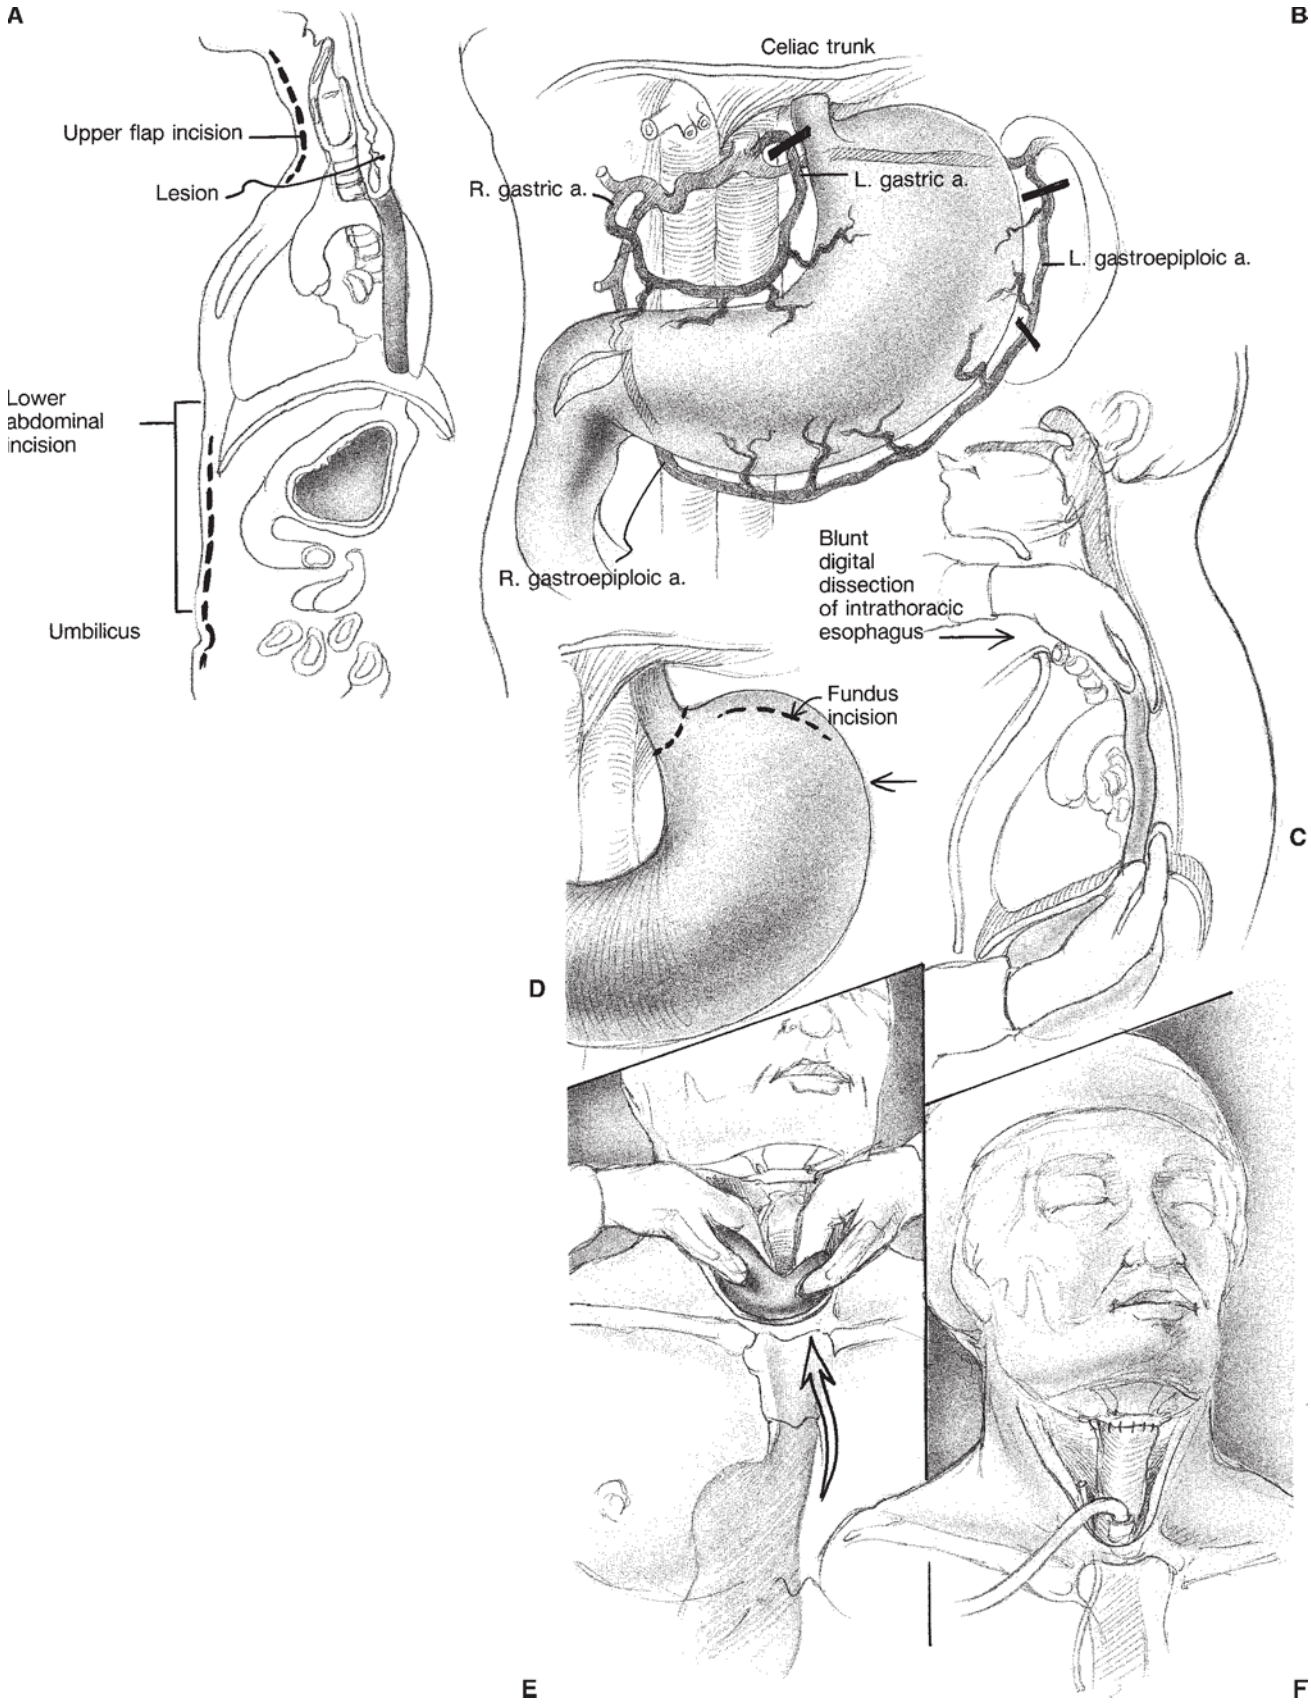

Figure 122.20 **A:** Gastric pull-up with pharyngogastric anastomosis is commonly used to reconstruct total esophageal defects. **B:** The intraabdominal procedure includes vagotomy with pyloroplasty. The duodenum is mobilized with the Kocher maneuver. **C:** The esophagus is removed without thoracotomy, using bimanual transabdominal and transcervical dissection. The stomach is brought up through the chest into the neck in the posterior mediastinum. **D:** The fundus is opened to provide the greatest length for anastomosis. **E:** Fundus in neck. **F:** Fundus surgery.

carcinomas (75). They reported a response rate of 78% in all hypopharyngeal patients and complete response rate of 83% in patients who had a response to induction chemotherapy. The larynx was preserved in 69% of the patients. Most importantly, there was not a significant survival difference between the nonsurgical group and the surgical group. These results were followed by a prospective evaluation of larynx preservation in hypopharynx cancer developed by the EORTC. It was a phase III, randomized controlled trial comparing induction cisplatin and 5-fluorouracil (FU) followed by radiation therapy and conventional surgery with adjuvant radiation therapy (2). No difference was found in local/regional control rates and disease-free survival at 5 years. Functional laryngeal preservation was 35% at 5 years. This study concluded that functional larynx preservation is possible without compromising survival in hypopharyngeal carcinoma.

The EORTC reported on a second larynx preservation for hypopharyngeal comparing induction chemotherapy to concurrent chemoradiation, similar to RTOG 91-11. This trial had 51% of patients with hypopharyngeal carcinoma (3). Patients were staged T2–4/N0–2 at the hypopharynx for entry into the trial and assigned to receive induction chemotherapy followed by radiotherapy or an alternating chemoradiation regimen. Local control rates were similar in each group at 32% at 5 years. Survival was not significantly different, with median survival 4.4 years (5-year overall survival estimate 48.5%) in the induction arm and 5.1 years (5-year overall survival estimate 51.9%) in the chemoradiation arm. The main weakness of this study is the alternating fractionation of the radiation, with the treatment regimen lasting greater than 7 weeks, and total dose delivered was reduced to 60 Gy. Due to these differences in treatment regimen, it is difficult to compare this result to conventional concurrent chemoradiation protocols. In contrast, the results of the RTOG 91-11 have shown that concurrent chemoradiotherapy had a greater loco/regional control compared to the sequential arm and radiation alone (74). This trial did not include hypopharynx carcinoma patients, but it does demonstrate that concurrent treatment similar to current regimens can result in improved locoregional control.

Chemotherapy and radiation have also been studied in the treatment of cervical esophageal carcinoma. Results of these studies combined all esophageal carcinomas. One study from M.D. Anderson Cancer Center retrospectively reviewed 132 patients who received concurrent chemoradiation (76). Sixty patients underwent esophagectomy after treatment and compared to the remaining 72 patients who had no surgery. Significant findings were noted in the surgical arm for local control (67% vs. 22%) and 5-year overall survival (52.6% vs. 6.5%). The addition of induction chemotherapy was found to be superior to concurrent chemoradiation and surgery alone in a subsequent study (77). The 5-year overall survival in the induction arm followed by concurrent chemoradiation and surgery was 71% compared to 22% in the concurrent chemoradiation and surgery arm. Additional investigation is required to validate the findings in these studies, but multimodality therapy in the treatment of esophageal carcinoma is noted to have significant survival benefit.

SALVAGE SURGERY

Salvage surgery for persistent or recurrent disease of the hypopharynx or cervical esophagus following the completion of chemoradiation therapy may be particularly challenging but can prolong disease-free interval (78). Uneven tumor regression, ill-defined tumor borders, radiation-induced soft tissue fibrosis, and poor wound healing make salvage surgery a challenging endeavor (79). However, median survival in patients with recurrent head and neck cancer without any additional therapy is 3.8 months (80). With salvage surgery, median survival increases to 14 months after treatment of recurrent disease in the pharynx (78). From these two observations, salvage surgery is a viable option to prolong survival.

A follow-up study to the RTOG 91-11 trial revealed that 24.9% of all the patients required salvage laryngectomy (81). No significant survival difference was observed in any of the treatment arms (range 69% to 76%), which makes the point that surgical salvage is independent of prior therapy. Another study with promising result in salvage pharyngectomy for recurrent hypopharyngeal carcinoma comes from Toronto (82). They reviewed 72 patients with recurrent hypopharyngeal carcinoma who presented for surgical salvage. Their results demonstrated a 5-year overall survival of 31% with 5-year local and regional control rate of 70% and 71%. The presence of extracapsular extension, positive surgical margins, lymphovascular invasion, and nodal status was a negative predictor of local and regional control. These data are comparable to results from M.D. Anderson Cancer Center, where the authors reviewed their experience with induction chemotherapy and radiation for patients with hypopharyngeal carcinoma (75). They found 2-year survival after salvage laryngopharyngectomy was 75%. Another report from Germany presented results that are more dismal after salvage laryngopharyngectomy (83). They reviewed 28 patients with recurrent/persistent hypopharyngeal carcinoma, out of 134 patients who originally had organ preserving therapy, for surgical salvage. They found that only 2 of the 20 patients who had histologically proven recurrence were actually tumor free and alive after a mean observation time of 43.9 months. The authors concluded that patients must be informed of high morbidity and poor oncologic outcome after salvage surgery.

An important point to address from these studies is the high morbidity in salvage surgery. The Toronto group reported a 75% pharyngocutaneous fistula, and the

German study reported 73% fistula rate (83,84). The high perioperative morbidity in the setting of marginal oncologic control points to careful patient selection when performing salvage surgery for the hypopharynx.

FUNCTIONAL OUTCOMES

The hypopharynx and cervical esophagus represent the region of tightest control of bolus passage in the upper aerodigestive tract. Therefore, patients can feel a significant impact in their ability to maintain oral intake after treatment for their cancer. In surgical series of laryngopharyngectomy patients, despite good local control, the permanent gastrostomy rate still approaches 16% (38). In a review of the reconstruction of 153 postlaryngopharyngectomy patients, a stricture rate of 15% was also observed (82).

Organ preservation protocols also have significant dysphagia during and after treatment (85). Stricture rates have been reported as high as 20% postradiotherapy, with the hypopharynx primary being the most significant predictive factor (86). The introduction of intensity-modulated radiation therapy presents a recent advancement in the treatment of head and neck carcinoma with the advantage of a more accurate delineation of target volumes to spare the pharyngeal constrictors. However, this benefit may not be relevant in hypopharyngeal and cervical esophageal carcinoma (87,88). A recent series at M.D. Anderson Cancer demonstrated a 7% gastrostomy tube rate 2 years after organ preservation treatment for hypopharyngeal primary (Bhayani, et al. 2012, unpublished data). The authors found that patients who performed therapeutic exercises under the guidance of a speech pathologist and maintained some oral intake through radiation were less likely to have long-term gastrostomy tube dependence. Therefore, the incorporation of the speech pathologist in the multidisciplinary team is critical to the functional preservation of swallowing in patients with hypopharyngeal and cervical esophageal carcinoma.

Restoration of speech following total laryngopharyngectomy is accomplished with a tracheoesophageal puncture (TEP) and voice prosthesis. Because the presence of a bulky flap and variable position of the esophagus and neopharynx may interfere with TEP success, placement of the TEP is preferred as secondary procedure (89,90). Vocal intelligibility was between 72% and 81% in these case series, which is similar to another series from Australia (91). Primary TEP in the surgical series by Yu and colleagues found speech intelligibility of 41%, owing the poor result to perioperative complications and poor patient selection; therefore, the authors recommended secondary TEP for voice rehabilitation in complex pharyngoesophageal reconstruction.

Functional rehabilitation of speech and swallowing is possible with any curative therapy. The presence of speech pathology service dedicated to head and neck rehabilitation is a necessity to ensure optimal functional results.

COMPLICATIONS

Complications encountered in surgery of the hypopharynx and cervical esophagus are similar to other major head and neck tumor resections (Tables 122.5 and 122.6). Poor wound healing and its sequelae, such as pharyngeal fistula, are the most common complications seen in the postoperative period. Patient comorbidities, such as malnutrition, prior radiation therapy, hypothyroidism, and hypovitaminosis, are critical factors in contributing to these complications. Technical details, such as suture type, tension at mucosal anastomosis, tumor at the pharyngeal margin, and reconstructive flap choice, also contribute to fistula formation.

Maintenance of a patent stoma is also a critical aspect in avoiding acute complications. Mucus plugging is a common occurrence postlaryngectomy. Diligent nursing care and frequent suctioning can avoid significant airway obstruction. This aspect also applies to patients who are tracheostomy dependent following partial laryngeal surgery.

Common delayed complications of surgery are stenosis and aspiration. Speech pathology consultation can provide therapeutic exercises to improve swallowing and reduce the risk of these issues. Regular dilation by either the head and neck surgeon or gastroenterologist, in conjunction with therapeutic exercises from the speech pathologist, can improve stenosis (92).

HIGHLIGHTS

- Patients with hypopharyngeal and cervical esophageal carcinoma are typically malnourished, causing multiple medical problems.
- Submucosal extension with satellite lesions and ill-defined margins is a hallmark of these tumors.
- Hypopharyngeal carcinoma patients have a 60% to 80% rate of lymphatic metastasis at presentation. Most common site of lymphatic metastasis is located in the jugulodigastric nodes. Paratracheal and paraesophageal nodal metastases are common in advanced-stage tumors.
- Cervical esophageal carcinoma patients have nodal spread to the paratracheal, paraesophageal, and upper mediastinal nodes.
- Retropharyngeal nodal involvement is common in tumors that extend into the retropharyngeal space. Surgical dissection of the space or radiation to these nodal levels is required as part of the treatment.
- Multidisciplinary evaluation by the head and neck surgeons, medical oncologists, radiation oncologists, plastic surgeon, radiologist, dentist, nutritionist, and speech pathologist is required prior to initiating treatment.
- Definitive radiation is an appropriate treatment for early-stage tumors of the hypopharynx. Surgery for these lesions may disrupt the pharyngeal plexus, which can create significant swallowing dysfunction.
- Advanced-stage tumors are best managed with total laryngopharyngectomy ± esophagectomy with free tissue reconstruction. Oncologic resection should not be compromised by reconstructive method.
- Organ preservation using chemotherapy and radiation therapy provides good local and regional control rates with acceptable morbidity. Surgical salvage is possible in the appropriately selected patient.
- Successful rehabilitation of speech and swallowing is feasible no matter the treatment modality in the motivated patient with a well-trained speech pathologist.

123 Early Laryngeal Cancer

Parul Sinha *Oluwafunmilola Okuyemi* *Bruce H. Haughey*

The term *"early laryngeal cancer"* refers to a mucosally derived neoplastic lesion that may invade deeply into soft tissue, but not into the underlying cartilage. The majority of literature reports include carcinoma *in situ* (CIS), T1 and T2 lesions in the spectrum of early laryngeal cancer. At the glottic level, early cancer implies a local lesion limited to single or multiple sites in the glottis or adjacent laryngeal subsites that might impair the cord mobility but does not cause cord fixation. Overall, these lesions display pathologic invasiveness and a potential to metastasize, which exceeds that of CIS but is less than deeply infiltrating carcinoma (1). By contrast, early supraglottic cancer may not be confined to the primary site because of its regional metastatic behavior. Pathologic invasion of the epiglottic cartilaginous foramina, short of entering the preepiglottic space (PES), is included.

EPIDEMIOLOGY

Laryngeal cancer is the second most common type of head and neck cancer worldwide, with an estimated incidence of 151,000 cases resulting in about 82,000 deaths annually (2). With a male-to-female ratio of 6:1, laryngeal cancer is also the 13th most common cancer in men worldwide (2). Geographic variations in the incidence and mortality of laryngeal cancer suggest that a larger proportion of the cases occur in South-Central Asia, Eastern Asia, Central Europe, and Eastern Europe (2): incidence in the United States has declined, associated with reduced smoking (3).

In the United States, laryngeal cancer accounts for about one-fourth of the annual cases of head and neck cancer with an estimated incidence of 12,720 cases (4). Overall, about 60% of laryngeal cancer cases are diagnosed as *"early laryngeal cancer"* and encompass the Tis, T1N0M0, or T2N0M0 categories (5). These commonly arise from the glottis and are mostly squamous cell carcinoma (6). Variation in site predominance, however, has been reported across ethnic groups; for example, glottic cancers appear to be the most common in Caucasians, while in African Americans, the incidence of glottic and supraglottic cancers appear to be equal (7).

RISK FACTORS

Smoking and alcohol consumption are well-established etiologic factors for laryngeal cancers. Their combined use has been associated with a multiplicative effect for the risk of developing laryngeal cancer (8,9). A recent study by Hashibe et al. (10) showed that the incidence of cancers attributable to tobacco and alcohol exposure was the highest in larynx of all head and neck cancer sites at 89%. About 5% of laryngeal cancers occur in nonsmokers and nondrinkers, suggesting that other factors such as diet, gastroesophageal reflux, previous radiation, and viral infection may also contribute (11). Human papillomavirus types 16 and 18 have been detected in frequencies ranging from 5% to 32% of analyzed samples in laryngeal cancer (11). Occupational exposures to wood dust, polycyclic hydrocarbons, and asbestos have also been associated with increased risk for developing laryngeal cancer (12).

TUMOR BIOLOGY

Genetics

Genetic alterations have been shown to underlie the development of precancerous lesions and their progression to invasive laryngeal carcinoma (13–15). Loss of heterozygosity and microsatellite instability at certain genetic loci has been identified in the progression to invasive laryngeal cancer (13).

1. Mutations in *p16*, a tumor suppressor gene located at chromosome 9p21, occur in over half of laryngeal squamous cell carcinomas and are believed to occur early in the progression to invasive squamous cell carcinoma (SCC) of the larynx (16).
2. Overexpression of *cyclin D1*, a key cell-cycle regulatory protein, results in increased cellular proliferation and tumorigenesis (17). It has also been shown to correlate with poor prognosis, recurrence, and lymph node metastasis (18).
3. Alterations in *p53*, a tumor suppressor gene that maps to the 17p13 locus, result in destabilization of genomic repair processes leading to tumorigenesis (17).

Pathology

Laryngeal cancer is thought to arise from precancerous lesions. These precancerous lesions are characterized by atypical cellular changes with malignant features (loss of cell maturation, nuclear atypia, increased mitotic activity) that occur in response to carcinogenic exposures especially tobacco smoke and alcohol. The precancerous lesions include *dysplasia* (graded from "mild" to "severe" depending on the extent of epithelial involvement) and CIS (involvement of the whole thickness of the epithelium). These preinvasive lesions are, by definition, confined to the epithelium of the larynx with an intact basement membrane. Progression to microinvasive and invasive carcinoma is characterized by infiltration of basement membrane and the underlying tissue.

Histologically, squamous cell carcinomas account for over 95% of primary laryngeal cancers and arise from the stratified squamous epithelium lining the larynx (8). Other less-commonly encountered histologic types of primary laryngeal cancer include verrucous squamous cell carcinoma (a highly differentiated variant with low incidence for metastases), adenocarcinoma, spindle cell carcinoma, fibrosarcoma, and chondrosarcoma. Neuroendocrine tumors, though rare, are the most common nonsquamous tumors encountered and have a predilection for the supraglottic larynx.

ANATOMY OF THE LARYNX

The laryngeal skeleton is composed of cartilages—thyroid, cricoid, arytenoids, epiglottis, cuneiform, and corniculate—interconnected with ligaments and membranes and moved by groups of intrinsic and extrinsic laryngeal muscles (see Fig. 124.2).

Anatomical subsites: The larynx is divided into three regions: supraglottis, glottis, and subglottis. The *supraglottis* extends from the epiglottis to the ventricular apices, encompassing the false cords, aryepiglottic folds, the arytenoids, and the laryngeal surface of the epiglottis. The *glottis* contains the true vocal cords, the anterior commissure, the interarytenoid region, and the floor of the ventricles. It extends inferiorly to 1 cm below the plane of the apex of the ventricles. The true vocal cords thicken at the anterior commissure and form the *macula flava*, anterior to which the ligaments merge into the Broyle tendon. The Broyle tendon, also known as anterior commissure tendon, gets inserted into the thyroid cartilage. The *subglottis* extends from 1 cm below the apex of ventricles to the lower border of the cricoid cartilage.

Laryngeal membranes: The *conus elasticus* or the cricovocal membrane arises from the inner surface of the cricoid arch and extends superiorly to attach anteriorly to the inner surface of the thyroid cartilage and posteriorly to the tip of the vocal process of arytenoids. Its free upper border thickens to form the vocal ligament. The *quadrangular membrane* extends between the arytenoids and epiglottis. Its upper border forms the aryepiglottic fold, while the free lower border constitutes the false cord. The *thyrohyoid membrane* is another fibroelastic membrane that attaches inferiorly to the upper border of the thyroid cartilage and superiorly to the posterior surface of hyoid bone.

Laryngeal spaces: Knowledge of laryngeal spaces is important to the understanding of the spread of laryngeal cancer and, therefore, planning of conservation surgical procedures. The *preepiglottic* space or the *space of Boyer* lies anterior to the infrahyoid epiglottis. It is bounded superiorly by the hyoepiglottic ligament, inferiorly by the attachment of epiglottis to the thyroid and anteriorly by the thyrohyoid membrane and upper part of the thyroid cartilage. It contains fibrofatty tissue and numerous lymphatic channels. Laterally, it merges with the paraglottic space. The *paraglottic space* surrounds the laryngeal ventricle and is bounded anterolaterally by the thyroid cartilage, posterolaterally by pyriform sinus mucosa, superomedially by quadrangular membrane, and inferomedially by conus elasticus. The paraglottic space provides an important route to extralaryngeal spread of cancer.

Lymphatic pathways: The supraglottis has a rich lymphatic network. The lymphatics drain primarily to the upper jugular (level II) chain of lymph nodes. It can extend to the middle (level III) and lower jugular groups (level IV), and depending on the site of tumor, cross-drainage may occur to the contralateral nodes. Lymphatic drainage from the glottis is essentially nonexistent although the cords themselves have a network of superficial mucosal lymphatics. The paratracheal (level VI) group of lymph nodes is the primary echelon of lymphatic drainage from the subglottis that may further spread to the delphian node and upper mediastinal (level VII) or the level IV nodes.

Blood supply: The arterial blood supply to the supraglottic larynx is derived from the superior laryngeal artery, a branch of the superior thyroid artery; the lower half of the larynx is supplied by the inferior laryngeal branch of the inferior thyroid artery.

Nerve supply: Sensation above the vocal fold is supplied by the internal branch of the superior laryngeal nerve, whereas the external branch provides motor supply to the cricothyroid muscles. Both sensory and motor innervations below the vocal fold are provided by the recurrent laryngeal nerve.

EARLY SUPRAGLOTTIC CANCER

Supraglottic squamous cell cancers comprise 30% to 40% of laryngeal cancers in the United States (5,19). The lesions are often silent in their early stages and may present with non–site-specific symptoms such as a sore throat or referred otalgia. Persistent dysphagia or aspiration does not usually manifest until the primary tumor attains significant bulk. Due to abundant lymphatic outflow, an enlarged metastatic neck node is another mode of presentation for early supraglottic tumors. The incidence of cervical metastasis at presentation, however, depends upon the T stage, location, and differentiation of the primary tumor and is reported to vary from zero to approximately 33% in T1–T2 tumors (20).

Surgical Pathology

Whole-organ laryngeal section studies (21,22) and numerous clinical observations (23–25) have postulated the supraglottic larynx as a distinct anatomic laryngeal subunit, above the true vocal cords. This compartmentalization is partly attributed to separate embryologic derivations, with the supraglottic structures emanating from branchial arches III and IV (buccopharyngeal anlage) and the glottic–subglottic structures from branchial arch VI (tracheopulmonary anlage). However, no specific anatomical structure has been identified that might act as a barrier between the supraglottic and glottic regions (23).

Early tumors spread within the confines of the supraglottic unit. This concept combined with an understanding of the key avenues of extension, makes supraglottic laryngectomy (SGL), endoscopic or open, a highly effective option for treatment of early-stage cancers. Infrequently, invasion of the glottis can occur when the tumor of the epiglottic petiole extends inferiorly or when extension from the undersurface of the false cord reaches the ventricle.

A certain subset of tumors arises in the (infrahyoid) angle between the epiglottis and the anterior false cord. Dubbed "engelkarzinom" by our German colleagues, this presentation may have considerable deep extension toward or into the PES.

The epiglottic perichondrium and the thyroepiglottic ligament limit anterior extension, but the tumor spreads into the fatty areolar tissue of the PES via infiltration through the epiglottic cartilage fenestrations. Involvement of PES implies a T3 stage, but insidious extension in this direction can occur in early supraglottic lesions, particularly if the tumor originates in the infrahyoid epiglottis. In the PES, there is a transition of the tumor edge from "infiltrating" to broad, "pushing" type with a pseudocapsule, probably arising from the expanded epiglottic perichondrium (21). A tumor-free space usually exists between the hyoid bone and the advancing front of the tumor, a feature that makes preservation of the hyoid in SGL oncologically safe and functionally superior. In late tumors, extralaryngeal spread occurs when extension is observed anteriorly from the PES, breaching the thyrohyoid membrane, sometimes reaching the strap muscles. Another late route of extralaryngeal spread is through the hyoepiglottic ligament to the vallecula and tongue base superiorly. Deep lateral extension of the supraglottic tumor to the thyroid cartilage is rare; ossified cartilage has higher susceptibility to invasion. Lesions of the aryepiglottic fold may spread laterally to involve the medial wall of pyriform sinus.

Staging and Treatment Planning

A complete workup to assess the patient, the subsite and stage of primary tumor, and the presence of cervical lymphadenopathy is indicated (Table 123.1). This includes a thorough history and physical examination, including neck palpation and fiberoptic laryngoscopy. This affords direct visualization of the tumor extent, arytenoid involvement, and cord mobility. Cord hypomobility implies paraglottic space invasion, and cord fixation upstages the primary tumor to T3.

Assessment of comorbidity, particularly, pulmonary diseases, is a crucial component of preoperative planning for conservation surgery. Patients with poor pulmonary reserve, as determined by forced expiratory volume in one second (FEV1) of greater than 75% or FEV1/FVC (functional vital capacity) ratio of less than 65%, are at greater risk of troublesome aspiration.

For T2 lesions, radiologic evaluation with computed tomography (CT) or magnetic resonance imaging (MRI) is performed to determine the extent of the primary and to rule out involvement of the PES, the paraglottic space, or the inner thyroid cortex, factors that escalate the T stage. CT, MRI, and especially gray-scale ultrasonography can reliably assess cervical lymphadenopathy, supplemented by ultrasound-guided fine-needle aspiration (FNA), if indicated. The latter is particularly useful in decision making for or against treating the contralateral neck (see "Management of the Neck"). Chest radiography, CT, or positron emission tomography (PET) is used to evaluate distant metastasis or second primary tumors in smokers.

Operative direct laryngoscopy should be performed along with photodocumentation to accurately assess the primary tumor and obtain biopsies for diagnosis and/or mapping in postradiation, recurrent cases. It also provides the opportunity to determine the suitability for a conservation procedure and decide the ideal approach—transoral or open. Occasionally, exophytic bulk conceals the accurate determination of the inferior tumor extent, whereupon rigid telescopes may be helpful. To detect synchronous primaries, a complete examination of the upper aerodigestive tract (UADT) mucosa is performed.

Treatment

Single-modality therapy with primary surgery or definitive radiotherapy (RT) are the two alternative treatment approaches for early supraglottic tumors. RT alone,

TABLE 123.1 DIAGNOSTIC APPROACH TO EARLY SUPRAGLOTTIC AND GLOTTIC CANCERS

Supraglottis	Glottis
• History and physical examination, office-based fiberoptic laryngoscopy • Imaging: Office neck ultrasonography, CT/MRI for assessment of primary tumor and neck, chest CT or PET • Pulmonary function test • Direct laryngoscopy under anesthesia for biopsy and assessment of – Site, size, and extent of primary tumor – Tumor extension to vallecula, tongue base, pharyngeal wall, medial wall of piriform sinus, arytenoid/ventricle – Cord mobility – Palpation of neck nodes – Adequacy of transoral exposure – UADT examination for second primaries	• History and physical examination, office-based fiberoptic laryngoscopy and videostroboscopy • Imaging: Limited role, evaluation of invasion in bulky lesions • Pulmonary function test • Direct laryngoscopy under anesthesia for biopsy and assessment of – Site, size, surface, and extent of primary tumor – Tumor extension to subglottis, arytenoid, supraglottis, anterior commissure, petiole of epiglottis – Cord mobility – Adequacy of transoral exposure, especially anterior commissure – UADT examination for second primaries

UADT, upper aerodigestive tract.

however, is less effective for local control (26), and high laryngectomy rates (14% to 31%) for recurrent tumors (27,28) have made this option less acceptable than primary surgery. T1 and T2 primaries are amenable to curative treatment by conservation surgery with an optimum oncologic control and minimal functional morbidity. Total laryngectomy was the only procedure commonly used for treatment of supraglottic cancer until 1946 when Alonso (29) first described the procedure of SGL. The SGL technique was later refined by Joseph Ogura in 1958 (30) and Max Som in 1959 (24). The modern paradigm of conservation surgery for supraglottic tumors, however, is minimally invasive, endoscopic transoral laser microsurgery (TLM), first introduced by Vaughan et al. in 1978 (31) and further popularized by Davis et al. (32) and Steiner (33–36). Numerous publications within the last two decades on TLM for supraglottic tumors demonstrate evidence of both comparable (or superior) survival rates and functional preservation rates compared to open surgical procedures. This makes TLM a widely preferred surgical tool in the armamentarium of organ preservation treatment for supraglottic cancer (37,38). Limited reports of technical feasibility also now exist for use of the da Vinci robotic surgical system (39).

SURGERY

Endoscopic Procedures

Transoral Laser Microsurgery

The concept of endoscopic management of supraglottic cancer dates back to 1939 when Jackson and Jackson (40) first described the use of the laryngoscope for resection of cancer of the suprahyoid epiglottis (Figs. 123.1A, 123.2, and 123.3). Coupling of the carbon dioxide (CO_2) laser to the operating microscope in 1969 by Strong and Jako (41) heralded the advent of TLM. The basic technique of *transtumoral* cuts to assess the depth of disease and *multibloc* transoral laser resection is distinct from the time-honored principle of *en bloc* tumor resection, espoused in open techniques, where exposure of large surface areas of dissected tissue occurs. The transoral approach, however, makes it possible to resect the primary tumor with optimally cleared histologic margins and, at the same time, preserve the anatomical and functional integrity of the noninvolved, surrounding tissue. The resection can be tailored according to tumor location and extension. A classification of different types of endoscopic SGL has been described by the European Laryngological Society (ELS) (Table 123.2) (42). The fundamental requirements for TLM include careful training in technique, knowledge of site-specific "inside out" anatomy, good endoscopic access, and strict enforcement of laser-specific precautions in the operating room.

Contraindications: The major contraindication to TLM for early supraglottic cancers is inadequate transoral access to the entire tumor. We have proposed 8 'T's (45) as limitations of endoscopic access: teeth (prominent), trismus, transverse dimensions (narrow mandibular arch), tori (mandibular), tongue (bulk), tilt (atlanto-occipital extension), treatment (prior radio- or chemoradiotherapy), and tumor (site and size). Once adequate exposure is obtained, there are few technical constraints in terms of curative resection with TLM, even in the presence of intraoperative upgrade of T2 tumors to T3, secondary to spread into the preepiglottic or paraglottic space, glottis, arytenoid, or thyroid cartilage. A further contraindication is disease that requires bilateral arytenoid resection, which causes a high

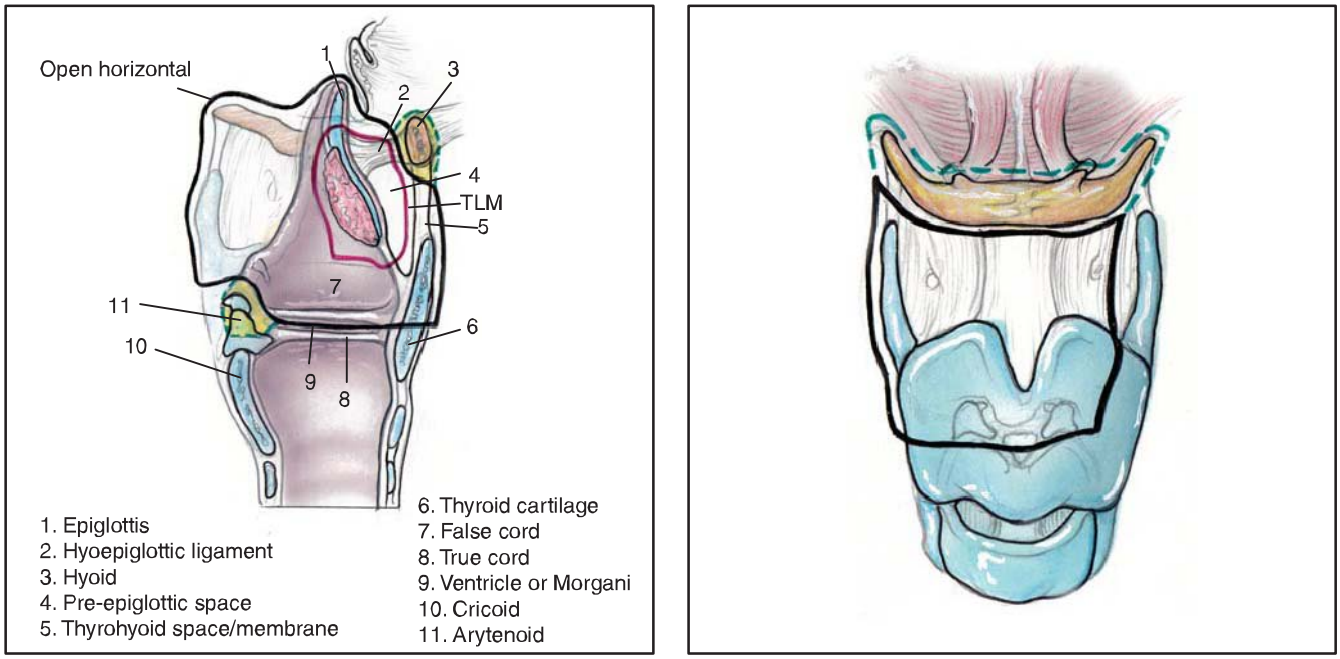

Figure 123.1 Supraglottic Laryngectomy. **A:** Incisions for TLM *(red)* and open horizontal *(black)* procedures, *sagittal view.* **B:** External incisions for open horizontal procedure. Note less resection of normal structures in TLM. Extensions (*dotted line*) in either technique may include hyoid and/or arytenoid.

potential for defunctionalization of safe swallowing, especially in context of poor pulmonary reserve, other major comorbidities, or compromised performance status.

Surgical technique: After induction of anesthesia and intubation with a 5-mm inner diameter (preferable) laser endotracheal tube, the usual safety precautions are observed for protection of eyes and face of the patient.

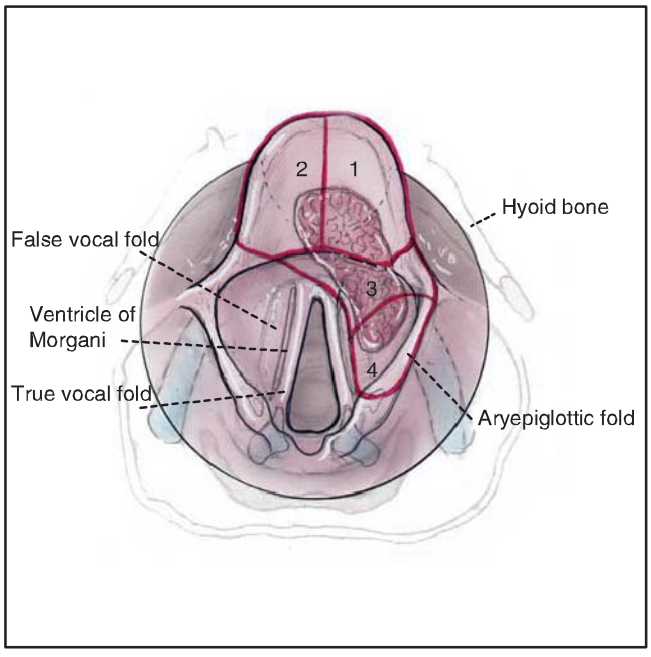

Figure 123.2 Incisions for multibloc TLM resection of supraglottic tumor. Blocs *1–4* are removed in numerical order.

An Aquaplast mouth guard is fashioned to protect the patient's teeth and upper gingiva. Optimum visualization of the operative site is obtained with introduction of laryngoscopes, standard tubed or bivalved, for example, Steiner, Weerda, Kleinsasser. The laryngoscopes may need to be changed or repositioned during the procedure for a satisfactory exposure. Transoral resection is performed with a CO_2 laser beam delivered either via micromanipulator or a handheld device, although rapid debulking may initially be performed with electrocautery. For margin management, the high-precision and relatively bloodless cutting characteristics of laser, under high magnification, facilitate clear intraoperative distinction between tumor and normal tissue. Surgical techniques specific to tumor size and subsite are described below.

Suprahyoid epiglottis: Small and well-circumscribed primaries may be resected *en bloc* for efficiency of margin evaluation. For larger lesions, the epiglottis is divided sagittally from superior to inferior, followed by lateral cuts across the vallecula, lateral pharyngoepiglottic fold, and the epiglottis, bilaterally if necessary, to complete resection of the tumor. Wide resection margins can be obtained at this site without swallowing morbidity.

Infrahyoid epiglottis: Early primaries of the infrahyoid epiglottis need to be addressed with caution because of close proximity to the PES. However, some tumors may be "keyholed" out of the epiglottis by excising a disc of mucosa and epiglottic cartilage containing the disease, with perichondrium, using the preepiglottic fat as the deep margin. When the disease is more extensive across the laryngeal surface of the epiglottis, the suprahyoid epiglottis may

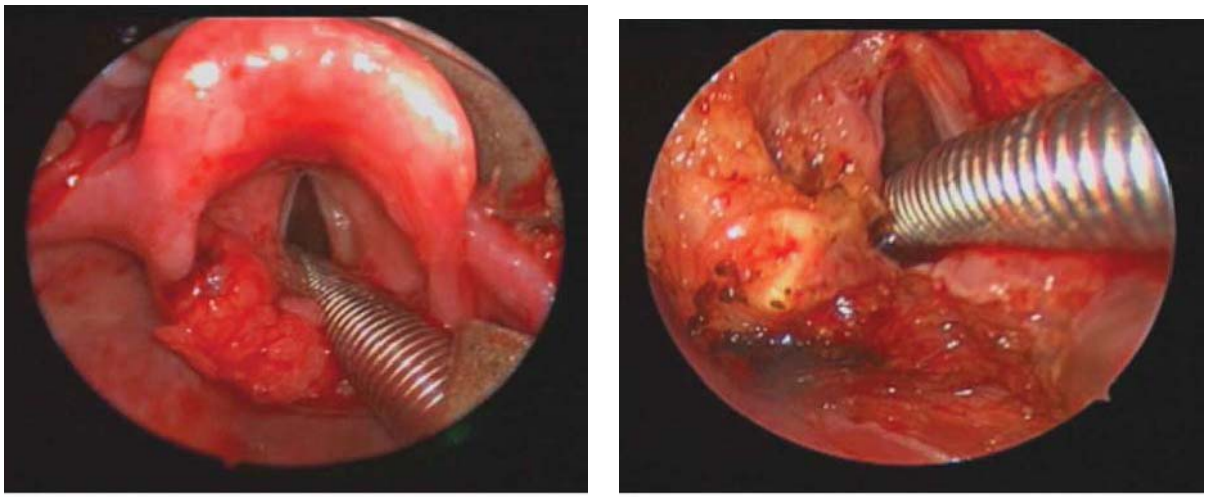

Figure 123.3 Endoscopic image of T2 supraglottic tumor, (A) pre- and (B) post-TLM resection.

be split sagittally (Fig. 123.2) and an ipsilateral hemiepiglottectomy performed. A second, medial to lateral cut is made in the nadir of vallecula to incise around the epiglottis with adequate margins of at least 5 mm. As this incision progresses to transect the lateral pharyngoepiglottic fold, identification of the superior laryngeal artery and/or its branches may be necessary. When identified, they should be clipped before division, failing which they may retract into the lateral soft tissues. Incisions are further made laterally, until the hyoid is reached, to detach the specimen and also partially excise the fatty areolar tissue in the PES. This is facilitated by application of neck pressure applied externally on the larynx to bring the hyoid into laryngoscopic view.

Should there be PES involvement, this tissue is completely excised by advancing the dissection caudal to the hyoid and peeling tissue off the inner thyrohyoid membrane until the superior border of the thyroid cartilage is identified. The dissection is continued further anteroinferiorly, along the thyroid inner perichondrium, past the midline thyroid notch to reach the level of the petiole immediately above the anterior commissure.

To facilitate removal of inferior tumor or remaining epiglottis, a mucosal incision is made across the aryepiglottic

TABLE 123.2 ELS CLASSIFICATION OF ENDOSCOPIC SURGERIES FOR EARLY SUPRAGLOTTIS AND GLOTTIS CANCER

Endoscopic SGL (42)	Endoscopic Cordectomy (43,44)
Type I, limited excision of small size, superficial lesions in any part of the supraglottis	Type I, subepithelial cordectomy
Type II, medial SGL without resection of the PES Type IIa, superior hemiepiglottectomy Type IIb, total epiglottectomy	Type II, subligamental cordectomy
Type III, medial SGL with resection of the PES Type IIIa, without extension to the ventricular fold Type IIIb, with extension to the ventricular fold	Type III, transmuscular cordectomy
Type IV, lateral SGL Type IVa, includes ventricular fold Type IVb, includes arytenoid	Type IV, total cordectomy
	Type V, extended cordectomy Type Va, encompassing the contralateral vocal fold and the anterior commissure Type Vb, encompassing the arytenoid Type Vc, encompassing the ventricle Type Vd, encompassing subglottis (1 cm)
	Type VI cordectomy for cancers of the anterior commissure Extension to one or both of the vocal folds, without infiltration of the thyroid cartilage

fold and extended inferiorly to cross the false cord, then proceeding anteriorly in the ventricle toward the midline, allowing removal of the remaining epiglottis. These incisions are made uni- or bilaterally according to tumor distribution.

False cord: Tumors at these sites can be completely resected using similar TLM techniques. The depth of excision is determined by a transverse cut through the tumor's epicenter, and the surface extent of tumor determines the design of the mucosal incisions; inferiorly, the dissection is usually carried to the level of the ventricle or the superior vocal cord. A safe lateral oncologic margin of 5 mm can be obtained for lesions confined to the false cord without any significant functional impairment. However, the inferior deep margin may be closer (1 to 2 mm) and histologic negativity is confirmed with frozen section.

Aryepiglottic fold: Small and superficial lesions can be excised *en bloc*. The resection is tailored depending on the tumor extent and any extension to arytenoids or medial hypopharyngeal wall is carefully assessed and addressed. The general principle is to split transversely through the tumor and the fold until sufficient deep tissue margin (2 to 5 mm) is established, followed by appropriately oriented perimeter cuts for mucosal clearance. When necessary, the arytenoid may be shaved away serially from anterior to posterior, leaving the posterior body undisturbed.

Hemostasis: Meticulous hemostasis should be ensured during and at completion of all TLM procedures for supraglottic tumors. Bipolar cautery using the 22-cm Stryker Silverglide bipolar forceps design, directly down the endoscope, is especially useful for mucosal bleeding, common along epiglottic and base of the tongue incisions. Because of proximity to or exposure of the superior laryngeal artery or its branches, hemostasis is critical when the procedure involves transection of lateral pharyngoepiglottic fold or dissection of lateral supraglottic mucosa. This vessel should be doubly or triply clipped at identification during TLM. It is also prudent to clip the superior laryngeal and/or superior thyroid artery during any neck dissection, to further obviate the risk of delayed primary or secondary hemorrhage. Before extubation, the laryngoscope is desuspended to allow for reduction of any temporary hemostatic tamponade, and Valsalva maneuvers are used to stimulate dormant bleeders. A tracheostomy, of course, provides optimal protection against major, unexpected late hemorrhage into the airway.

Frozen section analysis: Meticulous orientation of the specimen by marker (e.g., suture or clip) is recommended before removal from the patient, following which the surgical margin is inked carefully for pathologic analysis. It is incumbent on the surgeon to inform the pathologist that part of the specimen intentionally contains a nonmargin area of tumor cut through. Mono- or multibloc resection is performed until histologically negative margins are secured on frozen section. A minor discrepancy of about 2% (46) has been reported to occur between frozen section and permanent section results, but this can be adequately addressed with margin re-resection using repeat TLM. Heat or crush artifact may sometimes make adequate pathologic determination of the resection margin difficult and the surgeon's discretion becomes important in such situations to judge the adequacy of the actual extent of margin resection.

Postoperative care: A 3-week course of broad-spectrum antibiotics and antireflux measures is instituted in the postoperative period. Resection for early supraglottic cancer seldom requires prolonged intubation or tracheostomy. Nasogastric feeding is usually avoided for small resections but may be prudent in the initial postoperative period. Rehabilitation measures to improve swallowing with postural modifications and a supraglottic diet are commenced at an early stage. Functional recovery is usually rapid, with return to normal swallowing function within a relatively short period, facilitated by good pain control.

Complications: TLM procedures pose a risk of airway laser fire and methods of prevention include reduction of the inspiratory oxygen concentration to less than 30% (47), use of a laser endotracheal tube, or placement of laser-proof covering over nonlaser tubes. There is a risk of secondary hemorrhage following TLM during postoperative day 0 to day 21. This can be obviated by taking adequate precautions during the procedure as discussed above (48). Postresection edema of the remaining supraglottic mucosa, especially on the arytenoids, may compromise the airway in the postoperative period. This often resolves with administration of steroids in limited resection. Tracheostomy is seldom required. Airway obstruction may be more persistent after TLM for radiation-recurrent tumors, sometimes necessitating a tracheostomy or transoral laser resection of edematous supraglottic mucosa. Severe aspiration can result in pulmonary complications but is infrequently seen for early supraglottic tumor resection. Resection of the arytenoid, aryepiglottic fold, or tongue base will increase the risk of aspiration. Extensive defects may result in supraglottic stenosis. Complications due to laryngoscope pressure such as dental and mandibular trauma, pharyngeal tears, tongue swelling, laceration, and numbness or loss of taste may also occur.

Transoral Robotic Surgery

Transoral surgery using the da Vinci robotic surgical system was recently reported to be suitable for performing SGL in humans (38). The three-armed robotic system is said to confer improved, three-dimensional optics and tissue manipulating/cutting maneuverability. However, some optical resolution is lost over a high-quality operating microscope. The "endowrist" design allows for flexibility in movement at the *end* of the robotic instruments. However, the arms carrying such flexible working tips are straight, are rigid, and cannot be maneuvered down a laryngoscope, necessitating spatulate retraction of the tongue. In reality, laryngoscopic exposure may be required to obtain

optimum exposure and the rigid robotic arms cannot be used inside laryngoscopes, needing approximately 30 degrees of axial offset angle to work through the mouth and pharynx. Furthermore, with a 12-mm diameter endoscope for viewing plus two 8-mm (or 5-mm) surgical arms and a suction device, there is significant instrument crowding that currently limits this instrument's application in supraglottic tumors.

As a fledgling transoral approach, the setup time, expense, and compatibility issues of transoral robotic surgery (TORS) with the routine operating requirements, such as neck dissection, confine its niche to select treatment centers. Currently, the robot appears to offer no advantage over endoscopic laser resection although its application in supraglottic tumors may increase with future refinements.

Open Conservation Procedures

Horizontal Supraglottic Laryngectomy (see Fig. 123.1A,B)

"Open" SGL entails resection of the epiglottis, false cord, aryepiglottic folds, hyoid, and upper half of the thyroid cartilage. It includes complete resection of PES. This procedure spares the true cords, at least one arytenoid, and the tongue base, structures that are vital to phonation, respiration, and deglutition, and also avoids the need of a permanent tracheostomy. In early-stage tumors, the basic SGL can be modified to preserve the hyoid bone. "Extended" SGL may be performed for lesions extending to vallecula, tongue base, ipsilateral arytenoid, and medial wall of pyriform sinus. A tracheostomy is always required at the time of resection.

Contraindications: Paraglottic space involvement, cord fixation, thyroid cartilage invasion, bilateral arytenoid or interarytenoid space involvement, tumor extension to the pyriform sinus apex, and extensive tongue base involvement are contraindications for open SGL. The procedure is also contraindicated in patients with poor motivation and respiratory insufficiency.

Surgical technique: A preoperative laryngoscopy is performed to reassess the extent of primary tumor and a preliminary tracheostomy is secured. An apron incision is made and subplatysmal flaps are raised. The hyoid bone is skeletonized and infrahyoid muscles are detached from the body and greater cornua of the hyoid, in preparation for the superior pharyngotomy. The greater cornu should be skeletonized with care because of proximity to the hypoglossal nerve.

The superior thyroid neurovascular pedicle is divided and ligated on the side of the tumor and the constrictors are separated from the posterior edge of the ipsilateral thyroid ala. An incision is made through the perichondrium along the superior border of the thyroid cartilage and a perichondrial flap is reflected inferiorly below the level of the true cord, thus exposing the upper two-thirds of the thyroid cartilage. The thyroid cartilage is transected horizontally just above the midpoint between the thyroid notch and lower border including the superior cornu on the tumor side. The incision is extended horizontally across to the other side or obliquely to preserve the contralateral superior cornua of the thyroid cartilage.

The pharynx is entered superiorly infrahyoid, through the vallecula if the tumor is confined to the supraglottic larynx. For tumors with extension to the vallecula, a suprahyoid or lateral pharyngotomy approach through the contralateral pyriform sinus is utilized. The epiglottis is delivered outward through the pharyngotomy and retracted to visualize the laryngeal introitus. Connecting mucosal incisions are made through the aryepiglottic folds on both sides, anterior to the arytenoids. The cuts are extended through the posterior part of the false cords into the ventricle and connected to the thyroid cartilage incisions to complete resection. An inferior margin of about 2 to 3 mm normal mucosa has been found to be adequate to prevent recurrence at the glottic level (49). Resection of all supraglottic mucosa including uninvolved false cord is recommended to prevent postoperative edema. The role of cricopharyngeal myotomy in SGL for better swallowing outcomes lacks consensus.

After securing complete hemostasis, the defect is reconstructed by suturing the thyroid perichondrial flap to the deep musculature of the tongue base with 3-0 Vicryl. A second reinforcing layer is created by suturing the suprahyoid muscles to the cut edges of infrahyoid musculature. The neck incision is closed after placement of a closed suction drain. The tracheostomy tube is reinserted through a separate incision in the lower skin flap and care is taken to isolate the stoma from the major resection wound in order to prevent contamination of the neck.

Postoperative care: Routine care of wound, tracheostomy, and neck drain is instituted. Feeding is initiated through a nasogastric tube. As the postoperative edema resolves, the tracheostomy cuff is deflated, and depending upon the patient's tolerance and absence of signs of aspiration, a decannulation trial is commenced. Intensive swallow rehabilitation is initiated under supervision, with a "supraglottic" diet initially followed by a normal diet as judged by the patient's ability to swallow without difficulty or aspiration.

Complications: Severe aspiration after SGL can lead to recurrent aspiration pneumonia. Intractable life-threatening aspiration, particularly in patients undergoing extended SGL for tongue base or arytenoid involvement, may require a functional total laryngectomy. Hemorrhage, infection, accidental decannulation, and subcutaneous emphysema are other possible complications.

Supracricoid Laryngectomy

Supracricoid laryngectomy (SCL) was first introduced by Majer and Reider in 1959 as a conservation procedure for laryngeal cancer with later refinements in the procedure proposed by Labayle, Bismuth and Piquet (50). It entails *en bloc* resection of the PES, paraglottic space, and thyroid

cartilage, yielding outcomes comparable to total laryngectomy in selected cases but preserving functions of phonation and deglutition without a permanent tracheostoma. The indications of SCL in T2 supraglottic cancers are lesions that are not ideal candidates for SGL by the virtue of their extension to the ventricle, the anterior commissure, or the glottis with or without impaired cord mobility.

Contraindications: Invasion of the cricoid cartilage, bilateral arytenoid involvement, extension into the base of the tongue, vallecula or hypopharynx, and fixation of arytenoids are contraindications for SCL.

Surgical technique: A direct laryngoscopy is recommended at the onset for reevaluation of the tumor and its suitability for resection with SCL. After adequately skeletonizing the larynx, the inferior constrictors are incised along the lateral border of the thyroid cartilage followed by release of the pyriform sinuses from the inner thyroid cartilage. The external thyroid perichondrium is preserved bilaterally. During division of the superior laryngeal vascular pedicle, care is taken to preserve the internal branch of the superior laryngeal nerve. The cricoarytenoid joints are disarticulated with care bilaterally to preserve both recurrent laryngeal nerves, which lie just medial and posterior to this joint. A cricothyrotomy is performed just immediately above the cricoid following which ventilation continues through this new opening.

The pharyngotomy is performed by entering the vallecula on the uninvolved side, grasping and retracting the epiglottis through the vallecular incision. Sharp dissection is continued alongside the epiglottis to the aryepiglottic fold and in front of the arytenoid bilaterally, down to the cricoid cartilage and the cricothyrotomy incision, thus releasing the specimen. On the side of the tumor, incisions are made ensuring safe resection margins. If one of the arytenoids needs to be included in the surgical specimen, the incision down the aryepiglottic fold is made posterior to, instead of anterior to, arytenoid on the ipsilateral side.

Before closure, hemostasis is secured and the mucosa is approximated over the arytenoid in a manner that does not limit its movement. To prevent posterior prolapse of arytenoid, a single 3-0 Vicryl suspension suture is passed through the arytenoid, anchoring it forward to the cricoid cartilage. Neck extension is removed to perform laryngoplasty by approximating the cricoid and hyoid using interrupted, nonabsorbable 1-0 Vicryl sutures passed submucosally, one in the midline and one 1 cm on either side of the midline. Tightening of these cricohyoidopexy (CHP) sutures brings the arytenoids(s) closer to the tongue base. This facilitates vibration of the mucosa over arytenoids(s) against the tongue base, a mechanism that is responsible for phonation in these patients.

Once the trachea has been stretched up by the CHP, tracheostomy is performed at an appropriate site that allows the tube to exit skin through the neck incisions. The inferior and superior margins of strap muscle flaps are approximated to reinforce the CHP area. Neck incisions are closed after placement of suction drains.

Postoperative care: Routine care of wound, tracheostomy, and neck drain is instituted in the postoperative period. The patient is nursed in a position that ensures that the head is flexed toward the chest. Feeding is initiated through a nasogastric tube or a gastrostomy in the immediate postoperative period followed by swallow rehabilitation exercises. A decannulation trial is commenced after 6 weeks provided there are no symptoms of aspiration and good airway is maintained. Voice therapy is initiated after completion of wound healing.

Complications: Aspiration occurs commonly after SCL resulting in morbid pulmonary complications such as atelectasis and pneumonia (51). Older patients (greater than 60 years), chronic airway disease, smoking status, extent of arytenoid resection, and CHP are some of the factors associated with a greater risk of postoperative pulmonary complications. More frequent rates of aspiration have been observed in CHP versus cricohyoidoepiglottopexy (CHEP), possibly because of the absence of epiglottis and inadequate neoglottic closure in the former. Precautions recommended for prevention of aspiration are preservation of the superior laryngeal nerves, anterosuperior suturing and positioning of the cricoarytenoid unit, early decannulation, and early onset of swallowing rehabilitation (52). Hemorrhage, infection, wound dehiscence, accidental decannulation, subcutaneous emphysema, and pharyngocutaneous fistula are other possible complications.

Management of the Neck

Clinically or radiologically positive neck disease requires the patient to undergo neck dissection. Ipsilateral N^+ necks require ipsilateral dissection, and bilateral or contralateral N^+ necks require bilateral neck dissection. Neck dissection is performed at the same operative session as primary tumor resection, although a staged contralateral neck dissection may be carried out later if the ipsilateral neck was pathologically positive. Selective, lateral dissection of levels II, III, and IV is an effective and adequate procedure for management of the neck in early supraglottic cancer. For T1–T2 cancer of the infrahyoid epiglottis or lesions crossing midline, our preferred approach is to carefully assess the neck for ipsilateral and contralateral cervical metastasis by office ultrasound ± ultrasound-guided FNA.

Presence of multinodal or multilevel neck disease with extracapsular spread is an indication for postoperative RT or chemoradiotherapy. However, such adjuvant treatments should be used with caution since the potential is high for airway compromise due to stenosis or arytenoid edema.

The standard of care in early supraglottic tumors with an N0 neck is controversial. An occult metastatic rate ranging from 4% to 35% (20), combined with a high risk of contralateral metastasis, is cited as a rationale for performing a routine bilateral neck dissection. However, early cancer

confined to the suprahyoid epiglottis and well-lateralized primaries not crossing the midline are exceptions. Moreover, less than 10% of the early T1–T2 lesions are reported at risk of contralateral spread, which is infrequent in the absence of ipsilateral neck disease (53,54). Evidence from some studies indicates that bilateral dissection of the clinically N0 neck in T1 to T2 supraglottic cancer may not always be necessary (54,55) and its routine practice leads to overtreatment in 70% to 80% of cases with unnecessary increase in treatment-related morbidity (20,56).

Although surgery is preferred in neck management, RT alone to one or both necks can be used to control N0 or N1 necks. However, unwanted radiation to the larynx will occur, even with intensity-modulated radiation therapy, adding to the risk of prolonged airway edema and obstruction from arytenoid swelling.

OUTCOMES

Surgical therapy alone achieves oncologic outcomes equivalent to combined therapy in early supraglottic cancer. Postoperative RT is known to adversely affect the functional results of conservation surgery by increasing edema (especially arytenoid mucosa), which in turn compromises airway patency and voice, and may cause strictures. The decision for administering adjuvant RT should be judicious and based on high-risk neck indications. Lymph node metastasis is the most important prognostic factor in supraglottic cancer. In one of the most recent reviews of laryngeal cancer cases recorded in National Cancer Data Base (1985 to 2002), a decline in survival was observed among the early-stage supraglottic cancers, T1N0M0 and T2N0M0 (5). At this stage, no definitive links can be identified between outcomes and patterns of surgical treatment.

Oncologic: Excellent oncologic outcomes have been reported for TLM in early supraglottic cancer. A 5-year recurrence-free survival of 83% for early tumors, a 5-year local control rate of 100% for T1 and 89% to 97% for T2 tumors, and a 5-year laryngeal preservation rate of 86% to 100% are observed from the various studies reporting outcomes for laser resection (37,57). Few comparative studies found a higher 5-year disease-free survival (80% vs. 72%), 5-year laryngeal preservation rate (86% vs. 80%), and a 5-year disease-specific survival (89% vs. 80%) in the endoscopic laser group compared to open SGL group (57,58).

Functional: The functional results of transoral laser resection for early supraglottic cancers are superior to open conservation procedures by virtue of shorter hospital stays, lower tracheostomy rate, and better swallowing outcomes. The resection of critical barriers to aspiration in open surgery for SGL cancers combined with a sensory deficit from superior laryngeal nerve section results in interference with food bolus recognition and also weakening of the "glottic closure" reflex (59). Aspiration-related secondary laryngectomy rates for open conservative surgery have been reported to range between 3.5% and 12.5% (59). Preservation of normal structures including the cartilaginous framework and avoidance of damage to superior laryngeal nerve make rapid restoration of swallowing function feasible in endoscopic laser surgery. In spite of pulmonary status being a better predictor of aspiration pneumonia than a particular surgical approach, a lower incidence of aspiration pneumonia has been observed in patients undergoing TLM (11.5%) compared to open surgery (40%) for supraglottic cancer (60,61). Avoidance of wound dehiscence and pharyngocutaneous fistula are other advantages of endoscopic versus open resection for supraglottic cancers.

RADIOTHERAPY

Definitive RT is another treatment modality reported to be effective for management of early supraglottic cancers. The local control rates observed from review of large RT series (61,62) range from 75% to 100% for T1 tumors and 71% to 83% for T2 tumors, with a laryngeal preservation rate of about 80% (62). The success of RT is often correlated with the tumor volume; better results are reported for superficial and small-volume tumors (62). In the era of endoscopic approaches to early supraglottic tumors, RT is indicated for treatment of patients who are not physiologically suitable for conservation surgery because of cardiac or pulmonary insufficiency.

Recurrences after primary RT for early supraglottic cancer have been reported to be as high as 29% (63). Surgical salvage with conservation procedures or total laryngectomy is associated with a greater risk of complications, especially pharyngocutaneous fistula, tissue necrosis, wound breakdown, and carotid artery rupture. The rate of complications has been related to the dose of radiation therapy (64).

EARLY GLOTTIC CANCER

Glottic cancer accounts for about 50% to 60% of all laryngeal cancer cases. A change in voice with varying severity of hoarseness is almost universally associated with glottic tumors resulting in diagnosis at an early stage (5). These lesions do not cause airway obstruction or swallowing difficulty unless they progress to higher T stages. Lymphatic spread of early glottic cancer is extremely rare.

Surgical Pathology

Glottic cancer mostly arises on the mucosa of anterior true cords, a region with paucity of lymphatics. Tumor extension occurs along the cord in the submucosal space. The chief barriers to spread of glottic cancer are the vocal ligament, conus elasticus, and the thyroid perichondrium and cartilage. Spread may occur across the anterior commissure

to the opposite cord. The Broyle ligament offers a tough barrier to superior and anterior spread of the tumor. However, the site of insertion of the Broyle ligament at the anterior commissure is devoid of inner thyroid perichondrium, and once involved, it serves as a portal of entry of the tumor into the thyroid cartilage from where it can spread to involve the ossified portions of the cartilage or further to the extralaryngeal structures. Posteriorly, the lesions can spread to involve the thyroarytenoid muscle. This may result in impaired mobility, which should be carefully assessed during preoperative planning to differentiate from cord fixation. Further posterior spread may occur to involve the arytenoid cartilage or the posterior commissure.

Inferior extension can occur to the subglottis; spread of more than 1 cm below the free edge of the true cord can invade the cricoid cartilage. With superior extension, the tumor can spread along the floor of the ventricle and invade the glottic musculature. Extension to the false cords, filling the ventricle, makes the lesion transglottic. This is one of the mechanisms for involvement of paraglottic space from where the tumor can breach the cricothyroid membrane and involve the cricoid cartilage or extralaryngeal soft tissues and thyroid gland. Paraglottic space can also be involved following spread across the conus elasticus or lateral spread of the tumor along the superior surface of the true cord.

Staging and Pretreatment Planning

A detailed history of presenting symptoms, smoking, and reflux along with office flexible laryngoscopic evaluation of the upper aerodigestive tract mucosa is the initial step in management of patients presenting with hoarseness (Table 123.1). The site, size, appearance, and extent of the lesion are noted along with the cord mobility. Evaluation of fine cord mobility, amplitude of vibration, and mucosal wave by videostroboscopy facilitates assessment of the superficial extent as well as the infiltrative depth of early lesions (65). Imaging has a limited role in pretreatment planning of early glottic cancers and is usually not recommended except in bulky T2 lesions, for a better assessment of supraglottic or subglottic extensions and involvement of the thyroid cartilage.

A direct laryngoscopy and biopsy under anesthesia with additional telescope examination allows for accurate assessment and photodocumentation of the site, size, surface, and extent of the primary tumor. The procedure also facilitates evaluation of cord mobility, detection of second primaries, and adequacy of transoral exposure.

Treatment

The fundamental goals of treatment for early glottic cancer are disease cure, voice preservation, airway protection, and maintenance of function-preserving options for management of recurrences. Primary transoral laser microsurgical cordectomy (Table 123.2), open surgery (cordectomy, hemilaryngectomy), or RT are the three effective treatment modalities. All these have been reported to have excellent patient survival outcomes; thus, the decision for treatment of choice in a particular individual is guided by other variables. These include patient preference, age, and expectations for quality of voice; tumor stage, site, for example, extension to anterior commissure; the physician's expertise and skills; and treatment-related factors such as morbidity, cost-effectiveness, and availability of function-preserving salvage options.

Carcinoma In situ

CIS can exist alone, involving limited or extensive areas of true cords, or it can coexist with foci of invasive squamous cancer. Management plans described in literature include "watchful waiting" (66), cord stripping, excisional biopsy, transoral laser excision, or RT. A watch-and-wait approach, however, is not practical since 66% of the patients in a study reporting this policy progressed to squamous cell carcinoma (66). Modest local control rates from 56% to 72% and worsening of voice have been reported for vocal cord stripping as a surgical intervention for CIS (67–69). Cord stripping and excisional biopsy with cold instruments such as small cup forceps may not include truly representative samples for pathologists to rule out basement membrane involvement (70,71). In comparison, excisional biopsy with TLM not only improves the diagnostic yield for CIS by better estimation of the depth but also offers option of complete removal of all macroscopic disease in the same setting (72). A safety margin of normal tissue is taken around the superficial lesion. Recent publications by experienced practitioners (73–75) favor at least ELS type 2 resections (Table 123.2), that is, removal of the entire cord and ligament. A review of literature for TLM in glottic CIS reveals high local control rates ranging from 75% to 100% (67).

Definitive treatment with RT is preferred at a few centers for the treatment of CIS (70), but the long-term complications and increased treatment time and costs for comparable local control rates make this option less desirable than excision biopsy by TLM alone (76). It also exhausts the option of subsequent radiation for recurrent or second primary tumor.

Approximately 29% of the laryngeal CIS lesions have a potential to progress to SCC, transformation rates being higher (33% to 92%) in untreated cases (72,77). This forms a basis for recommendation of close follow-up in patients with CIS irrespective of the treatment modality used. Presence of CIS at the anterior commissure has a greater risk of conversion to invasive squamous cancer than CIS at the membranous cord, 92% versus 17%, respectively. This has been reported in one of the studies analyzing predictive factors for progression of CIS to SCC (72).

Invasive Squamous Cell Carcinoma

Surgery

Endoscopic Procedures. The concept of endoscopic excision of early glottic cancer was pioneered by Lynch in 1920 using suspension laryngoscopy (71). Excellent outcomes were reported by New and Dorton in 1941 with transoral diathermy excision of glottic cancers, followed by De Santo in 1973 (71). The results for transoral CO_2 laser excision of glottic cancer were first published by Strong in 1975 (78) and popularized later by Steiner in 1980s (33). Since then, the use of laser with its hemostatic properties has evolved to become the optimal tool of endoscopic excision, although cold steel is still used. Glottic tumors are difficult to access through the currently available robotic arms and exposure devices. Robotic laryngeal surgery was found technically feasible for cordectomy in a canine model (79) and a human pilot study of four patients with glottic cancer (80), although access is severely limited once the narrow restrictions of the larynx are reached, given the angle of approach needed for the da Vinci robotic arms.

Transoral Laser Microsurgery. Surgical technique: Adequate laryngoscopic exposure of glottis is the basic technical requirement for TLM (Figs. 123.4 and 123.5). For procedures restricted to true cord, the laser is usually kept at continuous super pulse mode and low power settings ranging from 1 to 3 W. Modern CO_2 lasers allow tumor dissection in bloodless field with minimal char formation; thus, the use of electrocautery for hemostasis is almost eliminated in glottic lesions, which translates to lesser tissue injury and better functional results.

T1a (Unilateral) and T1b (Bilateral) Glottic Tumor. Small superficial lesions can be excised *en bloc*. Resection of larger microinvasive tumors, as judged intraoperatively, is performed in two or more pieces with the first incision passing through the middle of the tumor for depth assessment. Prior resection, partial or complete, of the ipsilateral false cord may be required. Resection is commenced by this first incision through the center followed by a further incision in normal tissue, lateral and posterior to the tumor. The first specimen is obtained by continuing the dissection posteriorly, forward to backward direction, to excise the posterior half of the tumor. Next, the anterior resection is completed by making an incision in the normal tissue lateral to the tumor and advancing the dissection anteriorly to resect the anterior half of the tumor. A deep margin of 1 to 3 mm and mucosal margin of 1 to 2 mm are recommended. If the tumor reaches the vocal process, mucosa is resected in close approximation, anterior to the arytenoid cartilage, and depending upon the extent of involvement, the vocal process may need to be included in the resection specimen. Bilateral tumors can be removed transorally in two sessions to prevent web formation.

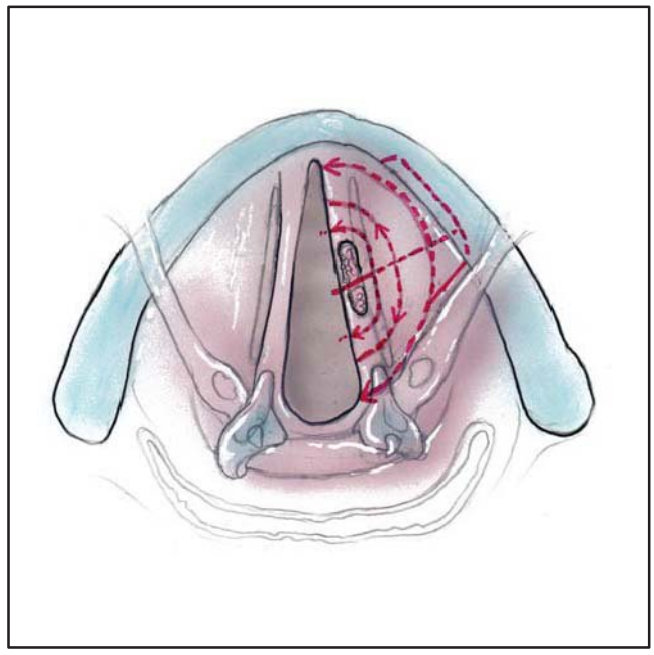

Figure 123.4 Transoral laser cordectomy for glottic tumors. *Dotted lines* indicate extended resections for lesions of increasing depth.

T2 Glottic Tumor (Supraglottis and/or Subglottis Extension, and/or Impaired Vocal Cord Mobility). T2 glottic cancers are amenable to complete excision with TLM irrespective of tumor extension into supraglottis, subglottis, or anterior commissure. The surgical principles applied are similar to laser surgery for other subsites. Again, false cord resection may be necessary for access to the ventricle and the paraglottic space. Tumor debulking is done for larger lesions followed by an incision through the tumor and further resection as necessary.

For tumors extending to supraglottic larynx across the arytenoid cartilage or interarytenoid mucosa, it is usually possible to preserve the arytenoid by peeling the tumor off the cartilage, if superficial. The exposed cartilage gets epithelialized after 3 to 4 weeks (36). Every attempt is made to preserve the posterior uninvolved mucosal cover of arytenoid for prevention of aspiration.

For tumors with suspected inferior extension, the subglottis is carefully evaluated, a procedure that often needs repositioning of the endotracheal tube and transoral access through smaller-caliber laryngoscopes for optimum exposure. The tumor is followed along the subglottic extensions if any, securing an adequate inferior margin.

Early Glottic Tumor with Anterior Commissure Involvement. In T1a tumors extending to the anterior commissure, a small tumor-free margin of the anterior part of contralateral cord should be included in the resection. This is sometimes associated with web formation at the anterior commissure. In T1b tumors, the bilateral cord lesion is usually resected together with the anterior commissure. The dissection is

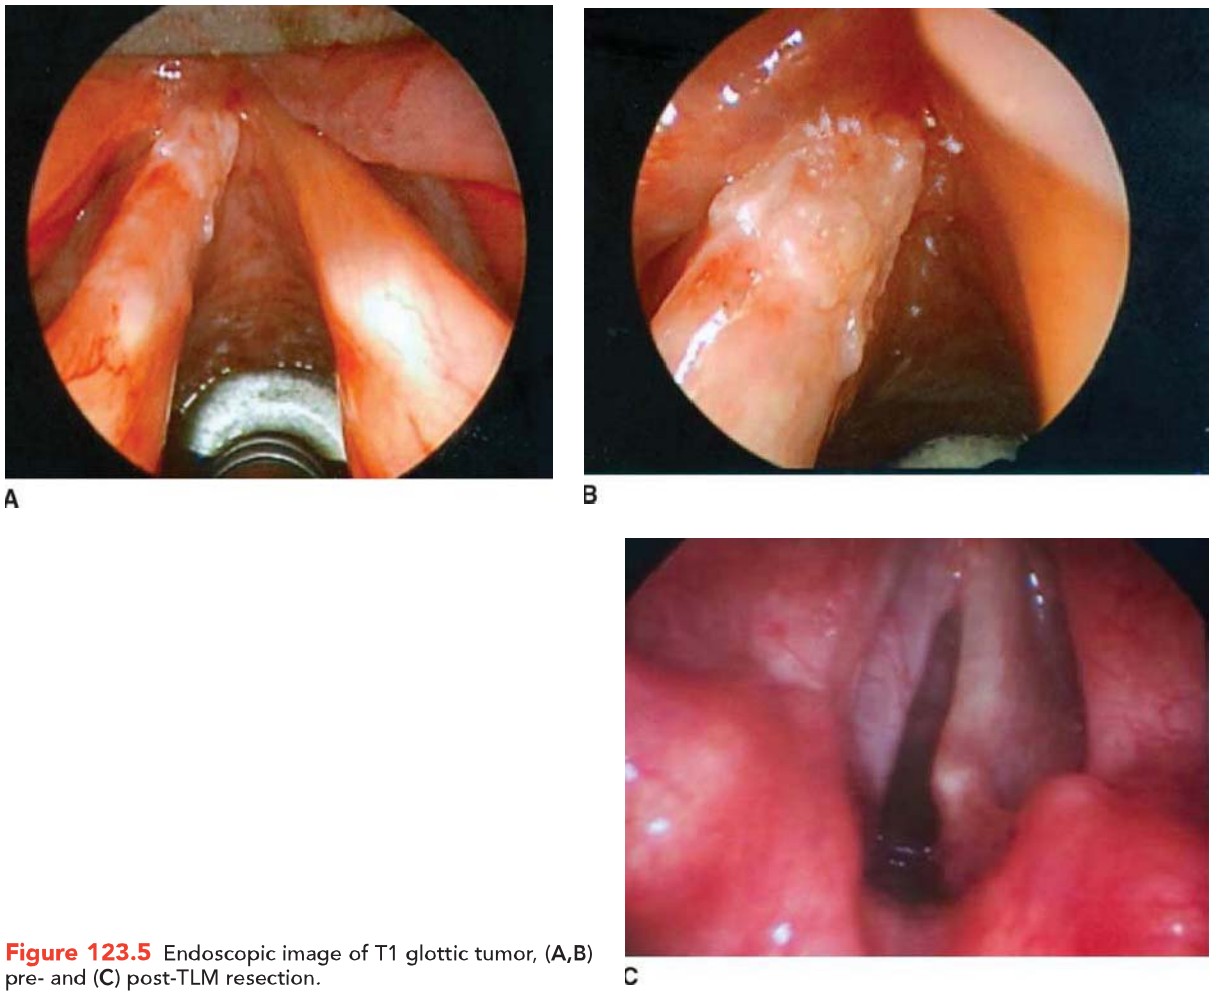

Figure 123.5 Endoscopic image of T1 glottic tumor, (**A,B**) pre- and (**C**) post-TLM resection.

also continued anteriorly along the thyroid cartilage, and with the help of frozen sections, it is ensured that the perichondrium toward the inside of the thyroid cartilage is free from the tumor.

Application of fibrin at the site of tumor resection at anterior commissure has been shown to reduce the incidence of web formation. If necessary, a silicone stent may be placed endoscopically as a prophylactic measure, which is removed after 6 weeks.

Postoperative care: Follow-up is recommended after 2 weeks. Strategies for cessation of smoking and alcohol consumption form an important component of postoperative counseling. Adequate gastroesophageal reflux preventive measures are initiated in all patients as reflux may impair wound healing, promote granulation tissue formation, and prolong edema. Wound healing is usually complete in 4 to 6 weeks following which voice rehabilitation therapy is scheduled. A small number of patients with persistent granulation or granuloma formation may require a second-look laryngoscopy.

Complications: Secondary hemorrhage is rare following resection of glottic tumors and can be managed conservatively if minor or with cautery at microlaryngoscopy. Postoperative laryngeal or tongue edema can occur particularly after resection of bulky T2 tumors with supraglottic spread to arytenoids. The airway obstruction may necessitate tracheostomy but is frequently managed by administration of intravenous corticosteroids and aerosolized topical vasoconstrictors. In certain patients, wound healing elicits a strong inflammatory response and formation of exuberant granulation tissue. If the granulation persists for more than 6 to 12 weeks or is a source of compromised voice quality, surgical removal may be required. Laryngeal stenosis occurs as a rare, late complication if tumor resection involved extensive subglottic, interarytenoid, or near circumferential resections. This phenomenon is more likely to occur in patients undergoing TLM for radiation failures. Poor voice quality is universally observed prior to epithelialization. Thereafter, quality of voice recovery is related to volume of tissue loss and recruitment of supraglottic vibratory structures.

Phonosurgical Management After Endoscopic Partial Laryngectomy. Endoscopic laser excision for early glottic tumors does not usually require any reconstruction of the glottic defect as in open conservation surgery. However, in

cordectomies requiring vocal muscle excision, poorer voice quality may result due to an aerodynamic glottic insufficiency caused by the concavity of the neocord (81). In such cases, phonosurgical techniques to augment the paraglottic space by microlaryngoscopic lipoinjection or cord medialization with Gore-Tex have been applied to optimize the voice restoration (81,82).

Open Conservation Procedures

Laryngofissure and Cordectomy. Laryngofissure and cordectomy are indicated for T1 lesions of vocal cord limited to the membranous cord when transoral resection is not possible. An endoscopy is performed prior to the surgery to reevaluate the suitability of the tumor for the procedure. A transverse skin incision is made at the level of midportion of the thyroid cartilage. Superior and inferior flaps are raised, strap muscles are retracted, and the thyroid cartilage is exposed in the midline. A midline vertical thyrotomy is performed and the larynx is entered through a short incision in the cricothyroid membrane. The thyroid ala is retracted laterally and the anterior ends of vocal folds are separated in the midline at the anterior commissure. The resection can include the true and false cords anterior to the vocal process of arytenoid, underlying thyroarytenoid muscle, internal thyroid perichondrium, and anterior commissure. The anterior commissure is reconstructed by anchoring the anterior end of the uninvolved cord to the thyroid lamina. The perichondrium and strap muscles are approximated and the incision is closed (Fig. 123.6).

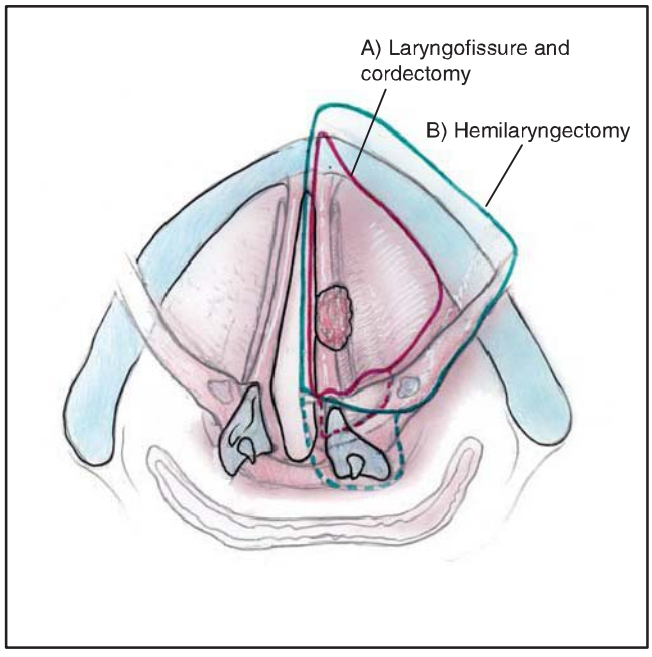

Figure 123.6 Extent of resection in laryngofissure and cordectomy (**A**) and hemilaryngectomy (**B**). Extensions (*dotted line*) in either procedures may include the vocal process of the arytenoids, if required.

Postoperative care and complications: Tracheostomy is generally not required in cordectomy due to enlargement of the laryngeal inlet by cord resection; exceptions are patients with unfavorable body habitus. Feeding can be successfully initiated on the day following the surgery. Subcutaneous emphysema has been reported as one of the complications and can be prevented by pressure dressing and a wound drain.

Vertical Partial Laryngectomy. Hemilaryngectomy: This procedure involves resection of the ipsilateral thyroid cartilage, arytenoid, true cord and false cord, underlying muscle, and mucosa from the aryepiglottic fold to the upper border of the cricoid cartilage from the posterior to anterior midline. For early glottic tumors, its indications include T1 lesions with suspicion of deeply infiltrating tumor or T2 lesions of vocal cords with extension to arytenoids (Fig. 123.6).

Frontolateral vertical hemilaryngectomy: The procedure is indicated for T1 cord lesions approaching or extending to the anterior commissure and not more than 1 to 2 mm of the contralateral cord. The thyrotomy incisions are made bilaterally on either side of the midline and the larynx is entered through the cricothyroid membrane, on the side of lesser involvement. The resection includes true and false cords and ventricle on the ipsilateral side, arytenoid when necessary, anterior commissure, and anterior contralateral cord. The contralateral mucosa is sutured to the external perichondrium in order to resurface the larynx.

Anterior commissure technique/anterior frontal vertical partial laryngectomy: The procedure is indicated for T1 and T2 cord lesions with significant "horseshoe" involvement of the opposite vocal cord. The vertical midline portion of the thyroid cartilage, inner perichondrium, true cord, false cord, and ventricle up to the vocal process, bilaterally, are included in the resection. Reconstruction is performed by silastic or keel insertion to allow epithelialization on either side without web formation. The keel is usually removed after 6 to 8 weeks.

Reconstruction after partial laryngectomy: The glottic defect from open partial laryngectomy procedures may result in unsatisfactory voice outcomes. Resurfacing and reconstruction of the glottic defect enable better functional restoration. Several techniques are described of which more commonly applied are strap muscle flaps. Mucosal flaps, external thyroid perichondrium flap, a muscle-based cartilage flap, or imbrication laryngoplasty are alternatives.

Postoperative care: Care of the tracheostomy tube to maintain a patent airway is important in patients undergoing vertical hemilaryngectomy. Decannulation is deferred until the patient's swallowing improves and wound healing is complete. Voice usually tends to be breathy following hemilaryngectomy and speech therapy is initiated after decannulation. This procedure may temporarily require feeding

through nasogastric tube or a gastrostomy but improves with swallowing rehabilitation.

Complications: Airway obstruction after vertical hemilaryngectomy from prolapse of supraglottic tissue or formation of excessive granulation tissue is managed by maintenance of the tracheostomy. Progression to glottic stenosis is a possible complication in postradiation cases, which may need to be addressed by surgical intervention. Dysphagia and aspiration may occur in immediate postoperative period, particularly in patients with arytenoid resection. In a study of 438 patients comparing outcomes for different surgical approaches, a lower complication rate of 1.2% including stenosis, dyspnea, bleeding, fistula, and aspiration has been noted for TLM compared to 17.6% in open cordectomy, 9.4% in vertical partial laryngectomy, and 13.6% in frontolateral laryngectomy (83).

Supracricoid Laryngectomy. SCL may be an effective procedure to conserve the larynx for T2 glottic cancers that involve the anterior commissure, ventricle, and bilateral vocal cords. The surgical details have been discussed earlier. Reconstruction in these cases may include a CHEP.

OUTCOMES

Early glottic tumors have a good prognosis and failure occurs mainly at the primary site. T stage, anterior commissure involvement, and epidermal growth factor receptor expression are correlated with poorer local control in early glottic cancer (84). In addition, overall treatment time greater than 50 days and total dose less than or equal to 65 Gy, especially for T2 tumors, have been found to be significant for reduced local control in studies of early glottic cancers treated by definitive RT (84).

Oncologic: A review of studies reporting on TLM for T1 glottic cancers from various centers reveals a 5-year local control rate ranging from 88% to 94% and laryngeal preservation in more than 94% of cases (34,85–91). Sjögren et al. (92) compared results of TLM versus RT in T1 glottic cancer and found a local control rate of 89% versus 75% and a laryngeal preservation rate of 100% versus 83%. In a similar study by Schrijvers et al. (93), local control rates between the two groups were similar but laryngeal preservation was 95% for TLM versus 77% for RT. Also, in patients with T2 neoplasms, good local control ranging from 75% to 85% for local control has been observed in patients with T2 neoplasms (87,94–97).

A comparison of outcomes for external versus endoscopic approach for patients with early glottic tumors revealed similar oncologic results. The group treated by laser surgery, however, was found to have a shorter clinical course, lower complications, and the best possibility of salvage therapy in the case of local recurrence (83,98,99). Depending upon the stage and site of recurrence following TLM, options for treatment include laser resection, partial laryngectomy, RT, or total laryngectomy. In a study investigating prognostic factors for local recurrence, the anterior commissure was the site of recurrent tumor in 54% of the cases, vocal muscle infiltration and subglottic involvement correlated with poor disease-free survival, and 91% of the recurrent cases could be retreated successfully (100).

Outcome for lesions involving anterior commissure: Involvement of the anterior commissure is considered to be a poor prognosticator for local control in early glottic cancer irrespective of the treatment modality. With exception of a few (101), most authors report lower responses to RT, possibly due to underdosage. The observed rates for local control in T1 carcinoma with anterior commissure extension vary from 57% to 89% (102–107). The organ preservation rates for tumors treated with RT range from 80% to 85% (103,106). Open procedures have been shown to offer higher organ preservation rates. These are correlated with good local control from 80% to 90% after frontolateral partial laryngectomy (108,109) and SCL (110,111) in early glottic cancers involving the anterior commissure.

TLM has been found to be effective for treatment of early glottic lesions with anterior commissure involvement, but the local tumor control rate has been found to be affected by the T stage as in other treatment modalities (104,112). In a study by Steiner et al., the 5-year local control rate varied from 84% for T1a to 73% for T1b and 79% for T2 lesions. The organ preservation rate in this study was high ranging from 93% for T1a to 88% in T1b and 93% in T2 lesions (112). The oncologic outcomes for open surgery were found to be comparable with TLM but functionally less favorable in terms of speech, swallowing, and a provisional tracheostomy (83). Measures cited to improve local control rates for TLM resections include adequate exposure, surgical experience and skill, resection of the thyroid cartilage, and careful attention to subglottic extension (36,113).

Functional: TLM is associated with minimal functional impairment. Tracheotomy is avoided in most patients undergoing TLM for early laryngeal cancer. Unlike open procedures, there is no disruption of structural integrity including the cartilaginous framework or the strap muscles. This results in better protection of the airway and swallowing that facilitate faster functional recovery. Furthermore, avoidance of RT preserves salivation and pharyngeal lubrication that assists in speech (104). The quality of voice is affected by the extent of cordectomy (114) and unsatisfactory outcome can be improved using phonomicrosurgical techniques. Whereas some authors advocate better voice outcomes with radiation than laser surgery (115), others have observed dysphonia due to RT-induced scarring and dryness of normal mucosa (116). Most of the comparative analyses show a reduced impact on patients' perception of voice quality after treatment with RT compared to TLM, but no significant difference could be detected by objective measurements (117–119).

RADIOTHERAPY

RT is employed as a treatment of choice for early glottic cancers at a number of centers. The cure rates for T1 lesions range from 71% to 95% (63,106,120–122). For treatment with RT, an endoscopic staging biopsy, usually under general anesthesia, is required to establish a histologic diagnosis followed by 5 to 6 weeks of treatment. Excision biopsy using transoral laser alone has been observed to yield a 92% recurrence-free survival at 3 years for T1 glottic cancers (71). Compared to this, definitive RT for CIS or T1 lesions is a radical treatment. The local control rates in studies advocating RT sometimes include surgical salvage of recurrences (106). Moreover, biopsy for making the histologic diagnosis is quite likely to remove the entire tumor in early localized lesions even before the initiation of radiation treatment (123). For T2 glottic cancer, the local control rates with RT vary from 50% to 80% (84,120). Successful local control and laryngeal preservation with RT have been shown to be affected by several factors including high tumor volume/bulk (102), anterior commissure involvement (124), and subglottic extension (125). Hyperfractionated RT has been associated with improved local control rates in patients with T2N0 glottic cancer compared to conventional RT (126).

Recent studies have employed chemotherapeutic agents such as carboplatin, tegafur-uracil, and fluoropyrimidine to improve results with RT in T2 glottic cancer (127–129). In a retrospective study of 30 patients, better 3-year local control rate could be achieved only when chemoradiotherapy was combined with transoral debulking microsurgery (95%) versus chemoradiotherapy alone (61%) (127).

Suitable candidates for radiation in early glottic cancer may include elderly patients with poor general health who are at greater risk of surgery-related complications, tumor extending to both cords, or when the physician lacks surgical expertise. Avoidance of RT is recommended in the younger populations for prevention of morbidity from both acute and late RT-related complications. In a prospective study of T1 glottic cancers treated with definitive RT ($N = 180$), a high rate of acute complications such as patchy or diffuse mucosal coating (65%) and chronic complications such as persistent arytenoid edema/polypoid lesions (8%) was observed (122). Other complications include xerostomia, persistent laryngeal edema, cervical fibrosis, glottic stenosis, hypothyroidism, chondronecrosis, and radiation-induced malignancy.

Management of Radiation Recurrences

Recurrences after failed radiation are often advanced at the time of diagnosis. A minority of radiation-recurrent glottic carcinomas can be salvaged by conservation surgery, but persistent aspiration, pharyngocutaneous fistula, delayed decannulation, and laryngeal stenosis can make such procedures particularly challenging with many tumors. Salvage partial surgery for localized T1 and T2 recurrences has shown acceptable survival rates and laryngeal preservation (130,131); however, total laryngectomy may be commonly required for radiation failures (113,132,133).

TLM has been identified as one of the effective salvage procedures in selected cases involving glottic post-RT recurrences. Radiation-recurrent tumors are also, frequently, submucosal and discontinuous in nature. Magnification with TLM helps in identification of atypical-appearing mucosa though with greater difficulty compared to primary tumors. Using TLM, Steiner et al. (132) reported a successful salvage in 71%, with laryngectomy needed in 21% cases only. Another study by Ansarin et al. (134) reported TLM as an effective salvage for early RT recurrent tumors with laryngeal preservation rate of 70%. The outcomes for TLM as surgical salvage therapy, however, may depend on the individual surgeon's skill and experience. The results may also be affected by tumor extension to the anterior commissure or the arytenoids (133,135).

PHOTODYNAMIC THERAPY

Photodynamic therapy (PDT) utilizes the activation of tumor-selective photosensitizing agents with light to induce tumor necrosis (136) by increased production of oxygen radicals and decreased vascular supply. The photosensitizer is delivered intravenously, topically, or orally followed by subsequent treatment with a pulsed dye laser. PDT is usually performed as an outpatient procedure and the known complications of the procedure include glottic edema, pain, necrosis, and sun-induced photosensitivity (136). PDT is U.S. Food and Drug Administration approved for clinical treatment of early glottic cancers; however, its application as a single-modality, minimally invasive treatment modality is still limited.

EARLY SUBGLOTTIC CANCER

Primary lesions originating in the subglottis are rare and account for about 1% to 5% of all laryngeal cancers (137,138). More common are secondary extensions of carcinoma from the glottis. About 68% of patients were reported to present with early subglottic cancer in a series of 39 patients (137); however, most of the other published studies have observed 60% to 80% of the tumors presenting at late stages with dyspnea and stridor that may necessitate tracheostomy (138,139). Hoarseness can also occur as an initial presenting symptom (140). The incidence of nodal metastases at presentation varies widely from 4% to 33% depending on the disease stage (138–140).

Surgical Pathology and Treatment Planning

Subglottic cancers are known to have a typical circumferential and inferior pattern of intraluminal spread. Tumor extension is contained in the early stages by the conus elasticus; invasion through this barrier can involve the vocal musculature resulting in impaired mobility or fixation

of the true cord. Vertical spread can occur toward the trachea caudally or the paraglottic space superiorly. Anterior spread through the cricothyroid membrane to involve the thyroid cartilage and the thyroid gland is a common mode of extralaryngeal spread.

CT and MRI with contrast are important for better delineation of the inferior extent of the tumors, invasion of the cricoid or thyroid cartilage, and the presence of cervical lymphadenopathy. Definitive diagnosis requires direct laryngoscopy with biopsy under general anesthesia.

TREATMENT

The rarity of subglottic tumors and variation in presenting stage preclude adoption of a uniform treatment paradigm. While surgery is recommended either as a part of combined modality or as definitive treatment for all stages of subglottic cancer in certain studies (137,141), some centers advocate definitive RT to the primary site, lower neck, and upper mediastinum with surgery reserved for salvage as an appropriate treatment for T1 and T2 cancers (139,140). Santoro et al. (142) reported that the 5-year disease-free survival rate for subglottic cancer was 0% with RT alone and 47% with surgery.

Using long, small-caliber laryngoscopes, resection with TLM combined with level VI neck dissection, if indicated, can be effectively employed to treat early lesions. Small, superficial-appearing tumors with deep infiltration can be dissected off the inside of the cricoid cartilage provided an adequate exposure is obtained (37). Infravestibular horizontal partial laryngectomy has been described for treatment of small series of patients with early subglottic lesions (142). Conservation of the upper half of the thyroid cartilage followed by adequate laryngeal reconstruction allowed restoration of natural phonation and respiration without requiring a tracheostomy in 75% of treated patients (143); however, application of this surgical procedure has not been widely reported.

Local recurrence of tumor is relatively common and is the primary cause of mortality in subglottic cancer (137,142). The most common site of recurrence is at the peristomal level, mostly attributed to nodal metastasis to the paratracheal lymph nodes (142,144). This emphasizes the need to address level VI nodes as an essential part of management for subglottic cancers (144). Distant metastasis is reported to occur in 12% to 50% patients with subglottic cancer (137,140,142). In a series reporting 15% of distant metastasis, three-fourths occurred in patients with early-stage disease at presentation (137), all of whom succumbed to the metastatic disease.

SUMMARY

TLM is an effective single-modality treatment for early laryngeal cancer and has supplanted the open conservation surgery with optimum oncologic outcomes, low morbidity, reduced hospital stay, reduced treatment time, and reduced cost (104,145–147). It has been established, by consensus of ABEA, as an oncologically safe procedure for laryngeal cancer when applied judiciously and by a skilled surgeon (147). The main advantage lies in the possibility of offering individualized treatment by tailoring the surgical resection to precise extent of the tumor, thereby preserving the uninvolved healthy tissues. Moreover, TLM does not preclude further treatment options in the form of functional salvage surgery or RT for recurrent or second primary tumors. Its repeatability has been observed to result in lower laryngectomy rate compared with the published series on RT (148). Though no randomized trial has been conducted to compare the outcomes for TLM versus open conservation procedures or RT, a sufficient quantum of evidence from various centers establishes TLM as a minimally invasive, tumor-targeted therapeutic procedure. Comparative meta-analyses have shown no differences in oncologic outcome between TLM and RT (119,149) with no significant difference in objective voice analyses. TLM was also found to be superior to RT from a cost-utility point of view (149).

Patient selection for TLM, however, remains paramount and open conservation surgery can be a valuable approach to treat patients not suitable for a transoral laser excision. Open partial laryngectomy is a salvage option in selected radiation-recurrent tumors though it is associated with higher rates of failure as well as complications in the form of aspiration and tracheostomy dependence that may culminate in total laryngectomy.

HIGHLIGHTS

- Larynx cancer incidence is on the decline in the United States: Early glottic tumor incidence is greater than supraglottic, due to symptom development.
- Supraglottic tumors spread early to the preepiglottic space (PES) via the epiglottic foramina.
- For glottic tumors, deep lateral spread is from the cord to the paraglottic space.
- The fundamental goals of treatment are cure with no ultimate compromise in voice and swallowing.
- TLM is an effective and efficient minimally invasive option.
- For TLM, endoscopic access is paramount for patient selection.
- *"en bloc"* resection is performed for small tumors, and transtumoral, multibloc for larger tumors.
- Open partial procedures confer excellent and equivalent levels of local control.
- RT, while offering local control, may impair laryngeal physiology and reduce options for function-preserving salvage.
- Level II, III, and IV dissection is adequate for surgical management of neck metastasis in supraglottic cancer.

Advanced Laryngeal Cancer

124

Bridget C. Loehn *Melda Kunduk* *Andrew J. McWhorter*

Laryngeal cancer affects nearly 12,720 men and women, and approximately 3,600 people will die of laryngeal cancer in the United States per year (1). The overall incidence of developing laryngeal cancer is approximately 0.7% with a mortality of 0% to 0.3% (2). If detected early, it can be effectively treated; however, over 40% of laryngeal cancers present with advanced-stage disease (3). Advanced-stage laryngeal cancer is defined as Stage III or IV disease, which includes not only T3 and T4 tumors but also tumors with regional cervical metastasis (N1 to N3 disease) (4).

The larynx produces one of the most complex motor functions of the body. It provides airway protection for respiration and deglutition as well as phonation. Any malignancy that affects the larynx can alter one or more of these main functions. Effects on this complex mechanism must be taken into account when formulating a treatment plan. The ultimate goal is to cure the patient of disease but with secondary goals to preserve phonation and deglutition and maintain a safe airway. There are many different treatment options for laryngeal cancer, but the clinician must balance quality of life (QOL) issues with the survival advantage of therapy. The treatment of laryngeal cancer should be a multidisciplinary approach to provide the patient with every opportunity available and the best oncologic and functional outcome.

Treatment of laryngeal cancer has evolved as medical advances have created more treatment options. Total and partial laryngectomy surgeries were the initial treatment for laryngeal cancer and were developed in the 19th century. Billroth is credited with the first laryngectomy in 1873 (5). Surgical advances in technique and antisepsis were major accomplishments that standardized surgical treatments and created reliable and safe conservation laryngeal surgery. With advances in radiation and chemotherapy and the use of multicentered prospective randomized trials, organ preservation therapy evolved to replace many of the surgical treatments and became the most common treatment for advanced laryngeal cancer. This shift in treatment paradigm during the early 1990s, from surgical excision to organ preservation using concurrent chemoradiation therapy, has provided similar survival to the gold standard total laryngectomy with postoperative radiation therapy but with a 73% organ preservation rate (6). Disappointing functional outcomes and new developments in minimally invasive techniques have further changed the treatment of laryngeal cancer with the popularization of endoscopic laser surgical resections in the 21st century.

EPIDEMIOLOGY

The larynx is the second most common site of primary epithelial malignant tumors of the head and neck. Laryngeal cancer accounts for 0.3% of all cancer-related deaths (2). Unfortunately, the 5-year survival for all stages of laryngeal cancer has worsened over the past 30 years despite efforts to improve treatment protocols. In between 1975 and 1977, the 5-year survival was 67%, and between 1999 and 2005, the 5-year survival has statistically decreased to 63% (1,7). There is an ongoing debate as to the etiology of the decrease in survival as to whether using chemoradiation versus total laryngectomy for earlier stage disease is the cause.

Laryngeal malignancies can occur in all three subsites of the larynx. The glottis is the most common site for laryngeal malignancy (51%), followed by the supraglottis (32%) and the subglottis (2%) (8) (Fig. 124.1).

From 2003 to 2007, the median age of diagnosis was 65 years with the highest incidence in the sixth and seventh decades (7). Men are more commonly affected than women with a male to female ratio of 3.6:1. The ratio of male:female has decreased over the years likely secondary to the increased rate of tobacco use in females. There are also differences in the 5-year survival according to race. Caucasians have a higher 5-year survival (67%) than African Americans (53%).

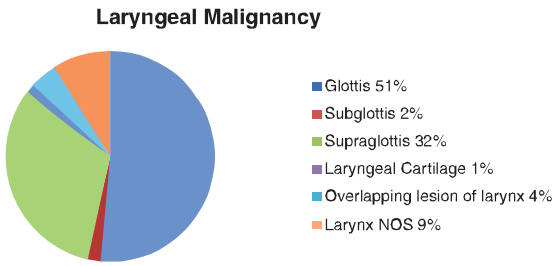

Figure 124.1 Incidence of laryngeal cancer by subsite. Compiled from the National Cancer Database and Hoffman et al. (8). Approval for use obtained.

Over 40% of laryngeal cancers present as advanced stage disease. The 5-year survival also varied according to clinical stage (Table 124.1). Stage III supraglottic and glottic cancer had a 5-year survival of 50% to 60%. Stage IV supraglottic cancer has a 5-year survival of less than 50%, and Stage IV glottic cancer has a 5-year survival of 30% to 57% (3).

ANATOMY

The larynx is found in the anterior neck at the level of the C3 to C5 vertebrae and connects the hypopharynx with the trachea. The larynx functions in airway protection, phonation, and respiration. These functions are made possible by the three valves contained within the larynx. These valves include the true vocal cords, false vocal cords, and epiglottis to the arytenoids. Any dysfunction of these valves can lead to aspiration, airway obstruction, and changes in voice. The larynx is divided anatomically and clinically into the supraglottis, glottis, and subglottis.

The supraglottic larynx is composed of the epiglottis (lingual and laryngeal aspects), aryepiglottic folds, arytenoids, and bilateral false vocal cords. Clinically, the inferior border of the supraglottis, according to the American Joint Committee on Cancer (AJCC), is defined by a horizontal plane passing through the lateral margin of the ventricle at its junction with the superior surface of the vocal cord (4). Anatomically, the inferior border is defined by the arcuate line, which marks the change from respiratory to squamous epithelium and is not reliably located at the apex of the ventricle. For staging purposes, the epiglottis is divided into suprahyoid and infrahyoid portions by a plane at the level of the hyoid bone. Histologically, the supraglottis is lined with ciliated columnar epithelium.

TABLE 124.1 OVERALL 5-YEAR SURVIVAL BY SUBSITE AND STAGE (8,9)

	Supraglottis	Glottis	Subglottis
Stage III	50%–60%	50%–60%	43%
Stage IV	28%–53%	22%–52%	25%

The glottic larynx is comprised of the superior and inferior surfaces of the true vocal cords, including both the anterior and posterior commissures. The inferior border is defined as the line 1 cm below the apex of the ventricle (4). Histologically, the glottis is lined with stratified squamous epithelium. The layers of the true vocal cord from outward to inside are the following: stratified squamous epithelium, lamina propria, and vocalis muscle. The lamina propria is composed of three layers: a superficial layer that is composed of loose fibrous tissue and creates Reinke space an intermediate layer and a deep layer composed of elastic and collagen fibers that create the vocal ligament.

The subglottic larynx is the region below the glottis down to the inferior rim of the cricoid cartilage (4). The subglottis has no subsites. It is rarely the primary site of laryngeal cancer but is commonly involved in the inferior extent of glottic tumors. Histologically, the subglottis is lined with ciliated columnar epithelium (Fig. 124.2).

PATTERNS OF SPREAD

The larynx contains several fibroelastic membranes and ligaments that divide the larynx into compartments, limit the spread of early cancers, and allow for partial resections with adequate margins. Tumors tend to grow in the path of least resistance into preexisting compartments including the preepiglottic space and paraglottic space. The preepiglottic space is bound by the thyroepiglottic ligament inferiorly, the hyoepiglottic ligament superiorly, and the epiglottis posteriorly. At this level, the thyroepiglottic ligament is an ineffective barrier and offers little resistance to tumor spread. Tumor may also spread directly into the

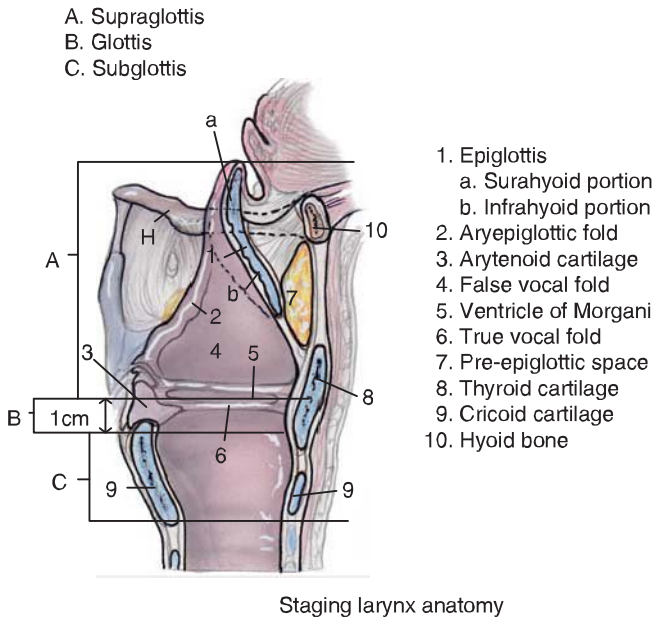

Figure 124.2 Midline sagittal section of the larynx demonstrating the supraglottis, glottis and subglottis.

preepiglottic space by traveling through lacunae on the laryngeal surface of the epiglottis into the space. The paraglottic space is another potential space bound laterally by the perichondrium of the thyroid cartilage and cricothyroid membrane and posteriorly by the mucosa of the pyriform sinus. Medially, the paraglottic space is bound by the quadrangular membrane above the ventricle and the conus elasticus below the ventricle. The conus elasticus extends superiorly from the superior border of the cricoid cartilage to merge with the inferomedial border of the vocal ligament. This ligament resists the extralaryngeal spread of early glottic and subglottic tumors. The paraglottic space allows tumors to become transglottic (superior and inferior to the ventricle) tumors and also to impair the movement of the true vocal cord. The preepiglottic space and paraglottic space communicate with each other.

At the level of the glottis, the vocalis tendon attaches to the thyroid cartilage through Broyles ligament, which is an ineffective barrier and will allow tumors to spread into the thyroid cartilage and preepiglottic space. This region where the tendon attaches to the thyroid cartilage has no perichondrium. The perichondrium is considered another barrier to the spread of early cancers. As previously discussed, the true vocal cords contain a lamina propria consisting of three layers. The superficial layer (Reinke's space) contains loose fibrous tissue and is almost void of lymphatics and blood vessels creating a resistance to the spread of early glottic tumors.

Lymphatic spread of the tumor usually occurs in a predictable manor and follows the embryologic origins of the larynx. The supraglottis is derived from the midline buccopharyngeal primordium and branchial arches 3 and 4. The supraglottis has a rich lymphatic supply. The glottis is derived from the tracheobronchial primordium and branchial arches 4, 5, and 6. In contrast to the supraglottis, the glottis has a very low lymphatic supply. These differences account for the high incidence of lymphatic spread for supraglottic carcinomas and the low incidence of lymphatic spread in glottic carcinomas. As a result of the rich lymphatic supply to the supraglottis, there is also a greater incidence of bilateral lymph node metastasis as compared to the unilateral spread in glottic tumors (10).

Since the lymphatic drainage of these sites is predictable, this allows surgeons to limit neck dissections to the lymph node levels most at risk. In 1972, Lindberg mapped out affected lymph nodes based on the primary site of the tumor. This study demonstrated that laryngeal carcinoma has lymphatic drainage to Levels II to V and that supraglottic tumors have a greater incidence of bilateral neck involvement (11) (Fig. 124.3).

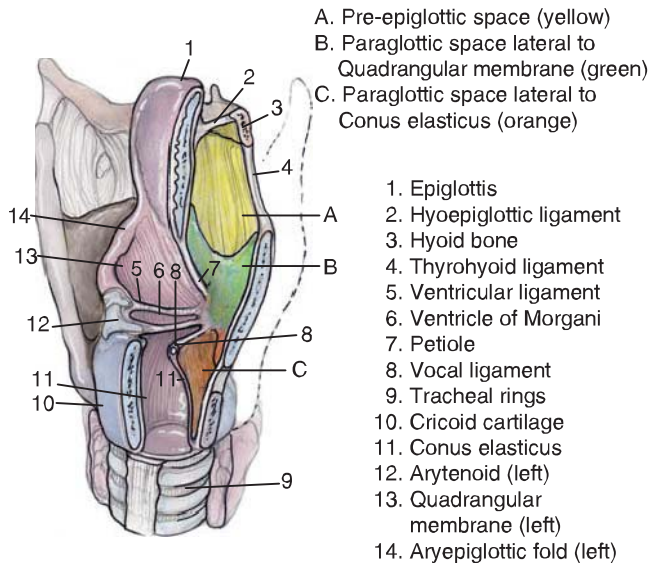

Figure 124.3 Parasagittal view of larynx demonstrating laryngeal spaces and cartilages and ligaments that compose them.

STAGING

The current staging system for laryngeal cancer is the Tumor-Node-Metastasis (TNM) staging system of the AJCC. This system is an anatomical staging system characterized by the extent of invasion of the primary tumor, cervical lymph node involvement, and distant metastasis. This information is obtained through physical examination, imaging, and endoscopic examination and finally confirmed by surgical pathology from the resected tumor. For purposes of this chapter, advanced laryngeal cancer will be defined as Stage III or IV on the AJCC staging system (4) (Table 124.2).

While this system stages tumors based on size and extent of the tumor, other important prognostic factors are not included. There are histologic factors that can indicate a poorer prognosis including perineural invasion, angiolymphatic spread, extracapsular spread of nodal metastasis, and histologic grade of the tumor. There are also studies showing that multiple chromosomal and molecular markers are indicative of a poor prognosis. Some of these markers include overexpression of mutant p53 protein (12), a high Ki67 or proliferating cell nuclear antigen score, and the expression of c-myc oncogene or int-2 gene (13,14). Bradford et al. (12) in 1997 found that high levels of mutant p53 are associated with decreased survival.

Other staging systems have been proposed for laryngeal cancer. Some propose using a high-resolution computed tomography (CT) to assess the volume of tumor. Others suggest that any tumor with any change in vocal cord mobility be considered a T3 or T4. There was also a five-part system devised that used the TNM system but separated it into clinical/diagnostic, surgical, pathologic, retreatment, and autopsy. Other research is including comorbidities into the staging system and is looking at how it relates to the overall outcome (15) (Table 124.2).

TABLE 124.2 STAGING LARYNGEAL CARCINOMA

Primary tumor (T): TX: Primary tumor cannot be assessed T0: No evidence of primary tumor Tis: Carcinoma *in situ*

Supraglottis

T1: Tumor limited to one subsite[a] of supraglottis with normal vocal cord mobility
T2: Tumor invades mucosa of more than one adjacent subsite[a] of supraglottis or glottis or region outside the supraglottis (e.g., mucosa of base of tongue, vallecula, medial wall of pyriform sinus) without fixation of the larynx
T3: Tumor limited to larynx with vocal cord fixation and/or invades any of the following: postcricoid area, preepiglottic tissues, paraglottic space, and/or minor thyroid cartilage erosion (e.g., inner cortex)
T4a: Tumor invades through the thyroid cartilage and/or invades tissues beyond the larynx (e.g., trachea, soft tissues of the neck including deep extrinsic muscle of the tongue, strap muscles, thyroid, or esophagus)
T4b: Tumor invades prevertebral space, encases carotid artery, or invades mediastinal structures

Glottis

T1: Tumor limited to the vocal cord(s) (may involve anterior or posterior commissure) with normal mobility
T1a: Tumor limited to one vocal cord T1b: Tumor involves both vocal cords
T2: Tumor extends to supraglottis and/or subglottis, and/or with impaired vocal cord mobility
T3: Tumor limited to the larynx with vocal cord fixation and/or invades paraglottic space, and/or minor thyroid cartilage erosion (e.g., inner cortex)
T4a: Tumor invades through the outer cortex of the thyroid cartilage and/or invades tissues beyond the larynx (e.g., trachea, soft tissues of neck, including deep extrinsic muscle of the tongue, strap muscles, thyroid, or esophagus)
T4b: Tumor invades prevertebral space, encases carotid artery, or invades mediastinal structures

Subglottis

T1: Tumor limited to the subglottis
T2: Tumor extends to vocal cord(s) with normal or impaired mobility
T3: Tumor limited to larynx with vocal cord fixation
T4a: Tumor invades cricoid or thyroid cartilage and/or invades tissues beyond the larynx (e.g., trachea, soft tissues of neck, including deep extrinsic muscles of the tongue, strap muscles, thyroid, or esophagus)
T4b: Tumor invades prevertebral space, encases carotid artery, or invades mediastinal structures

Regional lymph nodes (N) NX: Regional lymph nodes cannot be assessed
N0: No regional lymph node metastasis
N1: Metastasis in a single ipsilateral lymph node, 3 cm or less in greatest dimension
N2a: Metastasis in a single ipsilateral lymph node more than 3 cm but not more than 6 cm in greatest dimension
N2b: Metastasis in multiple ipsilateral lymph nodes, not more than 6 cm in greatest dimension
N2c: Metastasis in bilateral or contralateral lymph nodes, not more than 6 cm in greatest dimension
N3: Metastasis in a lymph node more than 6 cm in greatest dimension

Distant metastasis (M) MX: Distant metastasis cannot be assessed
M0: No distant metastasis
M1: Distant metastasis

Stage
Stage 0: Tis, N0, M0
Stage I: T1, N0, M0
Stage II: T2, N0, M0
Stage III: T3, N0, M0 or T1, N1, M0 or T2, N1, M0 or T3, N1, M0
Stage IVA: T1, N2, M0 or T2, N2, M0 or T3, N2, M0 or T4a, N2, or less M0
Stage IVB: T4b, any N, M0 or any T, N3, M0
Stage IVC: Any T, any N, M1

[a]Subsites include the following: suprahyoid epiglottis, infrahyoid epiglottis, vestibular folds (false vocal cords), aryepiglottic folds, arytenoids (each fold is one subsite).

EVALUATION AND DIAGNOSIS

History and Physical Examination

The majority of the time, the diagnosis of laryngeal cancer can be made through a complete history and physical examination. Presenting complaints can be site specific. Patients may complain of hoarseness (glottic carcinoma), muffled/hot potato voice (supraglottic carcinoma), dyspnea, dysphagia, and otalgia (usually supraglottic). Patients may also present with a history of aspiration pneumonia, stridor, hemoptysis, or sore throat. Constitutional symptoms may include weight loss, fevers, chills, and night sweats. Often, the initial complaint is that of a cervical mass. Glottic tumors usually present earlier than supraglottic

cancers due to the early change in voice. Supraglottic tumors present with fewer symptoms in the early stage and therefore are usually diagnosed at a later stage. Patients with supraglottic tumors tend to present with pain, dysphagia, and cervical metastasis. Subglottic tumors typically present as advanced stage disease with airway obstruction.

Past medical history is also important in assessing patient comorbidities, history of cancer, and immunologic status. Social history is important in assessing patient risk factors. More than 95% of patients with laryngeal cancer have a significant history of tobacco abuse (3). There is a positive relationship between the quantity of cigarettes consumed and the increased risk of developing laryngeal cancer. There is also a synergistic effect when tobacco is combined with alcohol use leading to even higher rates of malignancy (16). However, alcohol may be a risk factor by itself, but its role is less defined. Treatment of tobacco and alcohol dependency must be considered in the postoperative period. Delirium tremens and tobacco withdrawal can lead to a complicated and prolonged postoperative course and impaired healing.

Other risk factors include human papillomavirus, especially subtypes 16 and 18 (17); gastroesophageal reflux disease; and occupational exposures as seen in patients who are metal workers, construction workers (asbestos), and textile processors.

A complete examination including a complete head and neck exam should be performed on all patients to determine staging, the presence of second primaries, and other findings/comorbidities that may influence recommended treatments. A complete head and neck examination includes examination of the skin, eyes, ears, oral cavity, and pharynx, including palpation of the floor of mouth, base of tongue, and tonsils in addition to the larynx, neck, and cranial nerves. Dentition should be assessed for caries and periodontal disease. A more detailed exam of the larynx and pharynx is performed using flexible fiberoptic laryngoscopy at which time. The extent of the lesion as well as the mobility and position of the vocal cords are assessed. This also allows for assessment of the airway. Videostroboscopy can also be used to detect subtle changes in vocal cord function and mobility but is more helpful in early-stage disease. Palpation of the neck should occur bilaterally noting the location, size, and relationship of the lymph nodes to adjacent structures (18,19) (Fig 124.4).

Figure 124.4 Seventy-degree fiberoptic view of T3N0M0 SCCA supraglottis. Tumor extends from epiglottis onto left false fold.

Imaging

Physical examination is often limited in the evaluation of tumor depth and nodal metastases, and radiographic imaging is helpful in determining the extent of the disease. Imaging can provide information regarding cartilage invasion, extension into the preepiglottic and paraglottic spaces, and extralaryngeal spread of tumor. Imaging studies can also be used to assess cervical nodal disease. Both CT and magnetic resonance imaging are useful tools for this assessment. The CT scan is more specific for cartilage invasion (20), and in most centers, CT is considered the standard imaging modality for advanced laryngeal cancers (Fig 124.5).

Chest radiograph (CXR) should be obtained on all patients in the preoperative evaluation and staging of laryngeal cancer. This allows for the diagnosis of acute/chronic pulmonary disease as well as a synchronous or metastatic lung mass/tumor. Patients with abnormalities on CXR will usually require additional imaging (chest CT) for further work-up.

Another imaging modality used in the staging of many cancers, including laryngeal cancer, is positron emission tomography (PET). PET is a nuclear medicine technique that produces a three-dimensional image of the functional processes of the body. It utilizes fluorescence-tagged glucose molecules and then measures the uptake within the tissues. The hypermetabolic state of most malignancies will lead to increased uptake (10). PET has evolved to be an essential imaging modality in the assessment of advanced laryngeal cancer. It has limited utility in determining the

Figure 124.5 Axial contrast CT scan, T4N0M0 transglottic SCCA demonstrating paraglottic space involvement and thyroid cartilage invasion with extralaryngeal spread.

extent of the primary tumor; however, it is becoming the standard in the assessment of regional cervical metastasis as well as distant metastasis (21). The sensitivity and specificity of PET in detecting cervical metastatic disease range from 74% to 94% and from 82% to 100%, respectively, compared with the sensitivity and specificity of CT, which ranged from 67% to 81% and from 47% to 81%, respectively (22–27). Kyzas et al. (28) found that the overall sensitivity of PET in detecting cervical nodal metastasis was 79%; however, in tumors with nodal status as N0, the sensitivity decreased to 50%. Yamazaki et al. (27) found that metastatic nodes measuring greater than 1cm were detected 100% of the time whereas nodes measuring less than 5 mm were not detected. In the posttreatment period, PET has become useful in the identification of residual and recurrent disease (21). In the assessment of distant metastasis, Gourin et al. (29) reported that the sensitivity and specificity of PET–CT detecting distant metastasis were 86% and 84%, respectively.

Ultrasound is another useful imaging tool in the determination of nodal disease. This is most commonly used in Europe but is gaining prevalence in the United States. This tool is noninvasive, low cost, and is a good technique for lymph node assessment.

Laboratory Tests

Laboratory tests are ordered as part of the preoperative and metastatic workup, usually according to patient factors and institutional guidelines. These tests typically include complete blood count, complete metabolic panel, coagulation studies, as well as other tests. If abnormal liver function tests and calcium and alkaline phosphatase levels are noted, abdominal CT, bone scan, or PET can be utilized to further determine the etiology of these abnormalities.

Consultations

A multidisciplinary approach is used in the treatment of advanced laryngeal cancer. Prior to the start of treatment, other specialists, who will assist in the treatment, as well as posttreatment care, should evaluate the patient. The members of the multidisciplinary team usually include radiation oncology, hematology oncology, dental oncology, speech pathology, nutritional services, and spiritual care. The speech pathologist is critical in pretreatment assessment, counseling, education regarding changes in voice and swallowing including alaryngeal speech, and posttreatment rehabilitation.

Surgical Evaluation

Panendoscopy is a term used to describe the endoscopic evaluation of the entire upper aerodigestive tract. This includes direct laryngoscopy, tracheobronchoscopy, and esophagoscopy and is typically done under general anesthesia. With the advent of advanced flexible scopes and the advancements of in-office procedures, panendoscopy has been performed successfully in this setting (30); however, if conservation laryngeal surgery is being considered, it should not replace the operative endoscopy.

Exam under anesthesia allows the surgeon to make an accurate assessment of the boundaries of the primary site (T stage) and determine if the patient is a candidate for conservation laryngeal surgery by allowing superb visualization of the complex endolaryngeal anatomy. This assessment also allows for the evaluation of a second primary tumor. The overall incidence of second primary tumors is 8.9% creating a 5-year disease-specific survival of 35%. Second primary tumors are not statistically related to the primary tumor site, stage, or presence of regional or distant metastases (31).

Evaluation of the upper aerodigestive tract begins with a thorough examination and palpation of the oral cavity; oropharynx, including base of tongue and tonsil; and nasopharynx.

Direct laryngoscopy is then performed to assess the extent of the tumor, carefully mapping its margins. Rigid telescopes (0, 30, and 70 degree) are helpful in examining the ventricles as well as the subglottis and for photodocumentation (Fig. 124.6). The true vocal cords, vocal processes, and arytenoids are palpated to assess cricoarytenoid joint mobility and to differentiate vocal cord immobility from vocal cord fixation. Tumor involvement in the preepiglottic space and base of tongue is assessed through bimanual palpation. Biopsies are taken at the primary site to obtain the pathological diagnosis. Flexible or rigid esophagoscopy is performed to assess esophageal involvement by tumor, skip lesions in the esophagus or second primaries. Tracheobronchoscopy can also be performed; however, the

Figure 124.6 Seventy-degree telescope evaluation of left ventricle with SCCA involving left false vocal fold with clear ventricle and true vocal fold.

yield is low in the asymptomatic patient due to the limitation of only visualizing endobronchial lesions. With the patient fully relaxed, a complete neck examination is performed to assess for occult nodal disease that might have been missed on in-office examination.

DIFFERENTIAL DIAGNOSIS

Squamous cell carcinoma (SCCA) comprises 95% to 99% of laryngeal malignancies. SCCA can be represented by a linear continuum from dedifferentiation through invasive carcinoma. There are multiple histologic variants of SCCA. The most common of these is verrucous carcinoma representing 1% to 3% of all laryngeal malignancies. This variant has "pushing borders" with a high propensity for local recurrence but an extremely low rate of distant metastasis. It has the classic appearance of exophytic white-gray fronds. The treatment remains controversial, but as of now, surgery remains the treatment of choice (10,32,33).

Although SCCA accounts for the majority of laryngeal cancers, many granulomatous and neoplastic lesions can mimic its appearance, and therefore, a biopsy must always be obtained. Granulomatous diseases such as tuberculosis, Wegener granulomatosis, sarcoidosis, histoplasmosis, and blastomycosis may present with an exophytic or fungating mass resembling SCCA. Of the neoplastic lesions, the most common are sarcomas, minor salivary gland tumors, and neuroendocrine tumors. Multiple sarcomas have been described in the larynx, with chondrosarcoma being the most common sarcoma in the larynx, usually arising from the cricoid cartilage (Fig. 124.7).

Minor salivary tumors include adenoid cystic carcinoma, mucoepidermoid carcinoma, acinic cell carcinoma, adenocarcinoma, and malignant mixed carcinoma. These tumors are most commonly found in the supraglottis but can also be found in the subglottis (adenoid cystic carcinoma). Neuroendocrine malignancies are comprised of paragangliomas, large cell tumors, and small cell tumors and usually involve the supraglottis. Lymphoproliferative lesions also usually occur in the supraglottis, and the most common type is mucosal-associated lymphoid tissue, a subtype of non-Hodgkin lymphoma. Granular cell tumors usually affect the younger patient population and can be difficult to distinguish from invasive carcinoma.

It is also important to remember that the larynx can be the site of secondary spread through direct extension from neighboring structures such as the thyroid gland. Metastatic lesions can also occur in the larynx. Adenocarcinoma can metastasize most commonly from the breast or colon. However, renal cell carcinoma is the most common laryngeal metastasis (34).

Figure 124.7 Chondrosarcoma with cricoid and right arytenoid cartilage involvement with airway obstruction.

TREATMENT

Through the use of history and physical examination, imaging studies, laboratory data, and diagnostic surgery, the tumor can be accurately staged, and the appropriate treatment plan can be recommended. The treatment is then divided into surgical and nonsurgical pathways. Unlike early-stage laryngeal cancer, advanced laryngeal cancer usually requires multimodality treatment with surgery followed by radiation or radiation and chemotherapy. The goal of treatment for advanced laryngeal cancer is to cure the patient with secondary goals of preserving speech and swallowing function. The patient should be included in all aspects of the decision-making process and be allowed to make an informed decision on which treatment option is best for him or her.

Nonsurgical Treatment

Radiation Therapy

External beam radiation uses ionizing radiation to generate free radicals within cell nuclei creating cellular and DNA damage resulting in cell death. The goal of radiation therapy is to achieve better outcomes with tumor eradication while preserving normal tissue. Intensity-modulated radiation therapy was most recently designed to better achieve the above goals. It allows the radiation beams to be more precisely focused to limit the effects of the radiation on surrounding tissue.

The typical total treatment dose of radiation is 6,000 to 7,000 cGy given 5 days per week over a period of 6 to 7 weeks. Primary radiation therapy is indicated for T1, T2, and small T3 tumors. The necks are included in the field of radiation if there is N+ disease or if there is greater than a 20% to 30% risk of cervical regional metastasis. It is also useful in palliation in unresectable tumors and in patients who are poor surgical candidates. Adjuvant radiation may also be given in the postoperative period. Indications for

this include advanced stage disease, positive margins, extracapsular spread of tumor in a lymph node, perineural or angiolymphatic spread of tumor, multiple cervical lymph node involvement, and subglottic extension of tumor. Radiation therapy alone for advanced laryngeal cancer has a 5-year disease-specific survival of 56.5% for Stage III laryngeal cancers and 50% for Stage IV laryngeal cancers (35,36).

Complications of radiation therapy are divided into early and late. Early complications include mucositis, odynophagia, dysphagia, skin breakdown, loss of taste, and edema. These side effects can last up to 6 weeks after the completion of radiation. As a result of the dysphagia and edema associated with radiation, the patient may require the placement of a tracheotomy as well as a percutaneous gastrostomy to maintain nutrition. The late complications include fibrosis, xerostomia, edema, loss of taste, hypothyroidism, laryngeal stenosis, esophageal stenosis, chondroradionecrosis, and osteoradionecrosis. Chondroradionecrosis occurs in approximately 5% of patients with laryngeal cancer. The most common cartilage to be affected is the arytenoid cartilage (37). Osteoradionecrosis can be prevented by having a thorough dental exam prior to the start of radiation.

Chemotherapy

Chemotherapy is another modality used in the treatment of laryngeal cancer. It is most often used in conjunction with radiation therapy. The two most common methods of chemotherapy are induction and concomitant. Concomitant chemoradiation therapy has added a new dimension to the treatment of laryngeal cancer. The chemotherapeutic agent is used as a radiosensitizer while also providing a systemic antineoplastic effect.

Cisplatin and 5-fluorouracil are the two most commonly used agents. Chemotherapy may also be used in palliation when radiation therapy is not an option.

Concurrent Chemotherapy and Radiation Therapy

In 2003, a landmark trial (RTOG 91-11) by Forastiere et al. was conducted, which was the first prospective randomized trial specifically addressing the role of concurrent chemoradiotherapy in laryngeal preservation. Five hundred and forty-seven patients with resectable Stage III or IV SCCA of the larynx were randomized to one of three treatment arms. The three treatments included (a) induction chemotherapy followed by chemoradiation or surgery and postoperative radiation, (b) concurrent chemoradiation, and (c) radiation alone. Exclusions to the trial included all T1 tumors, T4 tumors if the tumor penetrated through cartilage or invaded greater than 1 cm into the base of tongue and any patients with distant metastasis. Any patient who presented with N2 or N3 disease had a planned neck dissection 8 weeks after completing radiation. Indications for total laryngectomy were inadequate response after two cycles of induction chemotherapy, biopsy-proven disease at the primary site at least 8 weeks after radiation therapy, or laryngeal dysfunction with aspiration or laryngeal necrosis. At 2 years, the patients who had an intact larynx after concurrent chemoradiation (88%) differed significantly from the groups given induction chemotherapy followed by radiation (75%) and radiation therapy alone (70%). The locoregional control was also found to be significantly better with concurrent chemoradiation as compared to induction chemotherapy and radiation and radiation alone. Overall 2-year survival was 76% for induction chemotherapy group, 74% for concurrent chemoradiation group, and 75% for radiation alone (38).

In 2006, Forastiere et al. performed a follow-up study to the original RTOG 911-11 trial, which examined this same group of patients 5 years after treatment. The 5-year results differ from the 2-year results by a significant improvement in laryngectomy-free survival for both the induction chemotherapy followed by radiation (44.6%) and concurrent chemoradiation (46.6%) compared to radiation alone (33.9%). The 5-year disease-free survival was better with induction chemotherapy followed by radiation (38.6%) or concurrent chemoradiation (39%) compared to radiation alone (27.3%) which is similar to the 2-year disease-free survival statistics. The overall 5-year survival was similar for the three treatments: induction chemotherapy followed by radiation (59.2%), concurrent chemoradiation (54.6%), and radiation alone (53.5%) (39).

Induction Chemotherapy

Induction chemotherapy has been found to have high response rates. The response to induction chemotherapy predicts the success of subsequent therapy with additional chemotherapy and radiation. In the original RTOG study, the early data on induction chemotherapy suggested a lower survival, but the follow-up study showed an increase in laryngectomy-free survival with induction chemotherapy (38,39). Recent studies have shown that there have been no adverse effects from the delay in surgery or radiation therapy with induction. There has been no difference in survival, but there is a decrease in distant metastasis in patients treated with induction chemotherapy (40,41).

The Veterans Affairs Study Group provided a landmark induction study for laryngeal cancer. Patients in the experimental arm were treated with two cycles of cisplatin and 5-fluoruracil and then reassessed. If there was a partial response, a third round was given followed by radiation. Poor responders after two cycles of chemotherapy were treated with surgery. The experimental arm was compared to the standard therapy of surgery and postoperative radiation. Patients treated with induction chemotherapy followed by radiation had a similar survival to those treated with total laryngectomy and postoperative radiation (68% at 5 years) (40). One of the limitations of this study was that there was no radiation-therapy-alone arm for direct comparison.

The European Organization for Research and Treatment of Cancer performed a study to determine if induction chemotherapy followed by radiation was comparable to surgery and postoperative radiation in patients with T2–T4, N0–N2b SCCA of the pyriform sinus or aryepiglottic fold. Two hundred and two patients were enrolled in the study. The induction chemotherapy patients underwent three cycles of cisplatin and 5-fluorouracil. Partial response and complete response were assessed after each cycle. Only the patients with complete response underwent radiation. The surgical group underwent partial laryngopharyngectomy and postoperative radiation. The results showed for the chemotherapy group a 3-year and 5-year disease-free survival of 43% and 25%, respectively, and the surgical group 32% and 27%, respectively. The overall survival at 3 years was 57% for the chemotherapy group and 43% for the surgical group. There was no difference in survival at 5 years between the two groups. There was also found to be no difference in local regional failure. There were fewer distant metastases and increased time to distant metastases in the chemotherapy arm of the study. A complete response was found in 82% of T2 tumors, 48% of T3, and 0% of T4 (41).

Both of these trials suggest that organ preservation is possible in patients with advanced stage laryngeal or hypopharyngeal cancer. Distant metastases appear to be decreased with chemotherapy. They also suggest that head and neck SCCA is sensitive to cisplatin and 5-fluorouracil.

A new development has been the addition of a taxane (T) (docetaxel) to the traditional doublet cisplatin and 5-fluorouracil (PF) regimen, thus creating a highly active triplet induction regimen, TPF (docetaxel, cisplatin, 5-fluorouracil). Data from randomized trials indicate that TPF sequential therapy may be an effective alternative to concurrent chemoradiation for some patients with locally advanced laryngeal cancer with extensive tumor load or low-neck disease. The TPF is well tolerated but is associated with higher incidence of hematologic events (neutropenia) than traditional PF. These side effects can be managed using prophylactic G-CSF and antibodies (42). In 2007, Posner et al. compared induction chemotherapy with TPF and with PF, both followed by chemoradiation. The 3-year overall survival was 62% in the TPF group compared to 48% in the PF regimen. There was better locoregional control in the TPF group, but the incidence of distant metastasis was not significantly different. The TPF group had higher rates of neutropenia, but there were more treatment delays in the PF group secondary to hematologic events (43).

Surgical Treatment

There are many surgical options for laryngeal cancer. The spectrum ranges from the less invasive microlaryngeal technique to the most invasive, total laryngectomy. The key to the surgical treatment of laryngeal cancer is to determine the correct patient for the correct procedure while accounting for the expertise of the surgeon. Not all patients are amenable to surgical options; however, this can be determined through a complete and thorough preoperative evaluation.

Endoscopic Transoral Laser Microsurgery

Endoscopic resection of laryngeal tumors was first designed for T1 and T2 tumors, but through experience in treating early disease and technical recent advancements, the procedure can be utilized for selected T3 and T4 tumors. The field was born in 1972 when Strong and Jako (44) first introduced the laser through the laryngoscope. The field of endoscopic transoral laser microsurgery was initially slow to develop, but through the work of Wolfgang Steiner and other European experts, it has become more widely accepted and commonly used in the United States in the 21st century. This technique utilizes endoscopes, carbon dioxide laser, and the microscope to excise both glottic and supraglottic tumors by following the pathway of the tumor. It challenged traditional views by transection of the tumor to assess tumor depth and to remove tumors larger than the laryngoscope in a multipiece fashion. This technique is less invasive than traditional open procedures. It does not deconstruct the larynx or its support mechanisms and does not require reconstruction, and major complications are very uncommon. This field is continuing to evolve and is used mainly for early laryngeal cancers, but its development has led to less open conservation laryngeal surgery for advanced laryngeal cancer. The major advantages of this procedure over open procedures are the frequent avoidance of a tracheotomy, swallowing rehabilitation is of shorter duration, and it does not remove the laryngeal support structures. Limitations to this procedure include surgical expertise and special instrumentation (Fig. 124.8).

Hinni et al. in 2007 performed a multicenter study on 117 patients with advanced laryngeal cancer of the glottis or supraglottis treated with transoral laser microsurgery from 1997 to 2004. They examined laryngeal preservation, overall survival, disease-free survival, local control, locoregional control, and distant metastasis. At 2 years, 92% of patients had an intact larynx after treatment. The 5-year Kaplan-Meier estimates were local control 74%, locoregional control 68%, disease-free survival 58%, overall survival 55%, and distant metastasis 14%. They concluded that in patients with advanced laryngeal cancer, transoral laser microsurgery with or without postoperative radiation therapy is a valid treatment option for organ preservation with low mortality and morbidity with good outcomes (44). Vilaseca et al. (45) found that vocal cord fixation and cartilage invasion were found to be negative prognostic factors for transoral laser microsurgery.

Open Conservation Laryngeal Surgery

Conservational laryngeal surgery is any procedure that maintains physiologic speech and swallowing without the need for permanent tracheostoma. The goal is to preserve maximal laryngeal function without compromising cure

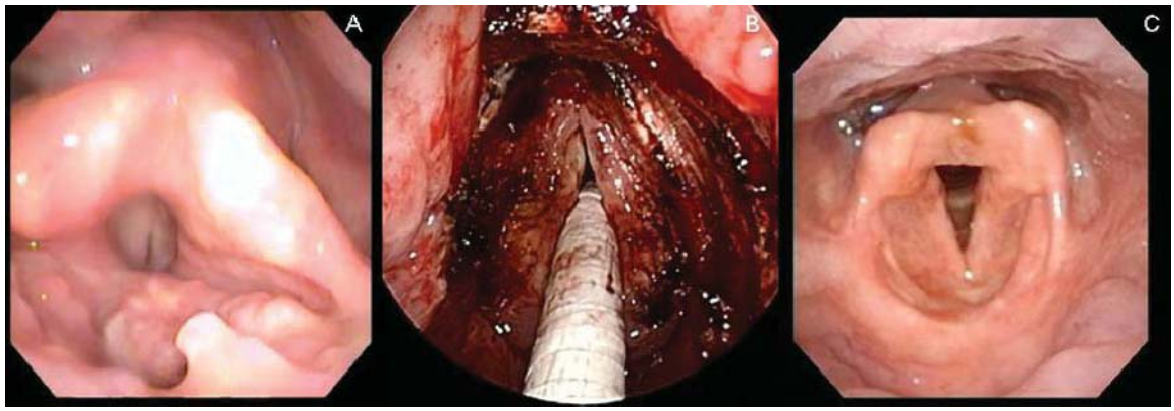

Figure 124.8 T3N0M0 SCCA treated with transoral laser microsurgery. **A:** Pre-op flexible laryngoscopy image demonstrating ulcerative cancer of laryngeal surface of the epiglottis in phonation. **B:** Intraoperative telescopic image in surgical position demonstrating postsurgical defect with hyoid visible superiorly with visible thyroid cartilage status post removal of false folds, epiglottis, and preepiglottic space with laser-shielded endotracheal tube. **C:** Postoperative flexible healed supraglottic laryngectomy defect on inhalation.

rates. Malignant disease is resected while preserving swallowing, respiration, phonation, and airway protection. In conservational laryngeal surgery, proper patient selection is critical. As long as one cricoarytenoid joint is preserved and one laryngeal valve (epiglottis, false vocal cords, or true vocal cords) is maintained, the patient is a potential candidate. The following are the partial surgical procedures and their indications.

Vertical Hemilaryngectomy

The vertical hemilaryngectomy is an organ-sparing procedure used for the treatment of glottic malignancies. This procedure allows for the en bloc removal of the involved vocal cord and a portion of the thyroid cartilage. It also addresses tumors that extend into the paraglottic space. In order for the tumor to be resected by a vertical hemilaryngectomy procedure, the tumor can be up to 5 mm onto the contralateral true vocal fold, up to 15 mm of subglottic extension anteriorly, up to 5 mm of subglottic extension posteriorly, and can extend superiorly up to the free edge of the false vocal fold. Candidates for this procedure include T1, T2, selected T3, and rare T4 glottic tumors. First, endoscopy and tracheotomy are performed. A horizontal skin incision is made separate from the tracheotomy incision. The strap muscles are retracted laterally to expose the larynx. The external perichondrium and musculature are elevated. A midline thyrotomy, cricothyrotomy, and a superior incision across the petiole are made. The lesion and thyroid cartilage are removed en bloc. The raised perichondrium and occasionally the strap muscles are used to reconstruct the neoglottis. Contraindications to this procedure include fixed true vocal fold, posterior commissure/interarytenoid involvement, invasion of bilateral arytenoids, bulky transglottic lesion, thyroid cartilage invasion, preepiglottic space involvement, subglottic extension that involves the cricoid cartilage, and extralaryngeal spread. Survival is similar between radiation and open surgical techniques. Voice outcomes are generally considered inferior to primary radiotherapy.

The extended vertical hemilaryngectomy can be subdivided into frontolateral vertical hemilaryngectomy and the posterolateral vertical hemilaryngectomy. The frontolateral hemilaryngectomy is for glottic lesions involving the anterior commissure and can encompass up to the anterior one-third of the contralateral vocal cord. The posterolateral vertical hemilaryngectomy is for lesions involving the ipsilateral arytenoid without fixation.

Vertical partial laryngectomies are used mainly for T1 and T2 tumors. Brumund et al. in 2005 studied 270 patients with previously untreated SCCA of the true vocal cord (232 T1N0M0, 35 T2N0M0, and 3 T3N0M0). These patients were treated with frontolateral vertical partial laryngectomy. The 5-year Kaplan-Meier survival estimate was 83.1% for T1 tumors and 67.2% for T2 tumors, and the local control estimate was 91% for T1 tumors and 68.7% for T2 tumors. Reduced survival was seen with advanced T stage, local failure, and nodal failure (46).

Supraglottic Laryngectomy

The supraglottic laryngectomy is also known as the horizontal hemilaryngectomy, which is used to remove the supraglottic structures superior to the true vocal cords including the preepiglottic space and leaves a portion of the thyroid cartilage and both arytenoid cartilages behind. The supraglottic laryngectomy does not clear the paraglottic space. This procedure may be indicated in T1, T2, or T3 supraglottic tumors with limited preepiglottic space involvement. Patients undergoing this procedure must have mobile vocal cords, no cartilage involvement, limited base of tongue extension, no pyriform sinus involvement, and good pulmonary reserve. All patients will have a temporary tracheotomy placed for pulmonary toilet. All patients aspirate after supraglottic laryngectomy, which is why the patients must have good cardiopulmonary reserve.

An apron incision is made separate from the tracheotomy incision, and the strap muscles are retracted laterally to expose the larynx. The perichondrium is elevated off of

the larynx, and a transverse incision is made in the thyroid cartilage at the junction of the superior one-third and inferior two-thirds. The supraglottic larynx up to the hyoid is removed. The perichondrium is then sutured to the base of tongue. Contraindications include anterior commissure or thyroid cartilage invasion, vocal cord fixation, or involvement of the pyriform apex, postcricoid mucosa base of tongue, bilateral arytenoids, and posterior commissure. The expected functional outcome is for excellent voice results and safe swallowing utilizing a supraglottic swallow.

Chun et al. in 2010 analyzed 68 patients with Stage I–IV laryngeal cancer. Forty-eight patients were initially treated with supraglottic partial laryngectomy (SPL), and 20 patients were treated with radiation therapy. In the patients receiving SPL, if they had positive nodal disease, they received postoperative radiation. The 5-year disease-free survival for patients with Stage I or II disease was 89% for SPL and 100% for radiation. The overall 5-year survival was 87% and 80% for SPL and radiation therapy, respectively. In patients with Stage III or IV disease, the 5-year disease-free survival was 85% for patients receiving SPL and 52% for radiation therapy. The overall 5-year survival was 83% and 61% for SPL and radiation therapy, respectively (47).

Supracricoid Partial Laryngectomy

This technique adds to the previous supraglottic laryngectomy to remove the supraglottis plus the true vocal cords and thyroid cartilage. This procedure not only clears the preepiglottic space but can also clear the paraglottic space. Supracricoid laryngectomy was first described by Majer and Rieder in 1959, as an alternative to total laryngectomy (48), and popularized in the United States through the work of Laccourreye and Weinstein (49,50). One functional arytenoid must be preserved; therefore, careful patient selection is critical. Indications for this procedure include supraglottic cancer with glottic and anterior commissure involvement, ventricle invasion, thyroid cartilage invasion, true vocal cord immobility, paraglottic space invasion, moderate preepiglottic space involvement, and transglottic tumors. The cricoid cartilage, hyoid bone, and at least one arytenoid cartilage are spared. This procedure is indicated for T2, T3, and T4 cancers of the glottis and supraglottis. As with supraglottic laryngectomy, the patient must have good cardiopulmonary reserve. The type of supracricoid laryngectomy is named for its reconstruction. Reconstruction is by cricohyoidopexy or cricohyoidoepiglottopexy depending on the absence or presence of an epiglottic remnant. This also determines whether the tumor that is being treated is supraglottic (cricohyoidopexy) or glottic (cricohyoidoepiglottopexy). This reconstruction helps to restore a symmetric valve, which aids the patient in voicing as well as airway protection. The functional outcome for voice and swallow is good, but like most conservation procedures requires a dedicated period of rehabilitation.

In 1990, Laccourreye et al. examined 36 patients with SCCA of the glottis who underwent partial horizontal supracricoid laryngectomy with cricohyoidoepiglottopexy. All 36 recovered physiologic deglutition and phonation. None required tracheotomy. The 3-year survival rate was 86.5% with a recurrence rate of 5.5% (50). Also in 1990, Laccourreye et al. examined 68 patients with supraglottic carcinoma who underwent supracricoid laryngectomy with cricohyoidopexy. Supraglottic laryngectomy was contraindicated in all patients. 95.4% of the patients recovered physiologic deglutition. The 3-year survival was 71.4%, and no local recurrences were noted (49). This procedure has been found to be a useful alternative for the treatment of selected cases of laryngeal cancer (Fig. 124.9).

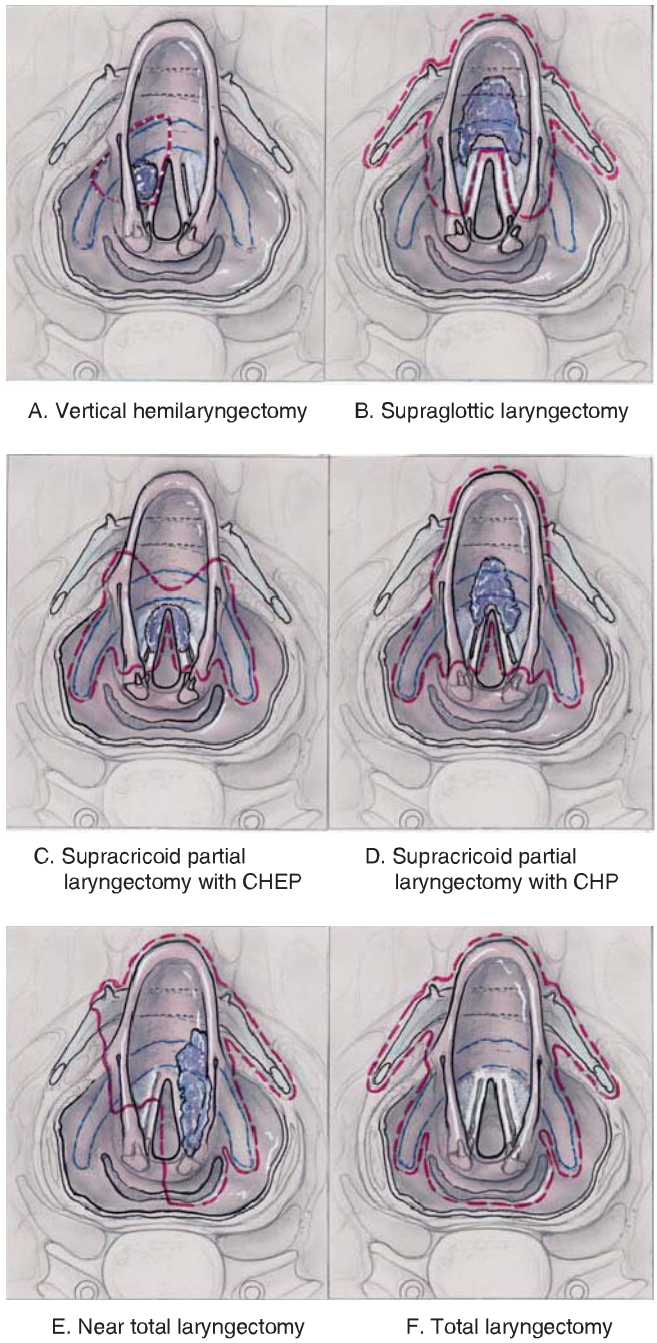

Figure 124.9 **A–F:** Resection outline by conservation procedure.

Near-Total Laryngectomy

Near-total laryngectomy, or the Pearson procedure, is a voice preservation surgery used for large T3 and T4 lesions of the unilateral larynx not amenable to supraglottic or supracricoid laryngectomy. The procedure includes resection of one hemilarynx with the anterior portion of the contralateral cord. It also includes the ipsilateral cricoid and can include a portion of the proximal trachea. A permanent tracheostoma is created for respiration, and voice is produced through a dynamic tracheoesophageal conduit. Contraindications to this procedure include interarytenoid involvement, postcricoid involvement, and the inability to preserve two-thirds of the contralateral cord. Functional outcomes include a permanent tracheostoma, normal swallow, and a speech fistula. This technique is technically challenging.

In 1998, Pearson et al. studied 233 patients who underwent near-total laryngectomy for laryngeal or pharyngeal cancer. They found that the control rates were similar to that expected for total laryngectomy of total laryngopharyngectomy. Conversational voice was achieved in 85% of patients surviving greater than 1 year. There were eight local recurrences (7%). Five of the eight recurrences occurred in patients whose near-total laryngectomy was for surgical salvage or irradiation failure. They concluded that near-total laryngectomy was an alternative to total laryngectomy but that it should not be used for surgical salvage (51).

Total Laryngectomy

Total laryngectomy is the gold standard treatment for laryngeal cancer and has the best oncologic outcome for which all partial laryngectomies should strive to achieve. It was first successfully performed by Billroth in 1873 (5) but has been further refined by Gluck and Sorenson in 1894 (52). It is indicated for T3 and T4 advanced stage laryngeal cancers, chemotherapy and radiation failures, and conservation laryngeal surgery failures. Total laryngectomy provides excellent control rates but with the sacrifice of natural voice. The procedure includes an en bloc resection of the larynx, including the hyoid bone, thyroid cartilage, and cricoid cartilage to the proximal tracheal rings inferiorly. Combined with this procedure may be resection of the pharyngeal wall and base of tongue. The trachea is then sutured to the skin to form a tracheostoma. The pharyngeal wall is closed upon itself to form a digestive path separate from respiration.

The key to success in total laryngectomy is maximizing QOL by maximizing alaryngeal function. Carefully creating an accessible stoma by releasing the sternal heads of the sternocleidomastoid muscle and suspending the trachea to prevent traction that can lead to stomal stenosis are helpful in patients managing their stomas and easing voice restoration with tracheoesophageal speech. In order to improve deglutition and alaryngeal voicing, a complete cricopharyngeal myotomy or pharyngeal plexus neurectomy should be performed. If not performed adequately, the patient may have difficulty swallowing and require esophageal dilatations or other measures to improve voice and swallowing. Voice restoration is obtained through tracheoesophageal speech, esophageal speech, or an artificial larynx.

Overall 5-year disease-free survival for T3 glottic tumors treated with total laryngectomy varies according to the study but ranges 49% to 80% (53–55). The 5-year overall survival is 54% (35). For T4 tumors of the glottis, the 5-year overall survival after total laryngectomy ranges from 32% to 63% (36,54,55). The overall recurrence rate for Stage III and IV glottic tumors was 37% with 19% recurring at the primary site and 17% recurring in the neck (36).

Advanced laryngeal tumors can involve structures outside of the larynx. Tumors can extend to directly involve the hypopharynx or oropharynx. Hypopharyngeal tumors with the piriform sinuses and postcricoid mucosa making up two of the hypopharyngeal sites are in direct contact with the larynx. Tumors that cross these boundaries frequently require extended surgical resections that can encompass the entire pharynx, namely, a laryngopharyngectomy. Similarly large tumors that involve the subglottis or the hypopharynx often involve the trachea and/or the esophagus necessitating extended excisions that may require an esophagectomy to ensure adequate margins.

Salvage Total Laryngectomy

Patients who fail organ preservation therapy with chemoradiation therapy for their advanced laryngeal cancer require surgical salvage. Once the patient has received chemoradiation therapy, only in highly selected cases are patients still candidates for conservation laryngeal surgery with most requiring salvage total laryngectomy. Many studies looking at overall survival in treatment with chemotherapy and radiation therapy include salvage laryngectomy in their outcome data. Patients requiring surgical salvage whether it is through conservation surgery or with total laryngectomy have a higher surgical complication rate. Salvage total laryngectomy is also frequently required if a patient fails conservation laryngeal surgery. In 2006, Fowler et al. examined the overall survival in patients undergoing salvage total laryngectomy. They found the 5-year and 10-year overall survival after salvage total laryngectomy to be 65.2% and 37.7%, respectively (56).

Postlaryngectomy Recurrence

Laryngeal cancer not only has a risk of regional and distant metastases; it can recur locally as well after total laryngectomy or salvage total laryngectomy. The most common location for the local recurrence is in the tracheal stoma. The incidence of stomal recurrence is 2% to 25% (57). The Sisson classification was developed to identify the location of the recurrence and the appropriate management and outcome (58). Type I is localized to the superior aspect of the stoma without esophageal involvement. Type II is

localized to the superior aspect of the stoma with esophageal involvement. Type III originates in the inferior aspect of the stoma with involvement of the superior mediastinum. Type IV has extension laterally beneath the clavicle and into the superior mediastinum. Type I and II stomal recurrences are best treated with salvage therapy. However, Sisson type III and IV are generally considered unresectable, and nonoperative management involving chemoradiation or re-irradiation should be used (59,60).

Subglottic Carcinoma

Subglottic carcinoma usually presents with airway obstruction and hemoptysis. It is rare to find a primary subglottic carcinoma. Since there are so few, there are no studies examining treatment protocols and outcomes. Subglottic carcinomas have no barriers to the spread of disease and usually present with extensive cartilage invasion. The accepted treatment for subglottic carcinoma is total laryngectomy and tracheal resection below the level of the disease.

In 1998, Dahm et al. performed a retrospective review of 39 patients treated for primary subglottic cancer. 32.1% of the patients were diagnosed with advanced stage subglottic cancer. The 5-year overall survival and disease-free survival were 57.7% and 46.2%, respectively. Patients treated with radiotherapy alone, surgery alone, or both had disease-free 5-year survival of 22.2%, 41.7%, and 100%, respectively (9).

Surgery versus Chemoradiation

Over the last two decades, survival from laryngeal cancer has unfortunately decreased. There has been a great interest in determining the etiology associated with the decreased survival. In 2009, Gourin et al. performed a retrospective review of patients diagnosed with laryngeal cancer between 1985 and 2002. They found the 5-year survival rates were 85% for Stage I, 77% for Stage II, 51% for Stage III, and 35% for Stage IV disease. Survival for patients with Stage I–III disease was similar for patients treated operatively and nonoperatively. Patients with Stage III disease had a worse survival when treated with radiation alone as compared to chemoradiation. Patients with Stage IV disease had better survival after surgery (55%) as compared to chemoradiation (25%) or radiation alone (0%) (61).

In 2007, Chen et al. examined factors predictive of survival in advanced laryngeal cancer. During 1995 to 1998, 10,590 patients (7,019 patients included in the study) with Stage III or IV SCCA of the larynx were examined. These patients were treated with total laryngectomy, radiotherapy, or chemoradiation. They found that total laryngectomy, when compared with radiation therapy or chemoradiation, had increased survival. Death rates with radiotherapy alone and chemoradiation were 60% and 30% higher, respectively, than those following total laryngectomy. In Stage IV disease, the death rate was 43% higher with chemoradiation than with total laryngectomy. In Stage III disease, there is no significant disadvantage for chemoradiation relative to total laryngectomy. However, radiation alone was associated with significantly higher death rates relative to total laryngectomy in stage III as well as stage IV patients. They found that overall survival was decreased in men, African American patients as compared to Caucasians and in patients with Medicare, Medicaid, or uninsured (62).

In 2010, Chen et al. identified 19,326 patients through the National Cancer Database who were diagnosed with advanced laryngeal cancer between 1996 and 2002 and were treated with chemoradiation therapy, total laryngectomy, or radiotherapy. The objective was to determine if patients treated at a high volume teaching facility had a better survival. They found that patients who received treatment at low volume facilities had a poorer survival when compared to those treated at higher volume facilities. It was also found that patients with advanced T4 disease who were treated with total laryngectomy had an increased survival when compared to chemoradiation therapy (63).

Treatment of the Neck

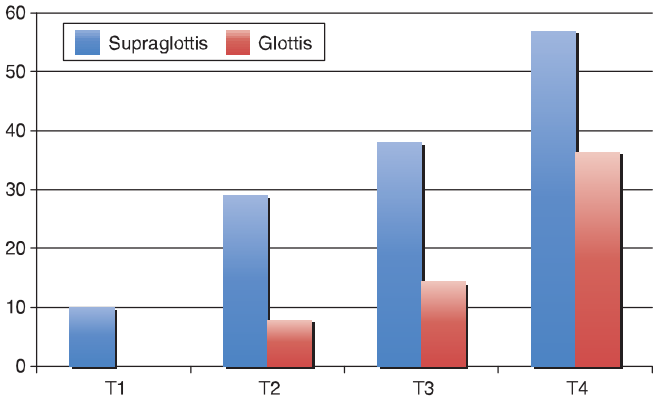
When deciding whether to treat the neck, the likelihood of regional spread into the cervical lymphatics must be taken into account. As previously stated, the supraglottic larynx has a rich lymphatic supply as compared to the glottis, and also tends to spread to bilateral cervical lymph nodes. As a result of the poor lymphatic supply to the glottis, there is unlikely to be cervical spread until the primary tumor is stage T3 or greater. The nodal basins that are of greatest risk are levels II–IV and the central compartment level VI. Generally accepted guidelines suggest that the neck should be treated if there is a 20% to 30% chance of regional metastasis. T3 glottic tumors have a 10% to 20% risk of regional spread, and T4 glottic tumors have a 25% to 40% risk of spread. Whereas T3 supraglottic tumors have a risk of 38% to 65%, T4 supraglottic tumors have a greater than 57% risk of lymphatic spread (64–69) (Table 124.3).

The N0 neck at risk for nodal metastasis and the N1 neck can be treated with radiation or surgery depending on the treatment of the primary tumor. If radiation is the treatment option, the field can be extended to include the nodal basins at risk. If surgery is the best treatment option, a selective neck dissection can be performed with limited morbidity. For N2 and N3 disease, the neck is best treated with multimodality therapy including surgery and radiation therapy. Occasionally, advanced neck disease will require a more extensive neck dissection including levels II–V as a modified radical or radical neck dissection depending on which structures are involved.

Surgical Complications

As with all head and neck surgery, complications arise including hematoma, infection, and skin flap necrosis.

TABLE 124.3 INCIDENCE (%) OF CERVICAL METASTASIS BASED ON SITE AND T STAGE



Redaelli de Zinis LO, et al. The distribution of lymph node metastases in supraglottic squamous cell carcinoma: therapeutic implications. *Head Neck* 2002;24(10):913–920; Zhang B, Xu ZG, Tang PZ. Elective lateral neck dissection for laryngeal cancer in the clinically negative neck. *J Surg Oncol* 2006;93(6):464–467.

Head and neck surgery is considered a clean-contaminated procedure, and the risk of postoperative infection is increased. Therefore, prophylactic, perioperative antibiotics are given. There are many other complications that occur specific to laryngeal surgery. One important early complication is pharyngocutaneous fistula. This occurs as a result from failed surgical closure of the pharynx or larynx allowing contents to travel from the pharynx/larynx through the neck to the skin. The risk of fistula formation increases with poor nutritional status, previous radiation therapy, and in patients who received preoperative chemotherapy and radiation therapy. Small fistulas can be treated conservatively with holding of oral feeds and local wound care. Larger fistulas may require additional surgical procedures including debridement, closure of the fistula, regional tissue transfer, or free tissue transfer. Recurrence or residual cancer should be suspected for fistulas that fail to respond to treatment or for late-occurring fistulas. Other early complications include aspiration pneumonia, wound dehiscence, hypocalcemia, and chyle leak/fistula. This can be avoided by meticulous dissection in Level IV to avoid injuring the thoracic duct.

Figure 124.10 Post total laryngectomy pharyngocutaneous fistula on barium esophagram. Lateral cervical x-ray with *arrow* pointing to contrast leaking from pharyngeal closure, staple line visible.

Late complications include pharyngeal/esophageal stricture, which can lead to swallowing dysfunction and failure of esophageal and tracheoesophageal speech. This may require periodic esophageal dilation. Tracheal stoma stenosis is another late complication that can be prevented by avoiding excess tension on the stoma, by releasing the medial heads of the sternocleidomastoid muscle, by beveling the transected trachea when making the tumor cuts, and by "walking" the stoma out to the skin while sewing it during stomal construction. Hypothyroidism can also occur after surgery or radiation. Serial thyroid-stimulating hormone testing should be used to prevent the consequences of hypothyroidism (Fig. 124.10).

POSTTREATMENT QUALITY OF LIFE AND FUNCTIONAL OUTCOMES

The larynx's primary function is airway protection with its vital role in breathing and swallowing. It is equally essential in voice, and all three functions are at risk with laryngeal cancer and its treatment. Surgery, chemotherapy, radiotherapy, and combined modality treatments can have transient or permanent effects on voice, swallowing, and breathing. The resulting deficits have a direct impact on patient's QOL, and pretreatment perceptions of these risks frequently color a patient's choice of therapy. Patients with voice and swallowing difficulties may experience tremendous frustration that can lead to severe depression due to the loss of social, cultural, and personal satisfaction associated with talking, eating, and drinking. Loss of voice can also impact the patient's work and income. Different treatment modalities for advanced laryngeal cancers may offer similar survival but may differ in health-related quality of life (HRQOL). It is very important to consider the potential HRQOL changes and organ function as an outcome of these treatment modalities and a component in helping patients select the optimal treatment modality.

One of the first studies to assess QOL issues in patients with laryngeal cancer was the "Fireman study" by McNeil et al. in 1981. In this study, 37 healthy volunteers (12 firefighters and 25 executives) were asked to choose a treatment option based on perceived changes in QOL after total

laryngectomy. Patients were also given a questionnaire to determine what impact these changes would have on them. Based on the questionnaires, McNeil et al. found that 10 years of survival with normal speech was equivalent to 7 years survival with artificial speech. They also found that 20% of subjects would choose a treatment to preserve their larynx even if it meant a possible shorter survival, based on the perceived adverse effect to QOL after total laryngectomy (70).

Terrell et al. (71) investigated the long-term QOL in surviving patients with advanced laryngeal cancer that originally participated in the Veterans Affairs Laryngeal Cancer Study (40). They used the University of Michigan Head and Neck Quality of Life (HNQOL) instrument (72) and Medical Outcomes Studies Short Form-36 (SF-36) (73). They found that the chemoradiation group (CT + RT) had better QOL scores than the laryngectomy and radiation group (TL + RT) after 10 or more years following initial grouping. They concluded that this result appeared to be related to more freedom from pain, better emotional well-being, and lower levels of depression rather than preservation of speech function. The authors reported that there were no statistical differences between the two groups in speech and swallowing domains of the HNQOL in the study. The authors also noted that the detectable speech intelligibility scores differences at 24 months between CT + RT and TL + RT groups as initially reported by Hillman et al. study (74) disappeared in their 10-year follow-up study. Fung et al. (75) measured the vocal function using Voice-Related Quality of Life Measure and reported that the chemoradiation group had worse scores compare to normal subjects but better scores than the salvage laryngectomy group. With respect to swallowing function, they further reported that the chemoradiated patients did as well as the laryngectomies but had more dietary restrictions.

Different studies however support different conclusions on functional outcomes. Hanna et al. (76), in a retrospective study, reported treatment-related toxic effects in patients who received intensive CT + RT for their advanced cancer of head and neck. The authors reported dehydration, pneumonia, and malnutrition as some of the most frequent causes for the unscheduled hospitalizations of the subjects, which had significant effect on the overall cost of treatment. In addition, 93% of their subjects required G-tube placement to offset weight loss, poor oral intake, dehydration, and malnutrition and electrolyte imbalance. Weight loss was a considerable problem among their patients despite the PEG-tube placement not only during treatment but even 1 year after treatment. In addition, PEG-tube placement did not substantially reduce the unscheduled hospitalizations in their study. The study also found that 40% of the subjects changed their diet posttreatment due to dysphagia. Other studies, however, (77,78) have reported similar overall QOL scores for patients undergoing total laryngectomy with those that receive chemotherapy and radiation therapy.

Conservation laryngeal surgery techniques such as supraglottic and supracricoid partial laryngectomy can be performed for advanced laryngeal cancers as a first-line organ-sparing procedure or as salvage following radiation failure. The success of these procedures depends not only on tumor characteristics but also on appropriate patient selection. Adequate pulmonary function and commitment to rehabilitation are as important as the remaining larynx being functional enough to ensure prevention of aspiration, while maintaining voice and airway. Almost all patients initially aspirate, and postoperative rehabilitation for voice and swallowing function begins as early as possible to restore swallowing function. The successful rehabilitation of voice and swallowing following conservation laryngeal surgery depends on comprehensive evaluation and teamwork between the surgeon, patient and family, and the rehabilitation team. An optimal protocol should begin with preoperative counseling and functional assessment as well as posttreatment evaluation and rehabilitation of voice and swallowing function.

EMERGENCIES

As with all emergencies, the airway must be established first, and patients with advanced laryngeal cancer can initially present with symptoms of airway distress and impending airway obstruction. Similarly, patients who receive radiation therapy can develop airway edema and airway obstruction. Managing airway distress without a tracheotomy when safe is preferable in untreated laryngeal cancer patients. If possible, the patient should undergo fiberoptic nasotracheal intubation followed by debulking of the tumor. If the patient must undergo tracheotomy, the tracheotomy should be performed high so that the tracheostomy may be removed with the resection. Other emergencies in advanced laryngeal cancer include complications of chondroradionecrosis or pharyngocutaneous fistula putting the great vessels of the neck at risk. It is important to have an awareness of these complications and provide appropriate management to avoid these emergencies.

HIGHLIGHTS

- The larynx produces one of the most complex motor functions in the body. It provides an airway for respiration, deglutition, and phonation. Laryngeal cancer can alter one or more of these functions.
- Five-year overall survival has worsened over the past 30 years (67% to 63%) despite efforts to improve treatment.
- The larynx contains several fibroelastic membranes, ligaments, and spaces that divide the larynx into compartments, limit the spread of early cancers, and allow for partial resections with adequate margins.

- Careful preoperative evaluation includes history and physical, flexible endoscopy, imaging through CT (to assess extent of invasion), and PET (to assess regional and distant metastasis).
- Surgical endoscopy is critical to map out the boundaries of the tumor, to determine cricoarytenoid joint mobility, and to differentiate vocal cord immobility from vocal cord fixation in order to accurately stage the tumor and develop the best treatment plan.
- Ninety-five to ninety-nine percent of laryngeal malignancies are SCCA.
- Treatment for advanced laryngeal cancer is multimodality therapy with surgery followed by radiation or radiation and chemotherapy.
- Endoscopic laser resection is used mainly for early laryngeal cancers, but its use on certain T3 and T4 tumors is becoming more accepted.
- Conservation laryngeal surgery is an option for advanced laryngeal cancer, but the tumor must be accurately staged and boundaries identified in order for these procedures to be performed.
- Total laryngectomy remains the gold standard surgical procedure for advanced laryngeal cancer from which all other surgeries are derived.
- Postoperative radiation improves locoregional control and survival.
- Chemotherapy (induction or concurrent) decreases the risk of distant metastasis.
- Treatment of the neck for nodal metastasis must be considered if the nodal metastases risk is greater than 20% to 30% or if there is palpable nodal disease.
- Postoperative complications increase after prior radiation therapy.

125 Voice Rehabilitation Following Laryngectomy

Anna M. Pou

The larynx is the second most common site for cancer in the upper aerodigestive tract, of which squamous cell carcinoma (SCCA) is the predominant type (95%) (see Chapters 123 and 124). Although organ preservation protocols and conservation laryngeal surgeries are in use today, patients with advanced or recurrent SCCA of the larynx continue to undergo total laryngectomy in the course of their treatment.

The operative procedure of total laryngectomy results in separation of the aerodigestive tract, establishing a permanent tracheostoma at the base of the neck. The pharynx is closed by simply closing the mucosa or, in more complex cases, by placing a flap to preserve an adequate lumen for swallowing. Total laryngectomy profoundly alters speech, lung function, respiration, and sense of smell and taste. It is the loss of voice that is most responsible for the psychosocial and economic consequences following laryngectomy. Effective voice restoration is essential for the rehabilitation of these patients.

Total laryngectomy includes removal of the entire larynx, hyoid bone, portions of the pharynx, the strap muscles, one or more rings of the trachea, and part or all of the thyroid gland. The resection may include neck dissection, upper mediastinal lymph node dissection, and dissection of portions of the tongue base. In order to resect the larynx, entrance into the pharynx away from the epicenter of the tumor is required. The resulting defect, a pharyngotomy, consists of varying amounts of pharyngeal and esophageal mucosa, constrictor muscle remnants, and tongue base. The closure of this defect depends upon the amount of remaining mucosa; it is closed using continuous or interrupted Connell sutures in a vertical or "T" fashion. Flap reconstruction (free fasciocutaneous flap; pectoral major flap) is used when there is insufficient mucosa to close the pharynx.

The usual approach to laryngectomy separates the pharyngeal constrictor muscles at the oblique line of the thyroid cartilage (Fig. 125.1). Specifically this includes the inferior pharyngeal constrictor and cricopharyngeus muscles. The junction of the pharynx and esophagus has been studied by speech pathologists as the sound source for alaryngeal speech and is called the "PE" segment. It is difficult to predict resultant voice or quality because of variations in anatomy, tumor extent, muscle bulk, and operative technique. Pharyngeal closure after laryngectomy is generally concerned with controlling secretions, swallowing, and prevention of fistula formation. In addition, attention has been directed to alaryngeal voice acquisition and the possibilities for maximizing voice results.

There are three methods of alaryngeal speech: electrolarynx speech, esophageal speech, and tracheoesophageal (TE) speech. Historically speaking, esophageal speech was the method of choice by which all others were compared. In this method, air is injected into the cervical esophagus and immediately expelled causing the vibration of the opposing mucosal surfaces of the pharyngoesophagus, which is then articulated into speech by structures of the oral cavity. This method is very difficult to learn, and only about 26% of patients are able to use this method in daily communications (1). Consequently, tracheoesophageal puncture (TEP) has replaced esophageal speech as the gold standard. All methods of alaryngeal speech are taught by a speech pathologist.

The characteristic esophageal voice is low in fundamental frequency (~65 Hz), is of short duration, and requires some effort to produce. The most common method involves trapping air in the mouth or pharynx and then injecting it into the esophagus by the propulsive action of the tongue. With diaphragmatic effort, the air refluxes through the esophagus and crosses the upper esophageal sphincter. The mucosa of this region is vibrated by the released air and produces a characteristic belch-like

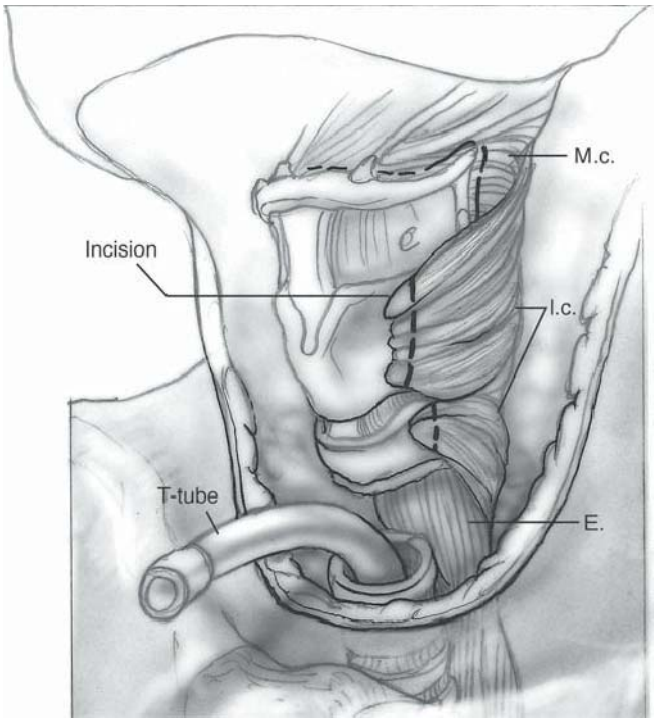

Figure 125.1 Separation of the pharyngeal constrictors from the larynx. E, esophagus; Ic, inferior constrictor; Mc, middle pharyngeal constrictor.

sound. This sound is then articulated into speech using the tongue, lips, and teeth. Rapid repetitive movements of injection and release produce fluent and understandable speech.

The artificial larynx is an instrument that serves as a voicing source. It introduces a mechanical sound into the tissues and air spaces of the vocal tract. This sound, emanating from the mouth, is again articulated into speech by structures in the oral cavity. The most common types of electrolarynx include one that is placed against a supple point on the neck or one that uses a tube adapter to direct the sound to the oral cavity, where it can be articulated with some reduction in intelligibility. The oral adapter is useful for patients whose necks do not transmit the electrical sound or in the immediate postoperative period when the neck is healing. A newer device consists of an electric sound source that is housed in a denture and is activated by a hand control or by the tongue (2).

The artificial larynx is rapidly learned and does not delay or interfere with the acquisition of other forms of alaryngeal speech. It has the advantages of low cost, availability, short learning time, and loudness. Its disadvantages are dependence on batteries (cost often not covered by insurance), mechanical sound, conspicuous appearance, loss of hands-free speech, and hygiene of the intraoral tubes or dental appliance. It also relies on the use of batteries and is often not covered by insurance policies. Nevertheless, many laryngectomized patients use the artificial devices as the primary method for speech communication.

SHUNTS AND VALVES

From the time of the first laryngectomies, it was known that tracheal air during exhalation can be shunted to the pharynx or esophagus through a planned fistula or tract, and this pulmonary-driven insufflation can produce effective speech. The same principles of speech production apply with articulation at the oral cavity and sound produced in the upper esophageal sphincter. The shunts, however, persisted with problems: shunt closure due to stenosis at the level of the trachea or pharynx and leakage of esophageal contents into the trachea through the patent shunt with resultant aspiration. For these reasons, some investigators developed mechanical valves to divert the secretions from the trachea or attempted to devise biologic valves (sphincters) for airway protection, but most of them failed.

The creation of a successful, surgical voice restoration technique did not occur until the introduction of the TEP by Singer and Blom in 1979. It was proposed as a secondary salvage technique for those who failed esophageal speech or those who were displeased with the electrolarynx voice (3). The guidelines used to create this revolutionary method for voice restoration were no oncologic compromise; applicability in an irradiated field; normal swallowing without aspiration; reliable voice; surgical simplicity; rapid recovery; reliability and reproducibility; inclusion of an uncomplicated, cost-effective prosthetic valve to prevent stenosis and aspiration; and limited cost (4). TE voice restoration has gained worldwide acceptance over the past 32 years and is the preferred method of postlaryngectomy speech. TEP is safe, reliable, and reproducible and should be considered in all patients undergoing total laryngectomy and in those who have failed to master other methods of alaryngeal speech.

The TEP pioneered by Singer and Blom (3) is not very different from the self-inflicted TEP made by a laryngectomy patient using an ice pick in 1931. An endoscopic puncture is made through the party wall through which a one-way silicone valve is placed. This tubular prosthesis (silicone) maintains the puncture site, protects the airway from aspiration of saliva and foods, and allows pulmonary air to be directed across the pharyngoesophageal mucosa for voice production. Airflow is only limited by the vital capacity of the lungs. The prosthesis is biologically compatible, removable, and inexpensive. Various modifications and improvements have been made on the prosthesis since 1978 (3). Other prostheses have also been introduced (Provox, Groningen).

SECONDARY TRACHEOESOPHAGEAL PUNCTURE

Patient Selection and Timing

There are a few factors that guide patient selection and they are similar to those listed for primary TEP. The timing of secondary puncture depends upon the extent of resection,

the complexity of reconstruction, and the need for postoperative radiation therapy. Secondary voice restoration should be delayed at least 8 weeks following postoperative radiation therapy or until the peristomal skin has recovered from radiation toxicity and at least 6 weeks following recovery from reconstruction of a total laryngopharyngoesophagectomy defect in order to allow healing of the flap to the posterior tracheal wall. Patients undergoing flap reconstruction for pharyngeal defects should also undergo barium swallow to evaluate the reconstructive changes and for the presence of a stricture. The stoma is outlined with a radiopaque marker, and the site for the proposed puncture is determined in relationship to the pharyngoesophageal segment. Pharyngoesophageal dilatation is performed if necessary (5).

Stoma size is critical to successful use of the voice prosthesis. Stoma size under 2 cm is suboptimal; this small size makes it difficult to place the prosthesis and may compromise the airway due to the prosthesis size. If microstomia is present, the stoma can be serially dilated using silicone laryngectomy tubes, or a stomaplasty can be performed at the time of puncture. Patients who have undergone radiation therapy whose tissues appear to be at risk are better managed by the former method. If a laryngectomy tube is used, it can be fenestrated posteriorly and simultaneously worn with the prosthesis in place. When necessary, the stomaplasty is performed prior to the puncture leaving the posterior wall intact. The stoma is enlarged using a Z-plasty technique on each side (5).

In order for fluent TE speech to occur, there must be sufficient relaxation of the pharynx. There was a subset of patients (20% to 40%) identified early on who presented with hypertonic or spastic speech. It was determined that failure to maintain fluent speech was due to spasm of the cricopharyngeus and inferior and middle constrictor muscles when speech was attempted (6,7). A hypopharyngeal bar corresponding to these muscles can be seen using barium swallow. A column of air distends the esophagus proximal to the bar when phonation is attempted. The status of the pharynx can be evaluated prior to puncture using the transnasal esophageal insufflation test (5).

The transnasal esophageal insufflation test is a subjective test that is used to assess the pharyngeal constrictor muscle response to esophageal distention in the laryngectomy patient (8). The test is performed using a disposable kit consisting of a 50-cm-long catheter and tracheostoma tape housing with a removable adaptor. The catheter is placed through the nostril until the 25-cm mark is reached. This should place the catheter in the cervical esophagus adjacent to the proposed TEP. The catheter and the adaptor are taped into place. The patient is then asked to count from 1 to 15 and to sustain an "ah" for at least 8 seconds without interruption. Multiple trials are performed to allow the patient to produce a reliable sample.

One of four responses is obtained following the insufflation test: fluent, sustained voice production with minimal effort indicating relaxed pharyngoesophageal muscles; a breathy, hypotonic voice indicating the absence of pharyngeal constrictor muscle tone; hypertonic voice characterized by intermittent production of effortful speech with gastric distension and posttrial burping; and spasm, which is characterized by no production of voice even with substantial pulmonary airflow. Insufflation testing is also done after flap reconstruction or gastric pull-up to determine the quality of voice (5). The voice quality is usually "wet" following jejunal reconstruction and hollow or breathy following gastric pull-up. Compression of the neck with an elastic band can enhance voice quality in the latter situation.

Examiner error can obscure the results of the test. Common errors include improper placement of the catheter (not inserted 25 cm into the cervical esophagus), too much digital pressure exerted by the patient or examiner on the tracheostoma, and attempting to swallow saliva or inject air from the mouth into the esophagus while simultaneously insufflating the esophagus. The patient errors can be prevented by having the patient self-monitor using a mirror (5).

Surgical Procedure

This procedure was first described by Singer and Blom in 1979 (3) and has been modified over the years. The following procedure is performed in the operating room under general anesthesia. The Blom-Singer tracheostoma puncture kit (InHealth Technologies, Carpinteria, CA) allows the surgeon to perform the secondary puncture in less than 30 minutes. Following esophagoscopy, the esophagoscope (surgeon's choice) is withdrawn to the level of the stoma with the bevel positioned against the posterior wall of the trachea so that the light can be seen and the bevel palpated. The position of the esophagoscope also protects the posterior esophageal wall from penetration. A number 14 sheathed catheter is introduced into the bevel of the esophagoscope about 5 mm below the mucocutaneous junction. The needle is withdrawn leaving the sheath in place (Fig. 125.2). A wire on a tapered catheter is threaded through the sheath and pulled out of the mouth of the esophagoscope. The wire is cut from the end of the catheter, which is then directed down the scope into the esophagus. The catheter is secured into place at the stoma (5). This kit can be replaced by using a curved 18-gauge needle, a 24-gauge wire, red rubber catheter, number 15 scalpel blade, and hemostat. The prosthesis can be placed immediately, but most clinicians wait 48 hours.

This technique has been modified by many clinicians over the years to include the use of local anesthesia, transnasal esophagoscopy (TNE), and the use of the KTP laser, among other methods (9–12). In patients who present with a stricture, fibrosis of the neck tissues following radiation therapy, or cervical spine deformity, it is often impossible to perform a secondary TEP using a rigid esophagoscope.

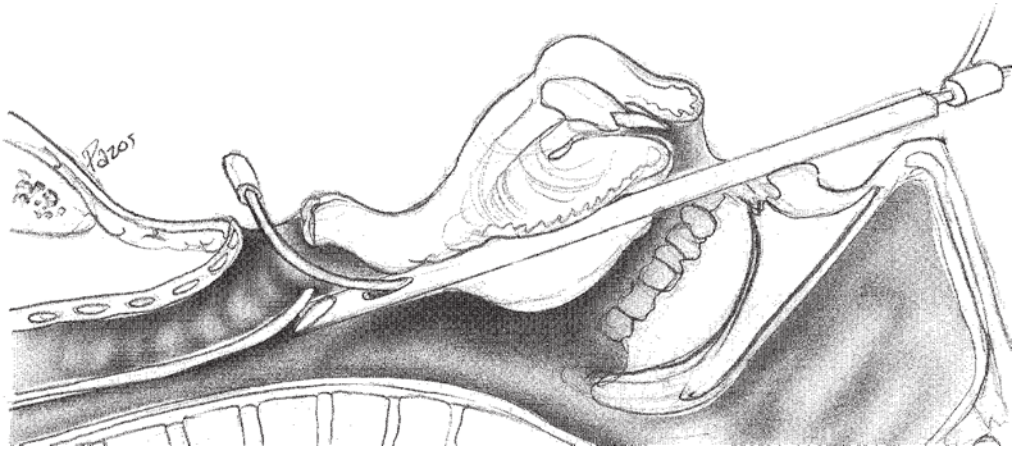

Figure 125.2 Endoscopic voice restoration (TEP).

Many surgeons have developed their own techniques for dealing with this problem, but the most common way to deal with this now is using flexible esophagoscopy in the office under local anesthesia (11,12). In a study performed by LeBert et al. (11), the overall success rate of TNE-assisted TEP was 97%. Only 1/39 patient attempts was unsuccessful. Regarding previous radiation therapy, myotomy, and type of reconstruction, there was no statistically significant difference among patients regarding difficulty with placement of prosthesis, development of complications, use of TEP prosthesis, or speech intelligibility.

The method of TNE-assisted TEP is described below. Pontocaine and Neo-Synephrine are sprayed into the more patent nare. Up to 1.0 mL of 1% lidocaine with 1:100,000 epinephrine is injected into the posterior tracheal wall at the intended TEP site. Pledgets soaked with 4% lidocaine or 2% lidocaine jelly are placed in the nasal cavity. The TNE scope is also coated with 2% lidocaine jelly. The TNE scope is advanced through the nasopharynx and oropharynx into the hypopharynx to reach the upper esophageal inlet. The anatomic subsites are evaluated for abnormal function and masses. The patient is then asked to swallow to assist with advancement of the scope into the esophagus. Flexible esophagoscopy to the limits of the lower esophageal sphincter is then performed under direct visualization, maintaining the view by air insufflation as needed. The exam is visualized using the video monitor. The endoscope is withdrawn until the light at the tip of the scope transilluminates the site of puncture of the anterior esophageal wall. This site is then confirmed by visualization of the indentation of the posterior tracheal wall by ballottement. A number 11 blade is used to incise the posterior tracheal wall. The esophageal wall is entered under direct visualization. A hemostat is used to dilate the puncture site. A dilator is introduced into the new TEP site and then removed. The prosthesis can be immediately placed if desired or the puncture site can be stented open with a 16-French red rubber catheter until the prosthesis is placed. If there is difficulty transilluminating the TEP site due to a bulky flap or scar tissue, this technique can be modified using the Seldinger guide wire technique (11).

PRIMARY VOICE RESTORATION

Selection Criteria

Maves and Lingeman (13) and Hamaker et al. (14) were the first to introduce TEP as a primary technique at the time of laryngectomy. Primary voice restoration developed from the concepts of secondary voice restoration. The only absolute contraindication to primary voice restoration is separation of the party wall at the puncture site. This occurs if the surgeon inadvertently separates the party wall or when a patient undergoes a total laryngopharyngoesophagectomy with gastric pull-up. If a puncture is performed following separation of the party wall, abscess formation, sloughing of the posterior tracheal wall, and possibly mediastinitis can occur.

Relative contraindications to primary (and secondary) TEP include the complexity of the reconstruction and the patient's inability to use and care for the prosthesis due to impaired mental status or decrease in manual dexterity due to age, arthritis, or neurologic insult/disease. With the introduction of the indwelling prosthesis and the hands-free valve, most of these obstacles have become manageable with the assistance of a care taker. Bilateral severe sensorineural hearing loss and limited pulmonary function are also relative contraindications to primary TEP due to the fact that the patient cannot hear the TE voice and limited pulmonary air restricts the fluency and volume of speech, respectively (15). Preoperative radiation therapy or the need for postoperative radiation therapy is not a contraindication for this procedure (14–16). Studies have shown that there is no difference in complication rates between these groups of patients (15,17). In addition, the rate of

pharyngocutaneous fistula, wound breakdown, stomal stenosis, and esophageal stenosis are similar to those reported in patients undergoing total laryngectomy without primary TEP (17).

If a patient is indecisive regarding primary TEP, a puncture can be performed and then allowed to close if the patient does not wish TE speech. This allows the use of the catheter for feeding until the pharyngeal closure is healed. This obviates the need for placement of a nasogastric tube (NGT) through the fresh pharyngeal closure, which may reduce the pharyngocutaneous fistula rate (17). When undecided preoperatively, the patient often commits to this form of alaryngeal speech in the immediate postoperative period after he/she understands stoma care and has had time to psychologically adjust to laryngectomy.

Primary TEP is felt to be safer than secondary TEP in the fact that there is less risk of mediastinal dissection and posterior esophageal perforation and there is elimination of an additional anesthesia (17).

Surgical Technique

The technique for primary voice restoration includes five basic steps, which are to be done in an ordered sequence to provide success without complication. These steps include incision (laryngectomy), followed by tracheostoma construction, TEP, unilateral pharyngeal constrictor myotomy or pharyngeal plexus neurectomy and buttressing the TE party wall (14).

Tracheostoma Construction

Following laryngectomy, the stoma is constructed. The optimal tracheal diameter is 3 cm or greater in order to prevent stenosis. The midline inferior skin flap is sewn to the midline anterior tracheal ring using half vertical mattress sutures, which allow coverage of the cartilage. Interrupted sutures are placed at 5-mm intervals on either side of the midline, pulling the trachea laterally. This creates a straight, horizontal membranous trachea, which is sewn to the superior skin flap. If the trachea is smaller than 3.0 cm, a stomaplasty is performed (14). The trachea is incised bilaterally for a vertical distance of 1 cm (two tracheal rings in length) between the midline and the most posterolateral aspect. An "X" is drawn in the midline of the inferior skin flap at the proposed stoma site. The skin and subcutaneous tissues of the superior and inferior areas of the "X" incision are discarded. The lateral triangles of skin are sewn into the apex of the lateral tracheal ring incisions causing the trachea to enlarge (5).

Tracheoesophageal Puncture

The TEP is then performed using a ruler, right-angled clamp, and a number 15 scalpel blade. The puncture is made 1.0 to 1.5 cm below the posterior cut edge of the stoma. A right-angled hemostat is placed in the esophagus through the pharyngotomy and pushed against the posterior tracheal wall. A 4-mm horizontal incision is made over the tip of the hemostat and the hemostat is pushed into the tracheal lumen (Fig. 125.3). The jaws of the hemostat are opened and a number 16-French Silastic Foley catheter is grasped and pulled through the party wall and fed down into the esophagus. Care should be taken at this step to ensure that the catheter is firmly grasped by the hemostat so that it does not slip while it is being pulled through the party wall. The catheter is sewn to the superior skin flap after the skin is closed and can be used to feed the patient in the immediate postoperative period (5,14).

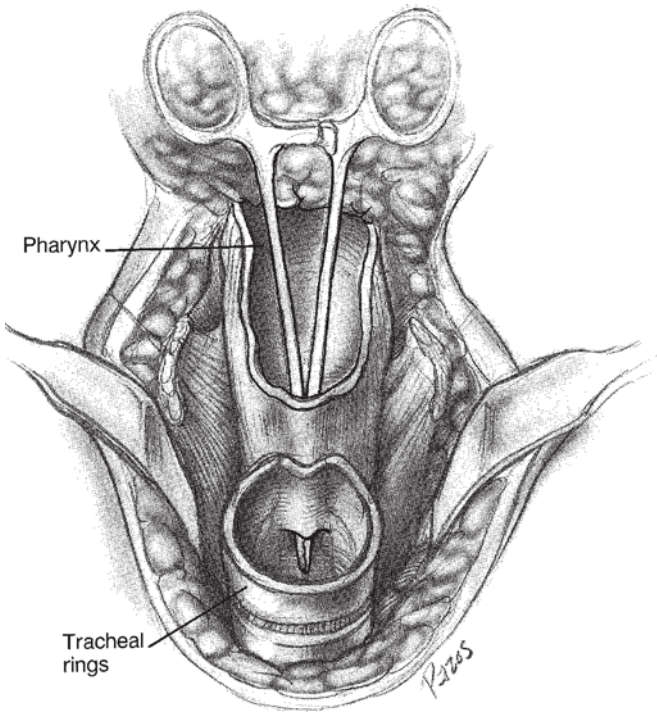

Figure 125.3 Primary placement of the TEP via the pharyngotomy.

Alternatively, the prosthesis can be primarily placed and the patient fed through a NGT. This is popular in Europe but has not gained wide acceptance in the United States. When using this method, after the red rubber catheter is pulled through the puncture into the esophagus, a prosthesis is attached to the catheter using a silk suture and pulled through the esophagus to the puncture site. The tab and tracheal flange are delivered through the puncture tract to the tracheal side.

The advantages of primary placement include no longer requiring a separate consultation for prosthesis placement; the prosthesis being more stable than the catheter and taking up less space, which allows for easier stoma care and placement of a laryngectomy tube; and the low profile of the prosthesis on the esophageal side that also allows for placement of a Montgomery bypass salivary stent. The only significant disadvantage is the need for an NGT or percutaneous gastrostomy (PEG) for feeding (18).

Pharyngeal Constrictor Myotomy

As mentioned previously, management of the pharyngeal constrictor muscles to prevent pharyngeal spasm is key to successful TE speech. The most reliable method for preventing spasm, if done properly, is a pharyngeal constrictor myotomy. The pharynx is rolled over a tubular structure, most often a finger, and the muscles are incised vertically in the posterior midline of the pharynx from the level of the puncture to the tongue base. The muscles are cut to the level of the submucosa. If bleeding occurs, careful use of bipolar cautery is recommended. If an inadvertent pharyngotomy is made, the mucosa is repaired at this time. If flap reconstruction of the pharynx is performed, the segment of muscle from the puncture site to the inferior flap is myotomized (5,14).

An alternative method that can be performed to prevent pharyngeal spasm is a unilateral pharyngeal plexus neurectomy (Fig. 125.4) (19). After laryngectomy, the pharyngeal muscles lay medially at the level of the superior thyroid artery. The plexus is found within the middle constrictor muscle. A nerve stimulator is used to identify three to five nerve branches by eliciting muscle contraction. The nerve branches are then cut and coagulated. If poor muscle contraction is seen following stimulation, this method is abandoned, and a myotomy is performed. This method is also useful when the pharynx is already closed and a myotomy was inadvertently not performed.

Buttressing of the TE Party Wall

The party wall usually separates about 3 to 5 mm above the site of the puncture. The party wall is buttressed using interrupted sutures of 3-0 chromic or 4-0 Vicryl, which obliterates this space. This prevents the collection of saliva in this area if a fistula develops and helps to maintain the integrity of the posterior stoma. If separation of the party wall extends below the area of the planned puncture, then the puncture is delayed as this can lead to pocket formation with abscess and loss of the posterior tracheal wall (5,14).

The voice prosthesis can be placed at the time of primary TEP as mentioned above until anytime after the patient is taking per oral feeds. Voicing, however, is delayed until 2 weeks postoperatively in order to allow the hypopharyngeal closure to heal. Voicing prior to this time may place too much air pressure on the new closure, disrupting the suture line. If the patient is discharged from the hospital with the Foley catheter in place, the balloon is filled with 2 mL of normal saline to prevent accidental dislodgement of the catheter from the puncture site (15). The patient is also given varying sizes of red rubber catheters and instructed on how to replace the catheter if it becomes dislodged.

Primary TEP results in development of successful TE speech in 50% to 93% of patients depending on patient selection criteria and the use of an indwelling prosthesis (14–,20). During postoperative radiation therapy, voicing may become interrupted due to mucositis or the patient's inability to occlude the stoma due to pain. Although not used, the prosthesis may remain in place during this time (14).

Despite an overall excellent success rate, some clinicians are still hesitant to perform primary TEPs based on lack of experience and fear of complications. Previous radiation therapy and flap reconstruction, as long as the party wall is not separated, are not contraindications to primary TEP; however, these two variables most commonly dissuade surgeons. When not performed primarily, TEP is rarely done as a secondary procedure likely due to patients' bias toward their initial form of speech and their reluctance to undergo another surgical procedure (17).

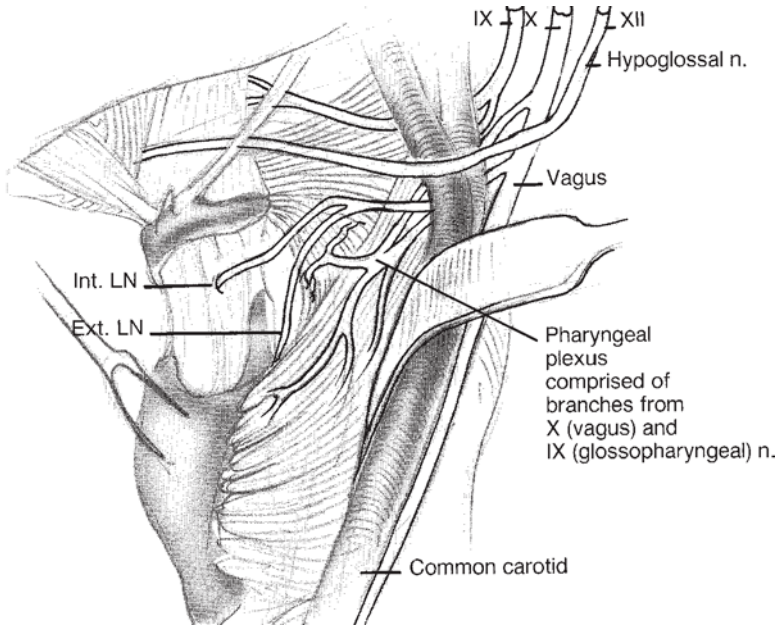

Figure 125.4 Surgical anatomy of the pharyngeal plexus during laryngectomy.

TREATMENT OF PHARYNGEAL CONSTRICTOR SPASM

Hypertonicity or spastic TE speech occurs when the esophagus extends with air on attempted phonation and the PE segment (cricopharyngeus, inferior and middle constrictor muscles) fails to relax to permit airflow for voicing. When the insufflation test reveals hypertonic or spastic speech or the patient fails the "open track" test following primary TEP, this must be addressed to obtain fluent speech. It was thought by some that a nonmuscle closure of the pharynx could prevent spasm, but this did not prove to be true over time (21). Injection of Botox toxin A has been found to be effective in treating spasm. It can be injected under electromyographic guidance or fluoroscopy into the pharyngeal constrictor muscles as chemical denervation of these muscles (22–25). Its effect usually occurs within 72 hours after injection and may require repeated injections approximately every 6 months. Open secondary pharyngeal constrictor myotomy, with its associated complication of fistula, and pharyngeal plexus neurectomy have essentially been replaced with Botox A injections to the PE segment. Recurrent tumor, pharyngeal stenosis, and fibrosis of the tissues should be identified as these patients will not benefit from this procedure.

When pharyngoesophageal spasm is suspected, it can be confirmed by anesthetic block of the pharyngeal plexus. The most effective method for analysis combines radiographic assessment with a plexus block. The patient is evaluated by videofluoroscopy using barium; the lateral view is preferred. An at-rest view is first obtained to rule out stricture, fistula tract, or persistent neoplasm. Several views during voicing are taken. Fluoroscopic visualization reveals a pronounced, transient, posterior pharyngeal muscle mass that protrudes into the lumen and restricts the egress of air. This is seen in the retropharyngeal radiographic plane as a bar (Fig. 125.5) (22).

The study is followed by the pharyngeal plexus block with local anesthesia (150 to 200 mg of 2% lidocaine without epinephrine). The neck skin is entered at the level of C2 to C3 immediately parapharyngeal and medial to the carotid sheath. The lidocaine is injected with a 23-gauge needle placed at the level of the prevertebral fascia. After 3 to 5 minutes, the patient is instructed to attempt voicing. The anesthetic can temporarily inhibit reflex tonicity resulting in fluent speech. The voicing dynamics are now analyzed by fluoroscopy. The typical appearance shows a reduction in the mass of the constrictor muscles, including the axial length, which is documented by radiographic examination. This indicates that the use of botulinum toxin A will most likely be successful in treating pharyngoesophageal spasm. Hamaker and Blom (22) reported a success rate of 79% following one injection of 100 units of Botox A under EMG and fluoroscopic guidance into the posterior pharyngeal "bar" seen with phonation. The patient undergoes preinjection videofluoroscopy to identify the area of spasm. The patient is asked to phonate and the area of spasm is marked. In addition, the area 1 cm above and 1 cm below the level of the spasm is marked in order to include all the muscles. EMG guidance is also used when injecting the Botox (the patient is asked to swallow and/or phonate to confirm the area). Fifty-five percent of these patients had fluent speech for more than 6 months. Following a second and/or third injection with Botox A, 66% of patients required no further treatment without relapse. It has been postulated that the sustained effects of Botox is related to the degree of surgical and/or radiation damage of the neuromuscular junction preventing regeneration. Other studies using slightly different techniques reported 88% and 87% success rates following subsequent injections with Botox, which were sustained (24,25).

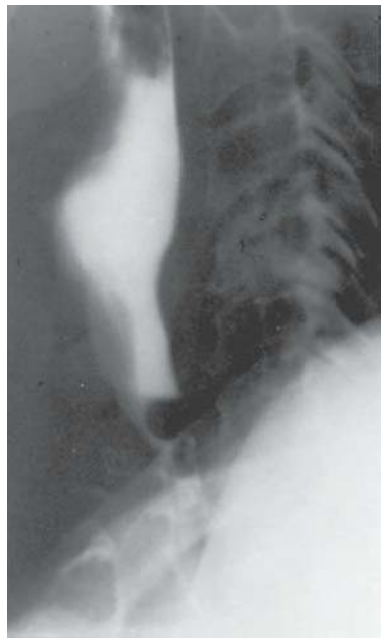

Figure 125.5 Lateral radiograph demonstrating the constrictor mass during esophageal distention. (Reprinted from Singer MI, Blom ED. A selective myotomy for voice restoration after total laryngectomy. *Arch Otolaryngol* 1981;107:670–673, with permission.)

COMPLICATIONS

The most common complications encountered following primary and secondary TEP include loss of the puncture site by dislodgment of the catheter placed at the time of puncture or partial or complete extrusion of the prosthesis, migration of the puncture site, formation of granulation tissue, aspiration of the prosthesis, cellulitis, stomal stenosis, and pharyngoesophageal stenosis (15,26–28). Sternoclavicular arthritis and manual pressure necrosis have also been reported (29). Violation of the posterior esophageal wall, passage of the catheter through a false passage, and esophageal perforation are unique to secondary TEP and can result in deep neck space infections, epidural abscess, vertebral osteomyelitis, and mediastinitis (28).

TABLE 125.1 COMPLICATIONS

Epidural abscess or vertebral osteomyelitis secondary to violation of posterior esophageal wall during secondary TEP
Mediastinitis secondary to dissection of party wall
Loss of the puncture site by dislodgment of the catheter placed at the time of puncture
Partial or complete extrusion of the prosthesis
Migration of the puncture site
Formation of granulation tissue
Stomal or pharyngoesophageal stenosis
TEP enlargement
Aspiration of saliva and foods through puncture site

An important local complication is enlargement of the puncture site relative to the size of the prosthesis resulting in leakage around the prosthesis and aspiration of foods and saliva (Table 125.1). The most common causes of enlargement of the puncture site are repeated trauma due to changing the prosthesis or thinning of the party wall. Recurrent tumor should always be considered as a cause. There are many ways in which to manage this problem. One way is to remove the prosthesis and place a red rubber catheter through which the patient can be fed and the fistula can contract around. Other ways include cautery of the edges, surgical closure, local flaps placed between the trachea and esophagus, and more recently the injection of biomaterials (collagen, Cymetra, Bioplastique) around the site to reduce its size and to stop leakage (28,30). Silicone "washers" can be placed behind the prosthesis against the posterior tracheal wall to increase the thickness of the party wall.

Reflux-associated morbidity includes prosthesis erosion, leakage, and granulation tissue formation, but reflux does not appear to effect intelligibility and overall quality of TE speech (31). Previous radiation (32,33), diabetes mellitus, chronic obstructive pulmonary disease, alcoholism, and extended laryngectomy have not been found to be significant risk factors for complications (34).

POSTOPERATIVE REHABILITATION

Postoperative TE voice rehabilitation is usually taught by a speech and language pathologist. There are three basic treatment goals following TEP. The first is to dilate and measure the puncture followed by placement of the prosthesis, the second is to instruct the patient and family in routine care of the prosthesis, and the third is to instruct the patient in finger occlusion of the tracheostoma and to apply and use a tracheostomal valve (35).

Briefly, the puncture must be dilated to the appropriate size to accommodate the prosthesis (e.g., 22 French for a 20-French prosthesis). A measuring device is then placed into the puncture and slowly withdrawn until the retention collar sits against the inner surface of the esophageal wall and the length of the prosthesis is measured (Fig. 125.6). If the length lies between sizes, the longer size is chosen to prevent underfitting, which can cause the puncture to heal from behind.

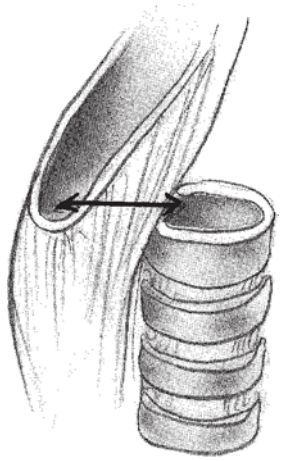

Figure 125.6 Fitting distance from the posterior trachea to the anterior esophagus.

The type of prosthesis to be used is chosen. The duckbill and low-pressure prostheses (Figs. 125.7 and 125.8) are removable prostheses, which the patient learns to clean and replace into the puncture. The indwelling low-pressure prosthesis is placed and removed by the physician or speech and language pathologist. The indwelling prosthesis is used in patients who cannot or prefer not to use the removable prosthesis. The life of any prosthesis in

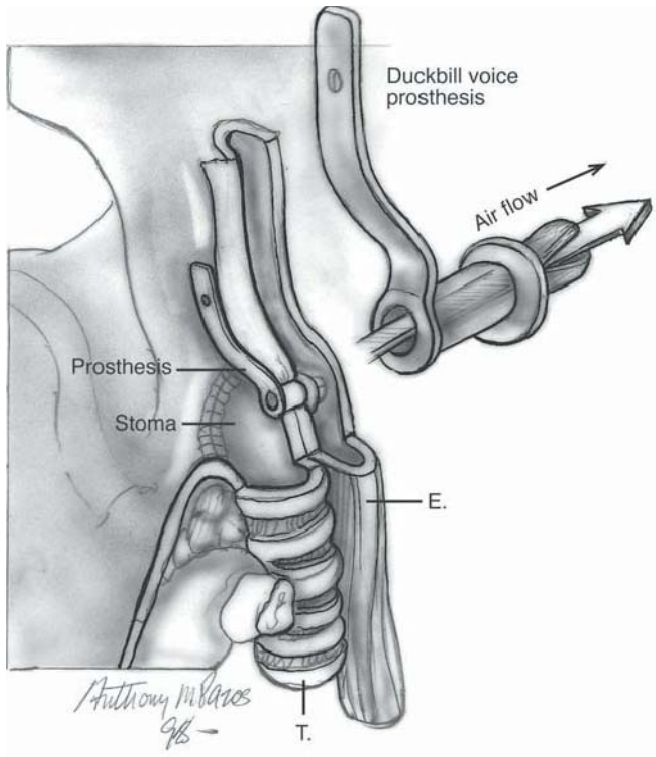

Figure 125.7 Duckbill (slit-valve) voice prosthesis.

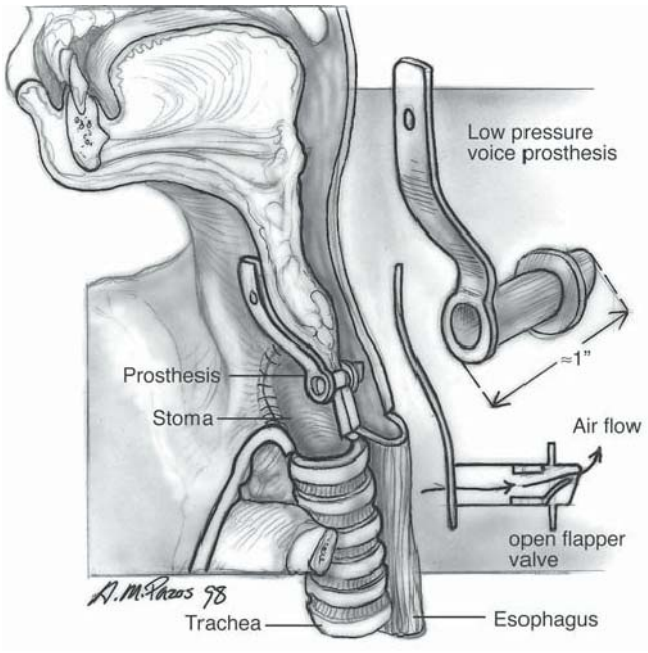

Figure 125.8 Voice prosthesis in place in the TEP.

general is about 3 to 6 months. It is the colonization of yeast (more common in indwelling prosthesis) that usually destroys the integrity of the valve, which causes leakage of saliva and foods and decreases the life expectancy of the prosthesis (14,15). A prescription for oral nystatin should be given to all patients for daily use to prevent yeast colonization, or the newly available pretreated prosthesis can be used. Prior to placing the voice prosthesis, an "open tract" test is performed. The patient is asked to voice without prosthesis in place. Poor voicing is either due to pharyngeal constrictor spasm or excessive finger pressure occlusion of the stoma.

The next steps include patient and family education regarding care of the prosthesis and patient instruction regarding finger occlusion of the prosthesis. It is usually necessary to assist the patient with accurate occlusion of the stoma at the initial visit while the patient watches in the mirror. About six sessions are required for the average patient to master removal, cleaning, and reinsertion of the standard voice prosthesis. For those patients who find finger occlusion unacceptable, a hands-free valve can be used.

PREDICTORS OF SUCCESSFUL TRACHEOESOPHAGEAL SPEECH

TE speech is closer to laryngeal speech than esophageal speech because its air supply is pulmonary; voice parameters including fundamental frequency, jitter, shimmer, words per minute, and maximum phonation time are closer to laryngeal speech.

Many variables have been studied by various clinicians in order to predict those patients who will achieve successful TE speech with primary or secondary puncture (17,33,34,36). The results of these studies have varied, although age, sex, and tumor size/stage appear to have no influence. Ethanol abuse and lack of transportation to follow-up visits correlated well with TE speech failure in some studies, but were not significant in others (17,36). However, many clinicians can anecdotally report alcohol abuse as a contributor to rehabilitation failure. In a study by Cantu et al. (36), 36 patients undergoing either primary or secondary TEP were evaluated for long-term success and predictors of successful TE speech. Nearly two-thirds had successful communication at an average of 4 years postpuncture. For the remaining patients who were judged as unsuccessful, reduced vision, limited hand and arm movement, and history of radiation therapy (but not timing of radiation therapy) were found to be significant. However, there were patients with good vision and hand coordination who did not develop good speech and those with previous radiation therapy who did develop successful speech. In a 16-year retrospective outcomes analysis of primary and secondary TEPs, neither pre- nor postoperative radiotherapy had any effect on voice restoration or complications (33). Therefore, the presence of these factors does not necessarily predict lack of success. The introduction of the indwelling prosthesis has reduced the problems associated with decreased function.

A study by Bozec et al. (37) evaluated patients using prosthetic voice restoration for clinical factors that correlated with functional outcomes. One hundred and three patients who underwent total laryngectomy or pharyngolaryngectomy were evaluated regarding speech and swallowing. Eighty-two percent of patients had successful voice rehabilitation. Hypopharyngeal tumors, circular laryngopharyngectomies, and the use of pectoralis major myocutaneous flaps were associated with the placement of a secondary TEP, and the only factor that correlated with speech failure was a high level of comorbidity (American Association of Anesthesiologist (ASA) score greater than or equal to 3). It is thought that reduced vital lung capacity, neurologic disabilities altering hand coordination, decreased motivation, chronic asthenia, and dyspnea, which are frequent in patients with severe comorbidities, could be the possible causes of unsuccessful vocal rehabilitation. Decreased life of the prosthesis was seen with flap reconstruction, which could be explained by decreased pharyngeal motility with food stasis around the valve resulting in more *Candida* colonization.

The timing of TEP does not appear to appear the influence communication effectiveness and the absence of pharyngeal stricture was the only significant predictor of good to excellent speech results in secondary TEP (34). In another study, it was found that 77.8% of patients undergoing primary TEP achieved excellent voice quality and 78.4% of these patients consistently used TE speech, while only 50% of those undergoing secondary TEP achieved

excellent voice quality and only 70.6% consistently used TE speech (33). Primary TEP may be preferable in view of superior voice quality, a shorter period of aphonia, and the fact that there is no need for a second procedure for voice restoration (33). In addition, primary TEP precludes major complications in the visceral compartment. As one can see, there are variable results found in multiple studies, which can make predicting success of TE speech challenging.

VOICE QUALITY

Preoperative and postoperative evaluation by a speech and language pathologist is vital to successful TE speech. The goal of voice restoration is to provide fluent, effortless, and intelligible speech. The patients should understand that voice quality cannot be controlled.

TE speech does generally improve over time and its use does not preclude the use of other methods of alaryngeal speech.

TE voice quality is usually harsh and often loses its sexual characterization (38). However, patients undergoing total laryngectomy already have varying degrees of dysphonia, and voice should be compared to the preoperative voice quality. In a study by Cantu et al. (36), one-third of patients or their significant others judged the success of their TE speech at a lower level than that of the primary investigator. This indicates that the clinician and patient may be using different standards of success; the patient and significant other may be using an "idealized" voice standard that cannot be produced using TEP. The patients should realize that there is a learning curve associated with TE speech and it generally improves over time (27). In addition, a functionally rehabilitated TE prosthesis user may find it easier to switch to esophageal speech (27). Acoustic analysis of TE speech has been compared to laryngeal, esophageal, and electrolarynx speech by many (39–41). The fundamental frequency, intensity, and rate of TE speech approximate that of normal speech. In a study by Robbins et al. (42), esophageal and TE speakers were analyzed for intensity, frequency, and rate of speech production. TE speech was found to be more similar to laryngeal speech than esophageal speech. When compared to esophageal speech, it gives superior voice quality in reference to volume and phrase length and is much easier to learn. Also, the rate of speech is faster and the intelligibility is superior to that acquired using the artificial larynx or esophageal speech (41,43,44). However, in the presence of noise, there is a lower rate of listener intelligibility of TE speech compared to laryngeal speech (40).

The prevention of pharyngeal spasm is paramount to the production of successful TE speech as mentioned previously. Acoustic analysis of TE speech was studied following three different surgical methods used to address the pharynx: pharyngeal plexus neurectomy, pharyngeal constrictor myotomy, and unilateral pharyngeal plexus neurectomy with a drainage myotomy limited to the cricopharyngeus. Patients undergoing pharyngeal plexus neurectomy had the highest fundamental frequency, which may be due to the residual resting tone in the pharyngoesophageal segment (39). Management of the pharynx with neurectomy may be desirable in women undergoing laryngectomy with voice restoration.

TE speech has been rated the most desirable form of alaryngeal speech by both speech pathologist and patients (45) and is the preferred method of alaryngeal speech by naïve listeners (41).

In a study by Gerwin and Culton (46), greater than 80% of laryngectomy patients (n = 16) reported a good quality of life satisfaction with TE speech using the University of Washington Quality of Life Scale and Functional Assessment of Cancer Therapy.

EMERGENCIES

Two urgent conditions may result for prosthesis users and should be attended to without delay. For patients who routinely change their prostheses, the inability to insert the tip of the prosthesis and collar into the lumen of the esophagus may occur, which results initially in increased voice resistance and, in some cases, complete loss of voice. The TEP tract will close over time from inside out, and it will be impossible after 24 to 48 hours to reenter the lumen. If this occurs, the TEP can be serially dilated with plastic catheters ranging from 10F to 18F and then stented with a flexible catheter for several hours before the voice prosthesis is replaced. Laryngeal and urethral dilators are also an effective instrument for TEP dilatation. Dilatation must be performed with as little resistance as possible because it is possible to dissect into the TE party wall and enter the anterior mediastinum.

The second urgent condition is aspiration of the voice prosthesis. This condition usually occurs when patients attempt to replace the device in the TEP and a cough is stimulated. The most common location for device impaction is at the level of the upper right mainstem bronchus and carina. This usually is well tolerated, but an uncomfortable dyspnea is present. Furthermore, if the TEP is not stented with a red rubber catheter, tracheal aspiration of saliva may occur. Should aspiration of the prosthesis occur, the patient should first securely stent the puncture and then attempt to bend over as far as possible and cough out the prosthesis. In the event of failure, the patient should go to an emergency medical facility as soon as possible. The size of the prosthesis prevents it from occluding the airway. The most efficient method for prosthesis retrieval is to use topical anesthesia and flexible bronchoscope with grasping forceps. After removing the foreign body, the TEP can be replaced. The patient may require additional training regarding removal and reinsertion of the prosthesis.

HIGHLIGHTS

- Alaryngeal voice restoration can be attained with the use of an electrolarynx speech, esophageal speech, and TE speech.
- TE speech is more acoustically similar to normal laryngeal speech and more intelligible than standard esophageal speech.
- Restoration of the voice after total laryngectomy must not compromise the established principles of surgical oncology.
- TE speech dysfluency may be the result of pharyngeal constrictor tonicity, excessive resistance to airflow by a prosthesis with high-resistance characteristics, or tissue changes related to edema, fibrosis, or recurrent disease.
- There are no absolute contraindications to secondary TEP.
- The only absolute contraindication to primary TEP is separation of the party wall. Separation of the party wall below the puncture site can lead to abscess formation, necrosis of the posterior tracheal wall, and possibly mediastinitis.
- Relative contraindications to primary and secondary TEP include the patient's inability to use and care for the prosthesis due to impaired mental status or decrease in manual dexterity, bilateral severe sensorineural hearing loss (patient cannot hear the TE voice), and limited pulmonary function (restricts the fluency and volume of speech).
- It is imperative that the puncture is through the party wall to prevent mediastinal dissection with the catheter resulting in mediastinitis.
- Radiation therapy is not a contraindication for TEP.
- Botulinum toxin A injections can be used to treat hypertonic or spastic TE speech.
- Secondary voice restoration can be performed using the TNE scope under local anesthesia in the office setting. It is especially useful in patients with esophageal strictures, fibrosis of the neck due to surgery, and radiation and cervical spine deformity causing rigid esophagoscopy to be challenging if not impossible.
- Pharyngeal constrictor myotomy or pharyngeal plexus neurectomy at the time of laryngectomy are paramount to attaining fluent TE speech.

126 Tracheal Tumors

Kevin L. Potts *Jeffrey M. Bumpous*

Tracheal neoplasms are rare, accounting for only 1% of all malignancies (1), but the impact on the individual is generally severe (2–4). With regard to incidence, these tumors may also be underreported, incompletely diagnosed, and undertreated because of the rarity, lack of mandatory registration, limited surgical experience, and the relative sporadic nature of the lesions (4). The most common tumors are classified as benign, primary malignant and secondary malignant in Table 126.1. Because these tumors occupy the main airway conduit, as they enlarge, the impact and potential fatality increase. Stridor, hemoptysis, and shortness of air are the most common symptoms, and many patients present in need of acute airway management. Injudicious airway management may precipitate airway obstruction and/or potentially interfere with subsequent definitive surgical management (4,5).

CLINICAL PRESENTATION

History

Tracheal tumors tend to cause progressive symptoms over several months to years due to their slow-growing nature often causing accurate diagnosis to be delayed (6). Gaissert et al. (7) reviewed 270 cases of squamous cell and adenoid cystic carcinoma of the trachea and carina, and the mean duration of symptoms was 12.2 months. The duration of symptoms was longer in adenoid cystic carcinoma and in tumors that were deemed to be unresectable (resected adenoid cystic carcinoma 18.3 months, resected squamous cell carcinoma 4.54 months, unresectable adenoid cystic carcinoma 23.7 months, unresectable squamous cell carcinoma 7.58 months, $P < 0.0001$) (6).

Symptoms at presentation depend largely on extent of airway obstruction and tumor type, but not location within the tracheobronchial tree (8). Dyspnea with exertion or phonation is the primary symptom when the tumor has caused significant airway obstruction. If lesions are ulcerative and mucosal irritation is severe, chronic cough and hemoptysis are common. Wheezing, stridor, hoarseness, difficulty clearing secretions, and frequent respiratory infections are also encountered.

Presentation may vary with tumor type with hemoptysis being the main symptom in patients with squamous cell carcinoma, and wheezing and dyspnea predominate in those with adenoid cystic carcinoma (Table 126.2) (9). Wheezing is often misdiagnosed as "asthma" and is refractory to bronchodilator therapy. Prolonged use of systemic corticosteroids is common, and patients may even be secondarily cushingoid at presentation (10).

Imaging

Imaging studies that are most frequently employed are CT scan with contrast and in some instances PET–CT. CT with contrast allows for adequate multiplanar imaging of the airway from hyoid to segmental bronchi. CT can be further exploited to derive three-dimensional images allowing for "virtual endoscopy." It is useful in the identification of involvement of mediastinal soft tissues, esophagus, and vasculature. It is additionally helpful in demonstrating coexisting pulmonary metastatic disease. PET–CT may be useful in distinguishing more aggressive pathology and may be more sensitive in the detection of paratracheal and mediastinal nodal involvement. MRI scanning may be useful in the examination of the cervical trachea, but mediastinal and thoracic structures may be significantly be distorted by motion artifact due to respiratory and circulatory movement (11–13). Figure 126.1A and B represent a demonstration of a high tracheal adenoid cystic carcinoma in both the axial and coronal planes.

TABLE 126.1 PATHOLOGY OF TRACHEAL TUMORS

Primary Tumor	Tumor Type
Epithelial (benign)	Papilloma
	Adenoma
	Myoepithelial tumor
	Pleomorphic adenoma
	Oncocytoma
Epithelial (malignant)	Squamous cell carcinoma
	Adenoid cystic carcinoma

INITIAL AIRWAY MANAGEMENT

For tracheal tumors, bronchoscopy is the mainstay of initial airway management and diagnosis. If the airway is stable at presentation, elective bronchoscopy can be arranged. However, in patients with acute airway compromise, urgent bronchoscopy may be needed to stabilize the airway. Bronchoscopy allows accurate estimation of the extent of airway pathology and airway obstruction. The exact tumor location, length of tracheal involvement, and its proximity to key anatomical structures can be determined. Tissue diagnosis is obtained during initial bronchoscopy, and margin mapping can be performed to help with treatment planning. For proximal tracheal tumors, rigid bronchoscopy is preferred over flexible bronchoscopy due to its ability to ventilate during the evaluation. Flexible bronchoscopy can provide additional information concerning the more distal airways.

Patients are sometimes able to tolerate significant obstruction (75% or more), but can decompensate rapidly with increased secretions or inflammation. In the event of an urgent airway, endotracheal intubation may not be feasible and could cause tumor dislodgement with subsequent complete airway obstruction. In this setting, rigid bronchoscopy can help stabilize the airway by dilating the stenotic segment, and tumor debulking can be performed. Flexible bronchoscopy alone can be dangerous, potentially causing edema and bleeding, which can precipitate complete airway obstruction. A rigid bronchoscope has the ability to tamponade bleeding while bypassing the site of obstruction for ventilation.

Emergency intervention via a surgical airway could prove troublesome depending on tumor location. Injudicious tracheotomy may transgress a lesion or make subsequent tracheal resection and reconstruction more difficult. If tracheotomy can be safely accomplished distal to the lesion, it may be warranted if the tumor is unresectable or patient comorbidities preclude definitive surgical management.

Finally, in addition to stabilizing the airway, therapeutic bronchoscopy can prepare and optimize a patient for airway surgery (14). Inflammation adjacent to the lesion may represent malignant submucosal extension or benign reactive changes. By delaying the resection and palliating the airway through repeated bronchoscopic

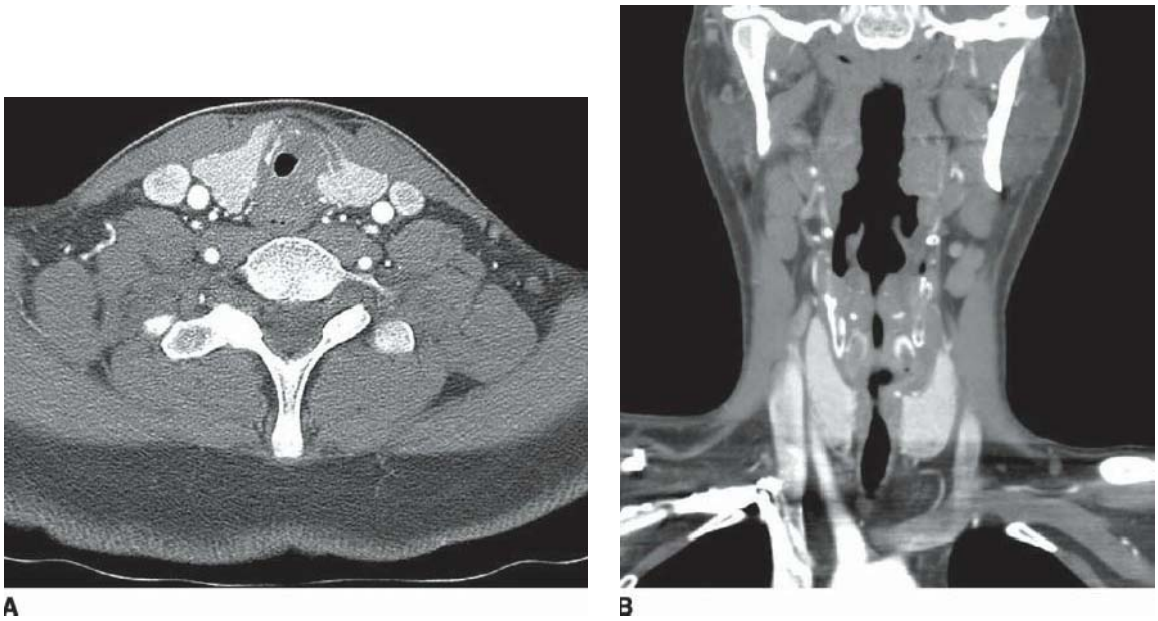

Figure 126.1 **A,B:** Adenoid cystic carcinoma. Contrast-enhanced axial CT showing a mass involving the lateral and posterior aspect of the proximal trachea. Adenoid cystic carcinoma. Coronal CT shows a submucosal lesion similar in appearance to tracheal stenosis.

intervention, obstructive pneumonia with resulting airway inflammation can be resolved. This allows for better delineation of margins and may decrease perioperative complications such as wound disruption and pneumonia (14).

DEFINITIVE SURGICAL MANAGEMENT

Tracheal Resection

Tracheal resection and primary reanastamosis is the preferred treatment for the majority of both benign and malignant tracheal neoplasms. The ability to perform this preferred management is predicated upon patient-, tumor-, and surgeon-related factors. Patient factors that are important include body habitus, medical comorbidities, and patient preference. Increasing body mass index (BMI) and a thick and short neck may be impediments to the execution of tracheal resection and reanastamosis. In this patient group, the mobilization of the trachea inferiorly and superiorly may be limited, and access to the segment of trachea containing the tumor may not be able to be accomplished solely through a cervical approach. Patients with coexisting chronic obstructive pulmonary disease may require a longer intubation and may be more prone to coughing exacerbations that may place additional strain on the tracheal repair. Furthermore, patients who have diabetes mellitus or are otherwise immunocompromised may have poorer wound healing, especially with longer segment resections that are under tension.

Tumor factors are important in decision making. The length of the proposed segment that would require resection for adequate margins represents one of the key factors in determination of treatment. Segmental resections of greater than 4 cm or six tracheal rings represent conditions in which the tracheal repair is under increased tension and dehiscence may be more likely. Submucosal, esophageal, mediastinal, and extensive tracheal or bronchial extension may require combined cervicothoracic procedures or nonsurgical treatment. A variety of extended tracheobronchial resections have been described and are best managed in a multidisciplinary approach with otolaryngologist and thoracic surgeon. Premature tracheotomy in the securing of an airway may create additional scar tissue and potential seeding of the soft tissues of the neck and make subsequent surgical resection efforts more difficult. Prior radiation therapy may additionally have an impact on the ability to dissect soft tissues, mobilize the trachea and larynx, identify critical structures, and allow for optimal wound healing.

Surgeon preference and experience may influence approach. Experience with benign tracheal stenosis, laryngectomy, and tracheal resection increases the confidence and ability of the surgeon to manage these lesions. Cooperation between otolaryngologists and thoracic surgeons allows for improved patient selection, procedure selection, and technical execution of these complicated cases (2–5,15). Contraindications for tracheal resection are relative rather than absolute in many cases. Because airway patency represents a fundamental goal in the management of patients with tracheal neoplasms, resection may be offered even in the face of primary tracheal tumors with regional or distant metastatic disease as well as selected metastatic lesions to the trachea. Lesions

that are involve greater than 4 cm or are greater than six tracheal rings may not be eligible for resection; factors ultimately affecting this decision include body habitus, ability to adequately mobilize the upper respiratory tract, and experience of the surgical team in both the procedure and management of its complications. Extensive extratracheal disease in the mediastinum involving the esophagus, mediastinal vessels, and prevertebral spaces represents cases in which resection is contraindicated and tracheotomy, endoscopic tumor ablation, and stent placement may be preferred.

Standard resection steps are predicated upon adequate bronchoscopic evaluation of the airway, imaging of the trachea and related neck and mediastinal structures, pathological confirmation, surgical team selection and approach, anesthetic preparation and management plan, and finally execution of the procedure. The steps of the tracheal resection procedure are as follows: transverse cervical incision outlined in cervical crease at midpoint between the sternal notch and the inferior border of the cricoid cartilage that are readily palpable landmarks. In extended cases or in cases in which cervical and extensive mediastinal dissection or proximity to the innominate artery is anticipated, both the neck and chest should be sterilely prepped and draped. The transverse cervical incision can be readily connected to a vertical chest incision for addition of a median sternotomy (total or partial). After preparation and skin incision choices are made, the steps of tracheal resection with primary repair are as follows:

1. Elevation of a subfascial, supramuscular flap above the strap musculature and the sternomastoid muscles sternal heads both superiorly and inferiorly into the suprasternal space of Burns.
2. Separation of the strap muscles from the thyroid cartilage to the sternal and clavicular origins of the muscles. Retraction of the wound may be done with a variety of self-retaining retractors, elastic stays, or sutures.
3. Exposure of the trachea requires the surgeon to anticipate extratracheal extension. For example, thyroidectomy may be required if resection is being performed because of well-differentiated thyroid cancer with focal tracheal invasion. In cases of endoluminal primary tracheal neoplasms, the thyroid isthmus should be divided with careful hemostasis, and the thyroid lobes mobilized laterally.
4. Recurrent (inferior) laryngeal nerve identification is not performed routinely, although identification of the nerve may be required for adjunctive procedures such as thyroidectomy, central lymphadenectomy, or extended cricotracheal procedures. Monitoring of the recurrent nerves may be helpful in maintaining integrity of the nerves and monitoring the condition of the nerve during retraction; there is no current evidence that use of neural monitoring improves recurrent laryngeal nerve outcome in these procedures.
5. Tracheal mobilization. The trachea should be carefully mobilized from the cricoid to two to three rings below the intended inferior margin of resection. Concomitant use and measuring of the lesion with imaging studies and intraoperative bronchoscopy may add accuracy to the determination of the segment requiring resection. Mobilization of the resection segment must be circumferential. Beyond the resection segment inferiorly, care should be taken to perform anterior and posterior mobilization, but careful lateral preservation of soft tissues in order to preserve the blood supply to the distal trachea from the inferior thyroid artery and other thyrocervical trunk arterial tributaries.
6. The majority of mobilization occurs from inferior mobilization for cervical tracheal defects.
7. Superior mobilization may provide from 1 to 2 cm of additional length. This may include either infra- or suprahyoid muscle release, which in effect allows for stretching or elongation of the thyrohyoid membrane.
8. The anesthesiologist and operative room team should be notified to remove any shoulder roll that was placed and to place the head in a neutral to flexed position.
9. Closure of the trachea should be performed with reabsorbable interrupted sutures. I prefer 3-0 dyed polyglactin-coated vicryl sutures. The posterior sutures are placed first. Placing a 0 silk suture through the Murphy Eye of the endotracheal tube allows for it to be withdrawn and retrieved safely without accidental extubation. All of the sutures posteriorly to up to the 3 and 9 o'clock positions of the trachea should be placed prior to tying the sutures. These sutures are then tied sequentially, while the surgical assistant removes tension from the proximal and distal ends of the trachea. The anterior sutures are then placed extraluminally around one tracheal ring inferiorly and one tracheal ring or the cricoid cartilage superiorly. Each of these sutures is interrupted and should be thrown but not tied. Once all anterior sutures are placed, they may then be tied by the surgeon (I prefer hand tying to monitor tension rather than instrument tying); while the surgical assistant removes tension from the proximal and distal tracheal segments.
10. Buttressing extraluminal permanent sutures (i.e., 3-0 Prolene or nylon) may be thrown from tracheal rings or laryngeal cartilages above and below the primary tracheal repair line in order to further remove tension of closure. This is not always feasible, and care must be taken not to tear the trachea or larynx.
11. The wound is then irrigated, and hemostasis is reviewed and insured. The surgeon should ask the anesthesiologist to perform a Valsalva or positive pressure ventilation with the endotracheal cuff inflated to review hemostasis and then with the endotracheal cuff deflated, while the wound is flooded with sterile irrigation in order to determine if the repair is air tight.

12. A drain may or may not be placed and is the preference of the surgeon based on the condition of the wound.
13. The strap muscles are closed.
14. Subcutaneous tissues and skin are closed.
15. A large retention stitch ("Grillo stitch") may be placed from the mandibular skin and periosteum to the sternal skin and periosteum with the patient's head in a flexed position in order to keep the head in this position in the postoperative period in order to reduce tension on the tracheal repair.
16. The patient may then be extubated when awake and able to protect his/her airway. This should be done in the operating room with both anesthesiologist and surgeon present in the untoward event that airway obstruction and subsequent reintubation or surgical management is required.
17. In extended procedures such as cricotracheal resections, a tracheotomy inferior to the repair site may be performed if laryngeal patency is in question.
18. If the procedure has been prolonged or significant edema of the airway is suspected, intubation over 24 hours with subsequent controlled extubation may be performed.

In the postoperative period, several potential problems must be actively monitored for and managed. Minor wound complications such as hematoma, seroma, or wound infection are rare, but they may become major complications if there is wound disruption of the tracheal repair itself. Earlier tracheal disruption may manifest with wound crepitance, extended neck and chest crepitance, and in its most extreme forms, pneumomediastinum and pneumothorax. This may require opening of the wound with placement of a drain, tracheal repair or tracheotomy, and chest tube placement. Late disruption is more likely to occur subsequent to wound infection and may require incision and drainage and possible tracheotomy placement depending on the severity of the wound and the airway condition. The second most serious condition is the development of tracheal granulation tissue. Suture granulation/granuloma occurring at the suture line may require bronchoscopy and removal either mechanically or by laser with possible adjuncts such as dilation, steroid injection, or topical application of substances such as mitomycin-c. In severe cases, stent placement or tracheotomy may be considered. Complication rates in experienced hands range from 17% to approximately 30%. Long-term restenosis is uncommon occurring at 1% to 14% of cases. The management of restenosis may require re-resection of the stenotic segment, endoscopic management with or without stenting, or placement of a tracheotomy (16,17).

Multiple surgical series have demonstrated that the overall survival of these rare tumors is best accomplished with surgical resection (16–18). Adenoid cystic carcinomas fare better than squamous cell carcinomas, which have as a category the worst prognosis. Negative surgical margins at the time of resection predict improved disease-free and overall survival for all malignant tumors (19). Application of adjuvant radiotherapy may improve survival for all squamous cell carcinomas and for other tumors with microscopic residual disease (17–19). Carcinoid tumors, sarcomas, and mucoepidermoid carcinomas demonstrate survival in excess of 78% with complete resection in experienced centers (18). Without surgical resection, long-term survival for malignant tracheal tumors is dismal (16–19). Extension of squamous cell carcinomas of the trachea into the thyroid or the regional lymphatics is a poor prognosticator, diminishing overall survival by more than 50% (20). (See Table 126.3 Survival For Malignant Tracheal Tumors for a summary of survivorship for common tracheal malignancies.)

TABLE 126.3 TRACHEA SURVIVAL

Tumor Type	5-Y Overall Survival (%)	5-Y Disease-Free Survival (%)	Sources
Adenoid cystic	31.6	47.4–77.9	9,10
Squamous	6	29	9
Other	19–90	38–90	7,9
Overall	21	27	9

Cricotracheal Resection

Cricotracheal resections may be appropriate for selected subglottic laryngeal tumors as well as proximal extension of primary tracheal tumors. This is most commonly applied for subglottic tumors that may have tracheal extension, for example, chondrosarcomas arising from the cricoid cartilage (21). Contraindications to cricotracheal resection included involvement of the true vocal cord and/or arytenoid. Tumor extension beyond the airway to involve the mediastinal vasculature or prevertebral fascia represents additional contraindications. The execution of a cricotracheal resection is similar to tracheal resection in terms of exposure and precautions regarding the length of resection. In addition, all or portion of the cricoid may be removed. Removal of the anterior cricoid represents a relatively technically easy exercise. The posterior cricoid is both taller vertically and thicker. Care must be taken in removing the posterior cricoid to avoid resection or damage to the arytenoid cartilages and to avoid inadvertent entry into the esophagus. Closure is accomplished by circumferential tracheal suture with suspension to the fibrous-mucosal cuff posteriorly and to the thyroid cartilage superiorly. If the thyroid cartilage is calcified, drilling holes with a surgical drill facilitates the placement of these suspension sutures (5,20,22). In experienced hands, successful airway patency without tracheotomy may be obtained in over 90% of patients (17).

Distally Extended Resections

Extended resections distally in the trachea may involve resection of segments of trachea greater than 4 cm, resections of the trachea with one mainstem bronchus, carinal resections, or resections combined with pneumonectomy. These extended thoracic procedures may be approached through median sternotomy, thoracotomy, or combinations depending on the extent of resection and if pneumonectomy is included. Some of these extended resections may require cardiopulmonary bypass (23,24). Overall 1-, 2-, and 3-year survivals in these extended tracheobronchial resections for malignancy are approximately 98%, 54%, and 50% (24). The majority of extended resections are reconstructed with tracheobronchoplasties that are tailored to the specific resection (23–25). Other reconstructive methods and tracheal replacement methods have also been described for extended tracheobronchial resections including the use of flaps (pectoralis major flap and engineered radial forearm) and aortic homografts (25–27).

Laryngeal–Tracheal Resections with Permanent Stoma

Some tracheal tumors with extensive laryngeal framework involvement, recurrent laryngeal nerve involvement, and significant laryngeal dysfunction may require laryngectomy, laryngopharyngectomy, or laryngopharyngoesophagectomy; in these cases, mediastinal resections with flap reconstruction, innominate artery mobilization, and management and creation of a mediastinal tracheostoma may be indicated. Overall survival at 3 and 5 years for these types of resections is approximately 57% and 43% (28).

Lymph Node Management

The role of lymphadenectomy in primary tracheal tumors is controversial. Obviously involved, resectable paratracheal and mediastinal nodes should be removed. In the case of the clinically uninvolved neck, the role of elective removal of paratracheal lymph nodes is less well understood. The presence of positive lymph nodes does not appear to adversely affect prognosis; however, over 80% of patients with pathologically positive lymph nodes have also received adjuvant radiation therapy in addition to resection (29).

ENDOSCOPIC AND NONOPERATIVE MANAGEMENT

Debulking and Stents

Tumor debulking is a good initial diagnostic and temporary therapeutic endeavor. Given comorbidities, the management may precede other nonsurgical interventions such as radiation therapy. Debulking can occur by mechanical removal, laser ablation, and cryoablation. These methods can provide in general short-term relief of airway obstruction, but are otherwise palliative rather than definitive treatment (30). Stents may be applied following biopsy or debulking procedures as a temporizing measure preceding definitive resection or as a means of extending palliative relief of airway obstruction. Stents may be placed by means of flexible bronchoscopy for metal-based stents or rigid bronchoscopy for metal or other plastic polymer stents. Additionally, drug-eluting stents have been used in the context of both benign and malignant airway stenosis management (1,30–35). Complications occurring most frequently with airway stent use include mucous plugging, stent displacement, granulation tissue formation, and rarely erosion (30,34). It is important to emphasize that although stents are used in the management of the airway for patients with tracheal tumors, with or without adjuvant therapies such as radiation, when complete tumor resection is feasible, it is the preferred management due to better long-term airway patency and oncologic outcomes (4,5).

Radiation Therapy

Radiation therapy may be utilized as either a primary or adjunctive modality in the treatment of tracheal neoplasms. Radiation may be delivered through external beam or brachytherapy techniques. In large series, upwards of 50% of patients receive radiation in addition to definitive surgical management (34). Indications for adjuvant external beam irradiation therapy include positive surgical margins, high-grade histopathology, lymphatic involvement, perineural invasion, and invasion that extends outside of the airway (18,36). External beam radiation therapy may be delivered to airway neoplasms using a variety of sources, energies, and techniques. Hypofractionated tomotherapy allows for three-dimensional coverage of at-risk areas following surgical resection and may limit dose to the esophagus and surrounding trachea, lung, and mediastinum and therefore lessen the side effects of radiation (37). Primary external beam irradiation therapy may be applied as primary therapy in patients who are not suitable candidates for surgical resection. The radiation therapy may be delivered with electrons or neutrons. Ideal fractionation and dosing has not been established. Fast neutron beam irradiation therapy for adenoid cystic carcinoma in median doses of 19.2 Gy offers actuarial 5-year overall survival of 54% with or without an endobronchial brachytherapy boost with ^{192}iridium. Neutrons may be superior to electrons in these minor salivary gland cancers (38). Neutron radiation therapy is not as widely available, however, and may not differ significantly with electrons with endobronchial brachytherapy boost. External beam irradiation therapy may also play a role in increasing locoregional control in patients with well-differentiated thyroid cancers that have required shave excisions from the airway (51% with radiation vs. 8% without) (39). However, segmental resection and reanastamosis of the involved airway may provide superior control in well-differentiated thyroid cancers. In general, endoluminal or full-thickness involvement

of the airway by well-differentiated thyroid cancers should be managed with segmental resections of the airway or laryngectomy and addition of adjuvant irradiation therapy (40,41). Endobronchial brachytherapy may be administered as a boost to external beam irradiation as discussed above or may be utilized as a largely palliative modality to limit endoluminal tumor growth in tracheal malignancy. Endobronchial brachytherapy requires special expertise, and while it may temporarily enhance tumor control, it may also be complicated by serious hemoptysis due to vascular erosion (30,42,43).

Chemotherapy

The role, either adjunctive or palliative, of chemotherapy in the management of tracheal malignancy is poorly defined. Unlike laryngeal cancer, there are no multicenter clinical trial results that define the role of combined radiation and chemotherapy for organ preservation. In unresectable or certain aggressive neoplasms such as basaloid squamous cancer of the trachea, concomitant chemotherapy and irradiation therapy may represent a possible management strategy (44).

PATHOLOGY

Tracheal tumors are uncommon with an overall incidence of 0.2 per 100,000 persons per year, and 80% of these neoplasms are malignant. Primary tumors originate most frequently from the epithelium or glandular tissues of the trachea. Squamous cell carcinomas and adenoid cystic carcinomas are the most common, occurring in equal proportions. These two carcinomas have been reported to represent between two-thirds and three-fourths of tracheal neoplasms (6,45). There are numerous additional benign and malignant neoplasms that have been described, and this group of heterogeneous lesions comprises the remaining one-fourth to one-third of tracheal tumors (Table 126.1) (6,7,18,29,45). Tracheal tumors occur equally among men and women; however, squamous cell carcinoma affects men at least twice as often as women. Adenoid cystic carcinoma occurs equally between men and women. A history of smoking tobacco is associated with squamous cell carcinoma, but not with adenoid cystic carcinoma. In a retrospective chart review of malignant tracheal neoplasms by Webb et al. (18), 75 patients with malignant tracheal neoplasms were identified, and there was a strong correlation between smoking and squamous cell carcinoma, but not adenoid cystic carcinoma.

Squamous Cell Carcinoma

This very aggressive epithelial malignancy can be ulcerative or exophytic. Arising from the surface respiratory epithelium, squamous cell carcinomas can occur throughout the entire trachea, and have been known to invade surrounding structures in the neck and mediastinum. Squamous cell carcinoma of the trachea is notorious for rapid growth and early regional lymph node metastasis. Synchronous or metachronous lesions are common (30% to 40%) and occur most frequently in the lung, larynx, and oropharynx, regions where smoking-related neoplasms are also common (45).

Adenoid Cystic Carcinoma

Adenoid cystic carcinoma arises from the minor salivary gland epithelium within the trachea, and they are usually indolent in their presentation and course. One study reviewed 208 patients with tracheal tumors and found that those with adenoid cystic carcinoma had symptoms three times as long as patients with squamous cell carcinoma (29). There is low risk for regional lymph node involvement; however, perineural invasion and hematogenous metastasis are encountered frequently. These tumors tend to displace surrounding structures rather than invade them. Hematogenous metastasis occurs in approximately 50% of patients and most commonly involves the lungs (46). Recurrence after definitive primary treatment is common and occurs at an average of 51 months compared to 18 months for other tracheal tumors (29).

Secondary Tracheal Tumors

Tumors from adjacent structures can invade the cervical or thoracic trachea. Cervical trachea invasion can occur from well-differentiated thyroid carcinoma, anaplastic thyroid carcinoma, cervical esophageal cancers, and advanced metastatic cervical lymph node disease. Thoracic trachea involvement can result from lung carcinoma, as well as esophageal and mediastinal lymph node disease similar to the cervical trachea.

Although death from thyroid cancer is the exception rather than the rule, when it does occur, tracheal invasion with airway obstruction and bleeding is the cause over 50% of the time (47). Invasion is often identified at the time of thyroidectomy unless luminal invasion has occurred with resulting airway symptoms. Management of tracheal invasion from thyroid carcinoma depends on the extent of invasion, histology, and patient-related factors. Early invasion can be addressed by shaving the tumor from the trachea with the expectation that adjuvant radiotherapy will be given postoperatively. Although controversial, tracheal resection with primary reanastamosis is also an option especially in advanced cases of invasion with intraluminal involvement and may offer more robust disease control (48). Invasion of the trachea or carina can occur from direct extension of a bronchogenic lung cancer. Resection is recommended if there is no regional lymph node involvement or distant metastasis. Tracheal invasion from esophageal carcinoma or metastatic lymph node disease should be considered unresectable, and nonsurgical therapy and palliation is recommended.

Metastatic Tumors

Metastatic tumors of the trachea have been reported and are most commonly from breast cancer, colon cancer, and cutaneous melanoma. Metastasis from renal cell carcinomas, adrenal gland tumors, and testicular cancers has also been described. As with any metastatic disease, prognosis is poor, and palliative treatment is recommended.

HIGHLIGHTS

- Tracheal neoplasms, either benign or malignant, are rare.
- Early biopsy, careful endoscopic mapping, and endoscopic debulking help establish both the airway and diagnosis.
- Prior to definitive management, imaging with CT, MRI, or PET–CT may be helpful in determining extent of disease, lymph node involvement, or extension of tumor outside of the airway.
- Segmental resection of the airway is preferable to nonsurgical or endoscopic management only.
- Extended resections such as cricotracheal resection, laryngotracheal resections with mediastinal tracheostoma, and tracheocarinal resections may be necessary in advanced tumors.
- Adjuvant radiation therapy is helpful in reducing locoregional recurrence in malignant tracheal tumors that have positive resection margins, high-grade histopathology, lymphatic involvement, and perineural invasion.
- In patients in which tumors are not resectable, endoscopic debulking with laser, radiofrequency ablation, or cryotherapy or by mechanical means and placement of airway stents may be helpful in palliation and airway protection.
- External beam radiation, with either electrons or neutrons, along with endobronchial brachytherapy may be used in the treatment of unresectable malignant tracheal tumors.
- The role of chemotherapy, especially in combination with radiotherapy, is emerging, but is poorly characterized. Squamous cell carcinoma is the predominant histopathology and is aggressive with frequent nodal metastasis.
- Adenoid cystic carcinoma is also relatively common and is less aggressive than squamous cell carcinoma and is more likely to exhibit perineural and hematogenous spread. A myriad group of tumors may present in the trachea, which makes accurate biopsy and diagnosis of paramount importance prior to instituting treatment.

Vascular Tumors of the Head and Neck

127

Mark Persky *Spiros Manolidis*

Vascular tumors of the head and neck consist of a variety of different entities that are unrelated to each other. This chapter focuses on acquired vascular tumors that present vexing clinical problems. Based on Batsakis classification of vascular tumors, a differentiation can be made: tumors that are congenital and/or arise on behalf of syndromes and those that are acquired (Table 127.1). This chapter focuses on acquired tumors.

PARAGANGLIA AND PARAGANGLIOMAS

Anatomy and Physiology of the Paraganglia

Paraganglia are part of a system of cell clusters that facilitate the baroreceptive and chemoreceptive reflexes of the cardiovascular system. They are diffusely distributed throughout the upper body. They contain cells that are capable of secreting neuropeptides that have the capability to influence vascular reflexes.

These structures are part of the diffuse neuroendocrine system that are derived from neural crest origin cells. Neural crest derivatives, produce the C cell of the thyroid gland, the melanocyte, and the paraganglia. Paraganglia are found in the adrenal medulla or diffusely distributed as the extra-adrenal paraganglia (1,2).

The latter, the diffusely distributed extra-adrenal paraganglia are divided into branchiomeric paraganglia and vagal paraganglia. The branchiomeric paraganglia are distributed along arteries and cranial nerves in the head and neck. The jugulotympanic paraganglia arise from the second branchial arch while the carotid paraganglia arise from the third branchial arch. The intravagal paraganglia do not follow this embryologic pharyngeal pouch distribution and are thus classified separately. Even so, unusual paraganglioma locations have been recorded that do not fit this classification: larynx, orbit, thyroid, nasal cavity, and sinuses as well as intracranial (3) (Fig. 127.1).

The carotid body is a chemoreceptor that senses changes in arterial oxygen pressure, pH, and carbon dioxide. Along with the cardiac and aortic bodies, these are the only chemoreceptors in the paraganglia. The carotid body is a discrete oval structure situated behind the carotid bifurcation and receives its blood supply directly from the carotid bifurcation via the glomic arteries. The afferent reflex is mediated by a branch of the glossopharyngeal nerve (nerve of Hering) (4) (Fig. 127.2).

The jugulotympanic paraganglia are distributed within the temporal bone in close association with the tympanic branch of the glossopharyngeal nerve (Jacobson nerve) and the auricular branch of the vagus nerve (Arnold nerve). The majority of the temporal bone paraganglia are located in the jugular fossa and the rest are located in the bony canal that transmits Jacobson nerve or in the submucosa of the tympanic cavity. There is a marked difference in the clinical behavior of tumors arising from the jugular paraganglia versus the tympanic paraganglia. This has significant therapeutic implications (5) (Fig. 127.3).

The vagal paraganglia are distinctly different from the jugulotympanic paraganglia. They do not form discrete bodies and are incorporated within the vagus nerve underneath the perineurium or interspersed within the vagal nerve fibers in the pars nervosa of the jugular foramen (which transmits the lower cranial nerves IX, X, and XI). The superior vagal ganglion is found at the level of the jugular foramen. The nodose vagal ganglion lies just below the jugular foramen. Both ganglia are in close proximity to cranial nerves IX through XII, the pars venosa of the jugular foramen, as well as the ascending portion of the petrous internal carotid artery (6). Thus vagal paragangliomas have distinct therapeutic implications based on their close association with the superior portion of the vagal nerve and their adjacent neurovascular structures.

The microanatomy of normal paraganglia is that of clusters that contain chief cells (type I cells) surrounded by

TABLE 127.1 CLASSIFICATION OF VASCULAR TUMORS OF THE HEAD AND NECK

sustentacular cells (type II). These clusters are interspersed by a web of blood vessels. The equivalent structures seen in paragangliomas are termed Zellballen, which retain part of this structural arrangement. The sustentacular cells do not secrete catecholamines and are similar in nature to the Schwann cells enveloping autonomic ganglia. The chief cells have abundant secretory granules, a characteristic of secreting cells. The biochemistry of paraganglia chief cells is characterized by catecholamine production (7). This sequence is characterized by enzymatic conversion of tyrosine to dopamine, norepinephrine, and epinephrine. Extra-adrenal paraganglia lack methyltransferase that is required for the conversion of norepinephrine to epinephrine. The metabolic breakdown of catecholamines to metanephrine (from epinephrine) and normetanephrine (from norepinephrine) as well as vanillylmandelic acid (VMA) can be detected in the urine. Actively secreting paragangliomas can be thus detected with appropriate urine and serum analysis (Fig. 127.4).

Paraganglioma Epidemiology and Pathophysiology

Paragangliomas are neoplasms of the paraganglia. Paragangliomas of the head and neck are rare tumors, comprising about 1 in 10,000 of all tumors in the head and neck area excluding intracranial tumors. The annual incidence of extra-adrenal paragangliomas is estimated at 1 in 300,000 (8). Carotid body tumors and jugulotympanic tumors account for approximately 80% of these, and vagal paragangliomas add another 5%. Significant referral pattern distortions make these numbers less reliable. Multiple paragangliomas are present in up to 22% of all patients with a paraganglioma, and these are frequently hereditary in nature with a family history of such tumors. Approximately 10% of sporadic cases will have a concurrent second paraganglioma. Multiple tumors may be metachronous, and this has implications for surveillance of patients with a paraganglioma. The most common pattern of a synchronous secondary paraganglioma is a second carotid body tumor, which is present in 20% of carotid body tumors. Bilateral carotid body tumors as well as an additional paraganglioma ipsilaterally or contralaterally present significant and challenging treatment problems due to the potential for cranial nerve deficits and loss in baroreceptor function, which results in labile hypertension (9–11).

Other than genetics, the only known predisposition for a paraganglioma is high-altitude living associated with chronic hypoxemia. Several studies show that there is an increased incidence of these tumors with high-

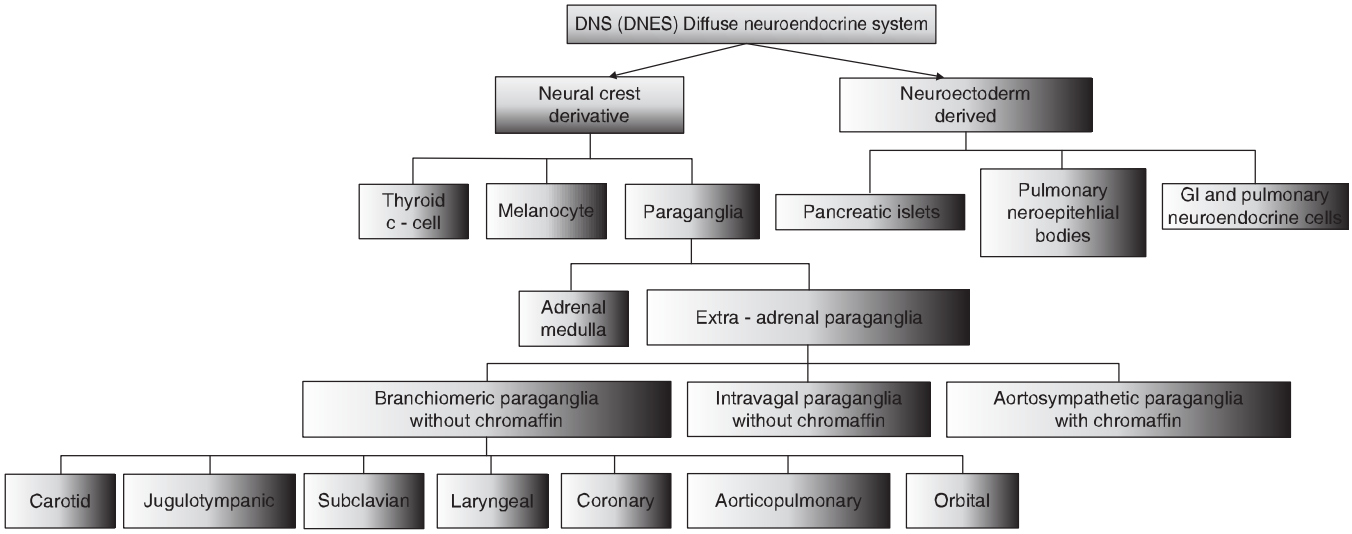

Figure 127.1 Classification of the diffuse neuroendocrine system.

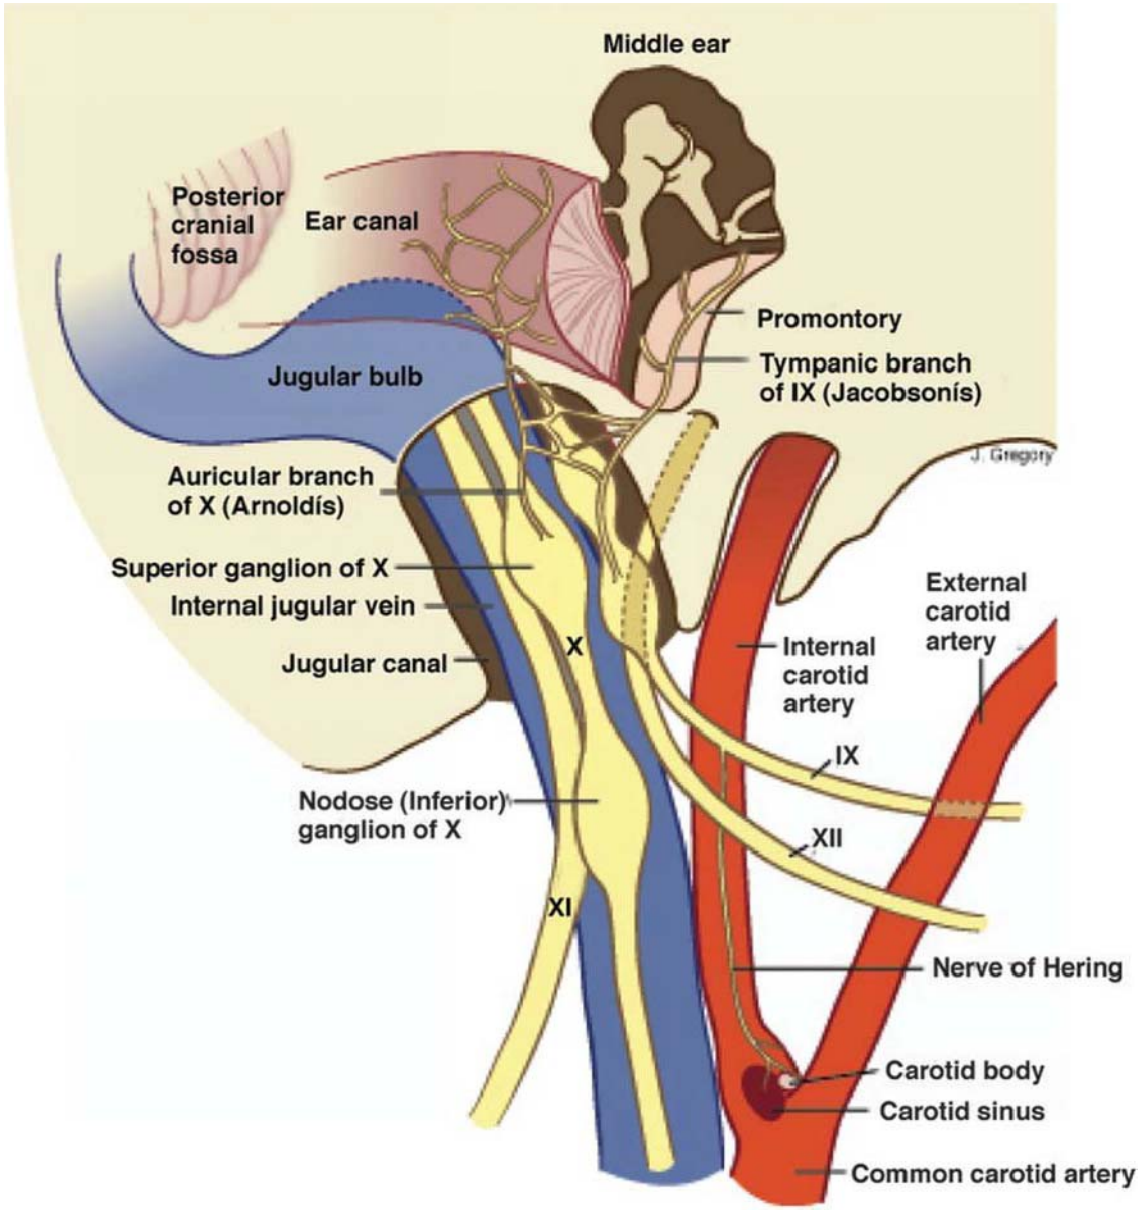

Figure 127.2 Schematic representation of lower cranial nerves at the level of jugular foramen.

altitude living, a ninefold increase for those living between 2 and 3 km and 12-fold increase for those living between 3 and 4.5 km above sea level. Patients forming these tumors at higher altitude show a lower rate of bilaterality and a lesser degree of familial history of paragangliomas (12–14).

Approximately 1% to 3% of paragangliomas secrete catecholamines. A fivefold increase in catecholamines is sufficient to produce symptoms. Secreting paragangliomas account for approximately 2% of all instances of secondary hypertension. Twenty-four–hour urine collection in these patients will show elevated levels of the catecholamine metabolites metanephrine and VMA. Serum catecholamines will show elevated levels of norepinephrine in functioning extra-adrenal paragangliomas. Elevated serum epinephrine is indicative of a concurrent pheochromocytoma (3,15).

Malignant paragangliomas represent a small subset of extra-adrenal paragangliomas that have a propensity for regional lymph nodes and distant metastatic disease, primarily to the lungs, liver, and bones. Sporadic paragangliomas have a higher rate of malignancy than familial-type paragangliomas. PGL4 syndrome is associated with a very high rate of malignancy as high as 54%. The rate of malignancy is site specific. Orbital and laryngeal paragangliomas have the highest rate of malignancy, approximately 25%. Vagal paragangliomas have a malignancy rate of up to 10%, followed by jugulotympanic paragangliomas with a malignancy rate of 5% and carotid body tumors being last at 3% to 6%. There are no histologic criteria by which primary tumor malignancy can be diagnosed. Malignancy is confirmed by tumor present in lymph nodes or distant metastatic sites. The presence of malignancy has profound implications in the treatment of these tumors (16–18).

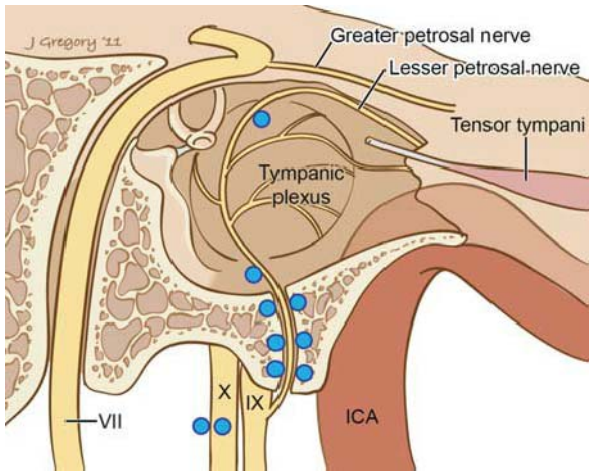

Figure 127.3 Distribution of frequent locations for glomus bodies in the temporal bone.

Genetics

Hereditary susceptibility to paragangliomas, mainly of the head and neck region, was recognized at least two decades ago and led to the identification through linkage analysis of three loci on chromosomes 11 and 1, named PGL1 on 11q23, PGL2 on 11q11.3, and PGL3 on 1q21–23. Following the discovery of SDHD (succinate dehydrogenase [SDH] subunit D gene) as the gene responsible for PGL1 in familial head and neck paragangliomas, it was recognized that two other subunits of this mitochondrial enzyme, SDHC (PGL3) and SDHB (PGL4, 1p36), were associated with heritable pheochromocytoma and/or paraganglioma. To date, the gene for PGL2 has not been identified (12,19–22).

SDH or succinate–ubiquinone reductase is the complex II of the mitochondrial respiratory chain located in the mitochondrial matrix. SDH couples the oxidation of succinate to fumarate in the Krebs cycle with electron transfer to the terminal acceptor ubiquinone. This prevents formation of potentially dangerous reactive oxygen species.

The molecular cascade between SDH mutations and tumor formation is unknown. It has been proposed that SDHD is a critical component of a cellular oxygen-sensing system. Mutations in SDHD may incapacitate the oxygen-sensing mechanism, leading to an apparent or real hypoxic state accompanied by chronic hypoxic stimulation and cell proliferation. Support for hypoxia-induced hyperplasia comes from evidence obtained in high-altitude physiologic studies. Cows, guinea pigs, rabbits, and dogs experience carotid body hyperplasia when living at high altitudes, which exposes them to a hypoxic condition, and this has also been described in humans. Another clinical observation lending support to these theories is the finding that patients suffering from conditions resulting in hypoxemia, such as cystic fibrosis, cyanotic heart disease, and chronic obstructive pulmonary disease experience carotid body hyperplasia and those suffering from chronic obstructive pulmonary disease have a higher rate of carotid body tumors. This relationship between SDHD, SDHC, and SDHB mutations and the oxygen-sensing mechanism, and the cascade of events between these mutations and tumor formation are not completely known (12,13,19–22).

SDH is an enzyme complex composed of four subunits encoded by four nuclear genes (SDHA, SDHB, SDHC, and SDHD). SDHC (cybL, 15 kDa, 169 amino acids) and

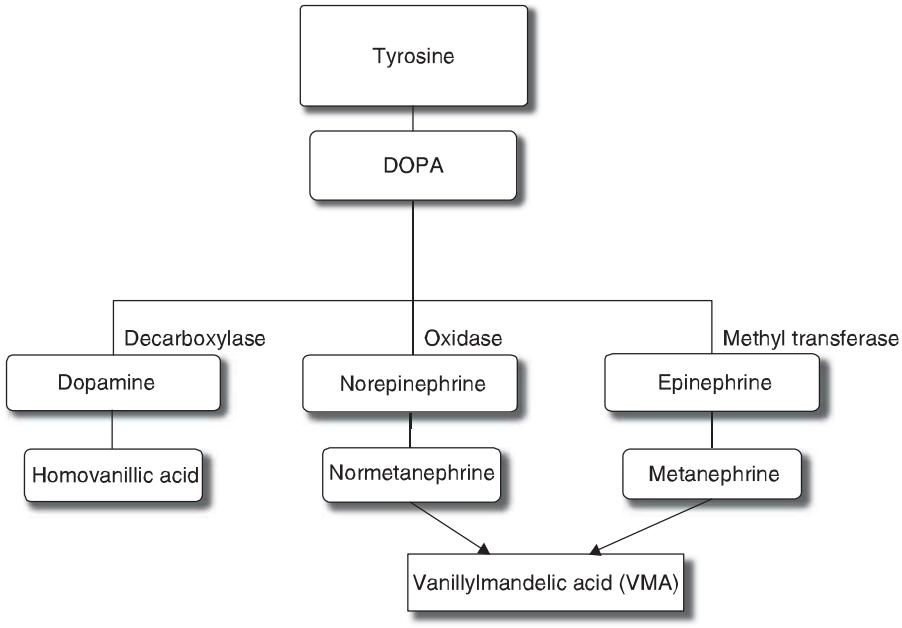

Figure 127.4 Biochemical pathway for catecholamine metabolism.

SDHD (cybS, 12 kDa, 159 amino acids) subunits are hydrophobic and provide membrane anchor and the binding site for ubiquinone. SDHA (flavoprotein, 70 kDa, 664 amino acids) and SDHB (iron–sulfur protein, 27 kDa, 280 amino acids) are hydrophilic with the former involved in substrate binding and oxidation and the latter in electron transfer. Both the SDHB (35.4 kb, 8 exons) and the SDHC (50.3 kb, 6 exons) genes are located on chromosome 1, the short and long arm respectively. The SDHD gene located on 11q23.1 spans 8.9 kb and contains 4 exons while SDHA lies on the short arm of chromosome 5 (5p15) and is composed of 15 exons spread in a genomic region of 38.4 kb. While homozygote germline mutations affecting the SDHA gene cause Leigh syndrome, a subacute necrotizing encephalomyelopathy during infancy, SDHD, SDHB, and SDHC heterozygous mutations cause a genetic predisposition to head and neck paragangliomas and adrenal/extra-adrenal pheochromocytomas (23). This inherited tumorigenic predisposition is transmitted in an autosomal dominant fashion with age-dependent and incomplete penetrance. However, for SDHD located on chromosome 11q, a parent-of-origin effect is apparent as the disease is manifest almost exclusively when the mutation is transmitted from the father. A maternal imprinting has therefore been postulated but despite the pattern of inheritance, SDHD shows bi-allelic expression in normal tissues and neural crest-derived tissues (12,18).

Neurofibromatosis type 1 is also associated with both pheochromocytomas and glomus tumors. Pheochromocytomas are also associated with multiple endocrine neoplasia type II with RET gene mutations, and with von Hippel-Lindau syndrome and mutations in the VHL gene (24).

In cases where successive generations of a family have been harboring the mutations, patients develop tumors at progressively younger ages. This finding is a good example of genetic anticipation, in which the mutation appears to be more severe with succeeding generations.

Familial glomus tumors constitute approximately 20% of affected patients, for which the genetic defects are known. One subgroup (10% of all glomus tumors) appears to be caused by sporadic mutations in SDHB and SDHD. The pathogenesis of the remaining 80% of tumors remains a mystery. Oncology research implicates several processes as important to tumor formation and growth. Two that attract a significant amount of attention are angiogenesis and apoptosis, and these processes have been examined in paragangliomas as well (25).

Angiogenesis is a critical event in the development and sustained growth of several tumor types. Given the vascular nature of paraganglion tissue, questions about the role that angiogenesis plays in the development of paragangliomas.

Vascular endothelial growth factor (VEGF) and platelet-derived endothelial growth factor (PD-ECGF) as well as endothelin-1 have been found in the majority of specimens examined. It has been postulated that this was consistent with a paracrine mechanism for tumor development (26).

Additionally, hypoxia induces expression of hypoxia-inducible factor 1, which participates in the angiogenesis cascade. Pheochromocytomas exhibit ubiquitous hypoxia-inducible factor 1 secondary to mutations resulting in cell hypoxia. This may represent a link between the mutation and tumor development (27).

In summary, the genetic associations in these paraganglioma syndromes are as follows:

- Patients with PGL develop tumors at a younger age than sporadic cases
- Other tumor syndromes: Neurofibromatosis type 1, MEN type 2 and von Hippel-Lindau predispose to paragangliomas
- In PGL 1, 2, and 3, the genetic transmission is autosomal dominant, with highly variable expressivity and reduced penetrance. Genomic imprinting is seen: the paternally transmitted genes lead to tumor development and the maternally transmitted gene gives carrier status without developing tumors
- PGL1 and PGL4 show multicentricity and pheochromocytomas
- PGL4 shows a marked increase in malignant paragangliomas
- PGL3 shows exclusively benign paragangliomas with no multifocality and no association to pheochromocytomas.

Clinical Presentation, Classification

The clinical presentation of paragangliomas is location specific. As these tumors enlarge, they tend to produce cranial neuropathies. Additionally, secreting tumors can produce hypertension, tachycardia, sweating, and nervousness secondary to catecholamine release.

Carotid Body Tumors

Carotid body tumors typically present as a slowly enlarging asymptomatic deep neck mass at the level of the carotid bifurcation. In a small minority of patients, pain is present around the tumor. Because of the association with the carotid artery they are laterally mobile, but rostrocaudally fixed on examination. As the tumor enlarges, a bruit may be auscultated and in addition to a neck mass, a parapharyngeal extension results in the lateral displacement of the soft palate medially and anteriorly. Cranial nerve paralysis symptoms are unusual and present in very large tumors with superior extension toward the jugular foramen. Shamblin classification is commonly used to stage carotid body tumors, and though this is based on intraoperative findings, it can be applied to radiologic findings prior to treatment (Table 127.2, Fig. 127.5).

Jugulotympanic Paragangliomas

Jugular and tympanic paragangliomas occur predominantly in the fifth and sixth decades of life with an overwhelming female predominance. They are slow growing,

TABLE 127.2 SHAMBLIN CLASSIFICATION OF CAROTID BODY TUMORS

Type 1	Relatively small tumor with minimal attachment to the carotid vessels
Type 2	Larger tumor with moderate attachment to carotid vessels but resectable with preservation of the carotid vessels
Type 3	Tumor encases the carotid vessel requiring arterial sacrifice with reconstruction

and their pattern of growth follows the pathways of least resistance in the temporal bone and surrounding skull base structures. In their later stages, both types produce similar symptoms including cranial nerve deficits, while in the early stages tympanic and jugular paragangliomas differ in presentation.

Tympanic paragangliomas present early with pulsatile tinnitus and conductive hearing loss. On otomicroscopic examination, a red–blue middle ear mass that blanches with positive pressure on pneumatic otoscopy is appreciated (Brown sign). With subsequent growth, there is ossicular erosion and filling of the middle ear cleft. Extension through the tympanic membrane will produce an ear canal polypoid mass that may spontaneously cause bloody otorrhea. Extension to the mastoid can occur through a number of pathways. Involvement of the facial nerve, usually in the mastoid, can produce facial paralysis as a presenting symptom. Anterior growth toward the pericarotid air cells can involve the petrous carotid artery and occupy the eustachian tube. Medial growth into the infralabyrinthine air cells can reach the petrous apex and petroclival area as well as cavernous sinus. Intracranial extension is possible through extension through the jugular foramen and/or petrous apex. More infrequently, there is involvement of the otic capsule and the inner ear with attendant sensorineural hearing loss and vertigo at presentation.

Jugular paragangliomas, due to their origin location within the jugular bulb, have the capacity for early and extensive skull base invasion with involvement of cranial nerves 9 through 12. Growth through Jacobson nerve canal and the hypotympanic air cells leads to involvement of the middle ear and mastoid bone leading to conductive hearing loss, tinnitus, and facial paralysis. Intracranial involvement through the jugular foramen is frequent. Erosion of the jugulocarotid spine leads to involvement of the vertical petrous carotid artery, and further anterior extension leads to involvement of the horizontal portion of the petrous carotid artery. More medial extension to the infralabyrinthine air cells lead to involvement of the petrous apex. Further medial extension along this pathway leads to involvement of the clivus and cavernous sinus. Occasionally, jugular paragangliomas will escape the confines of the temporal bone and involve the infratemporal fossa and parapharyngeal space. Lower cranial nerve involvement is frequent and ranges from 38% to 58% (28,29). Multiple cranial nerves are frequently involved with Vernet syndrome (paralysis of cranial nerves 9, 10, and 11) or Collet-Sicard syndrome (paralysis of cranial nerves 9, 10, 11, and 12) in at least 10% of those with jugular paragangliomas (Fig. 127.6). The attendant symptomatology is hoarseness, swallowing difficulty, hemipalatal dysfunction with nasal air escape, shoulder motion restriction, and dysarthria due to tongue hemiparalysis. Two surgical classification systems are in wide use today and can be used preoperatively based on radiographic findings: the Fisch classification system, which makes no distinction between tympanic and jugular paragangliomas and is predicated

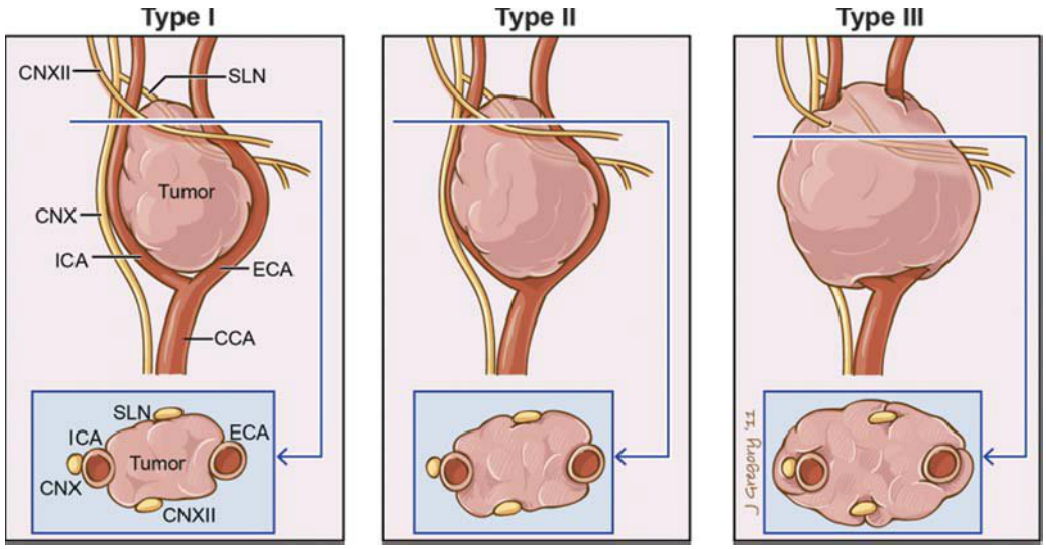

Figure 127.5 Shamblin classification of carotid body tumors.

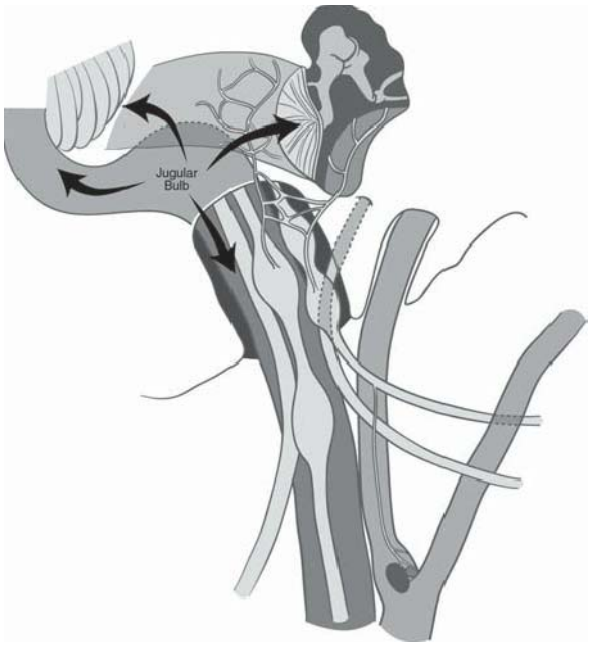

Figure 127.6 Modes of spread for jugular paragangliomas.

on detailed patterns of progressive disease extension, and the Glasscock-Jackson classification system, which treats tympanic and jugular paragangliomas differently (15,28) (Tables 127.3 and 127.4).

Vagal paragangliomas account for 5% of all head and neck paragangliomas and originate in the vagus nerve where the paraganglia are diffusely distributed in the superior, middle, and inferior vagal ganglia. There is a female preponderance of 3:1. Tumors originating superiorly will often present with a dumbbell appearance with an intracranial component in the posterior cranial fossa. Tumors originating inferiorly will extend into the poststyloid compartment of the parapharyngeal space. Vagal paragangliomas are frequently associated with multiple cranial neuropathies at presentation in up to 50% of patients. The vagus nerve is affected most commonly, followed by the hypoglossal and spinal accessory (30) (Fig. 127.7).

TABLE 127.3 FISCH CLASSIFICATION OF JUGULOTYMPANIC PARAGANGLIOMAS

Class A	Tumors arising on the tympanic plexus confined to the middle ear
Class B	Tumors arising from the inferior tympanic canal in the hypotympanum with middle ear and/or mastoid invasion, but jugular bulb and carotid canal intact
Class C	Tumors arising in the dome of the jugular bulb and involving the overlying cortical bone
C1	Tumors eroding the carotid canal but not involving the carotid artery
C2	Tumors involving the vertical petrous carotid artery
C3	Tumors involving the horizontal carotid canal but not foramen lacerum
C4	Tumors involving the foramen lacerum and cavernous sinus
Class D	Tumors with intracranial extension
De1	Extradural extension of <2 cm medial dural displacement
De2	Extradural extension of >2 cm medial dural displacement
Di1	Intradural extension of <2 cm
Di2	Intradural extension of >2 cm
Di3	Neurosurgically unresectable tumors

TABLE 127.4 GLASSCOCK-JACKSON CLASSIFICATION OF JUGULOTYMPANIC PARAGANGLIOMAS

Glomus tympanicum	
Type 1	Small mass limited to the promontory
Type 2	Tumor completely filling the middle ear
Type 3	Tumor filling the middle ear and mastoid
Type 4	Tumor completely filling the middle ear, extending into the mastoid or through the external auditory canal. May also extend anteriorly to involve the carotid artery
Glomus jugulare	
Type 1	Small tumor involving the jugular bulb, middle ear, and mastoid
Type 2	Tumor extending under the internal auditory canal. May have intracranial extension
Type 3	Tumor extending to the petrous apex. May have intracranial extension
Type 4	Tumor extending beyond the petrous apex into the clivus or infratemporal fossa. May have intracranial extension.

Diagnostic Imaging Studies

Computed Tomography

Computed tomography (CT) with contrast is an excellent imaging choice for the diagnosis and delineation of paragangliomas. Since these tumors are highly vascular, early and intense contrast enhancement is seen. The relation of the tumor to the external and internal carotid arteries, as well as the jugular vein, makes this modality essentially diagnostic (31). The delineation of the pattern of invasion of the temporal bone and skull base is indispensable in treatment and especially preoperative planning for paragangliomas. Carotid body tumors display the characteristic splaying of the internal and external carotid arteries by a well-circumscribed mass occupying the carotid bifurcation. Carotid body tumors displace the internal carotid artery posterolaterally. Vagal paraganliomas typically will displace the internal carotid artery anteriorly and occupy the high parapharyngeal space, with or without involvement of the skull base. Jugulotympanic paragangliomas can be distinguished in their early phases, especially when a tympanic paraganglioma is confined to the tympanic

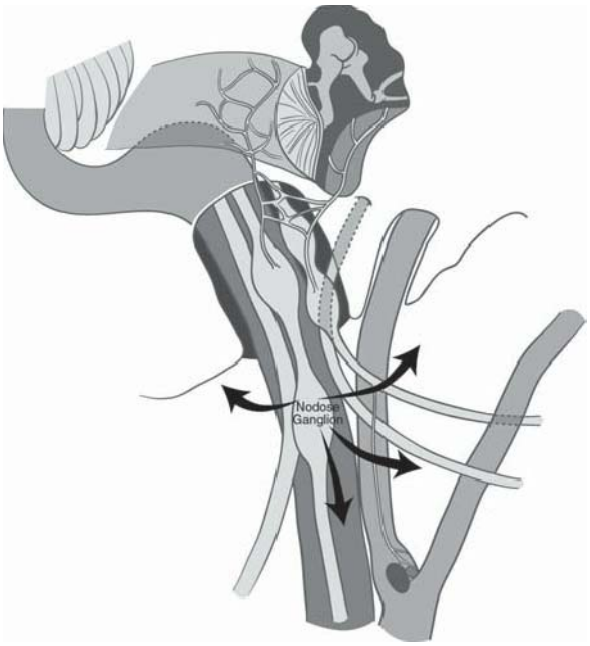

Figure 127.7 Modes of spread for vagal paragangliomas.

cavity. Characteristic patterns of bone destruction occur with jugulotympanic paragangliomas. These include erosion of the jugulotympanic spine, enlargement of the jugular foramen with bone destruction, and involvement of the middle ear and mastoid (31,32). Multiplanar reconstruction of high-resolution CT scans in the axial, sagittal, and coronal planes is of great assistance in the planning of operative management of these tumors. Middle ear and/or eustachian tube involvement will create postobstructive fluid accumulation in the aerated spaces of the temporal bone, including the mastoid (Fig. 127.8).

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) is a complementary and equally important imaging modality in the evaluation and treatment of head and neck paragangliomas. MRI with gadolinium contrast serves three purposes: delineation of the tumor in question, surveillance and detection of concurrent paragangliomas of the head and neck, and confirmation of the diagnosis of paraganglioma. The classic, "salt and pepper" appearance of paragangliomas on T2-weighted images is due to the high-flow vascular voids that are essentially pathognomonic. Paragangliomas show intense signal enhancement with gadolinium contrast (33). Fat-suppressed sequences are exceptionally useful in delineating the extent of the tumor. Patterns of carotid artery displacement can be accurately determined distinguishing carotid body tumors from vagal paragangliomas (33). More importantly, in tumors with intracranial extension, intradural versus extradural involvement can be appreciated, and the relationship of the tumor to important intracranial structures can be delineated. Specialized techniques such as MR angiography and contrast time-of-flight three-dimensional angiography increase the sensitivity of the diagnosis of concurrent tumors but do not supplant selective angiography in the preoperative planning setting (34,35) (Figs. 127.9 and 127.10).

Angiography

With the evolution of detailed MRI and CT techniques, angiography plays a much more limited role in the

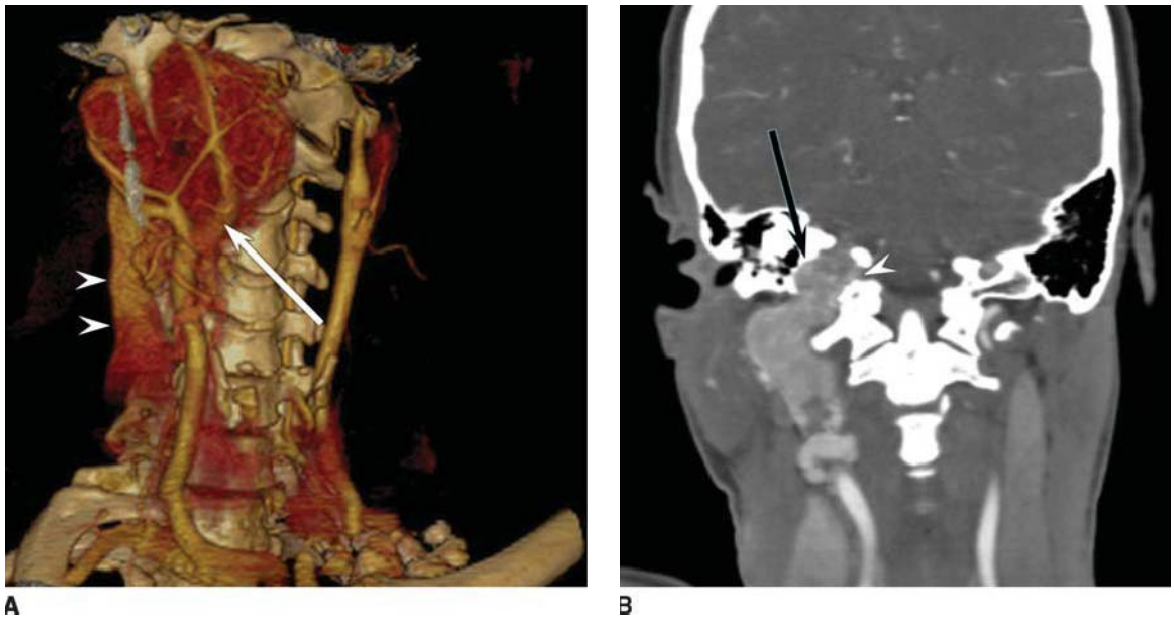

Figure 127.8 CT angiogram of a patient with a large paraganglioma. **A:** Volumetric surface rendering shows anterolateral displacement of the internal carotid artery (*arrow*) and narrowing of its lumen. Note the filling of the internal jugular vein (*arrowheads*) with contrast posterior to the common carotid artery, demonstrating the high flow within this tumor. **B:** Coronal reformat demonstrates involvement of the jugular foramen (*arrow*) as well as the hypoglossal canal (*arrowhead*) by tumor.

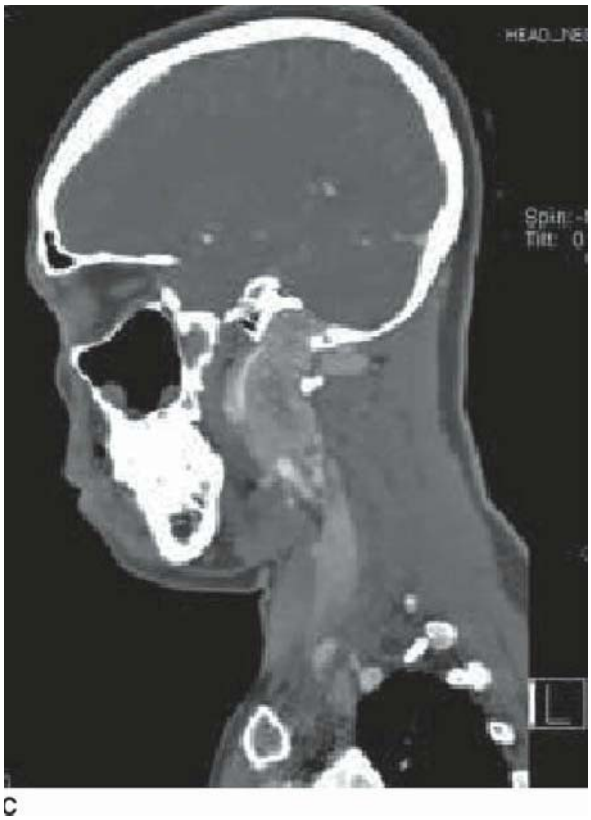

Figure 127.8 *(Continued)* **C:** Sagittal reformat demonstrates circumferential involvement of the internal carotid artery (*arrow*) with anterior displacement, with extensive involvement of the jugular foramen to its intracranial portion.

diagnosis of head and neck paragangliomas but is of paramount importance in preoperative planning for resection of these tumors. Angiography is essential in providing a detailed map of tumor blood supply and venous drainage, demonstrating the tumor flow dynamics and detailing the general vascular anatomy of the head and neck and intracranial space. Four-vessel cerebral angiography allows for qualitative and quantitative blood flow studies of the cerebral circulation. Preoperative preparation through superselective embolization of the feeding arterial supply to the tumor decreases the risk of intraoperative blood loss.

Arterial supply of carotid body tumors takes place directly from the feeding vessels to the carotid body that hypertrophies when a tumor is present (15,28,36). Arterial supply of jugulotympanic tumors is well defined when these tumors are early in their development and involve the ascending pharyngeal artery. As these tumors grow, they recruit additional blood supply that comes from the internal carotid circulation via the caroticotympanic arteries. With invasion of the posterior fossa and medial extension of the tumor toward the cavernous sinus, additional vascular recruitment is possible through the posterior circulation via the vertebral arteries through the clival anastomoses as well as the cavernous sinus microcirculation. This is significant in the preoperative angiographic and embolization management of these tumors. Assessing tolerance to interruption of the internal carotid artery is of paramount importance for extensive paragangliomas that involve the internal carotid artery that can be injured during surgery

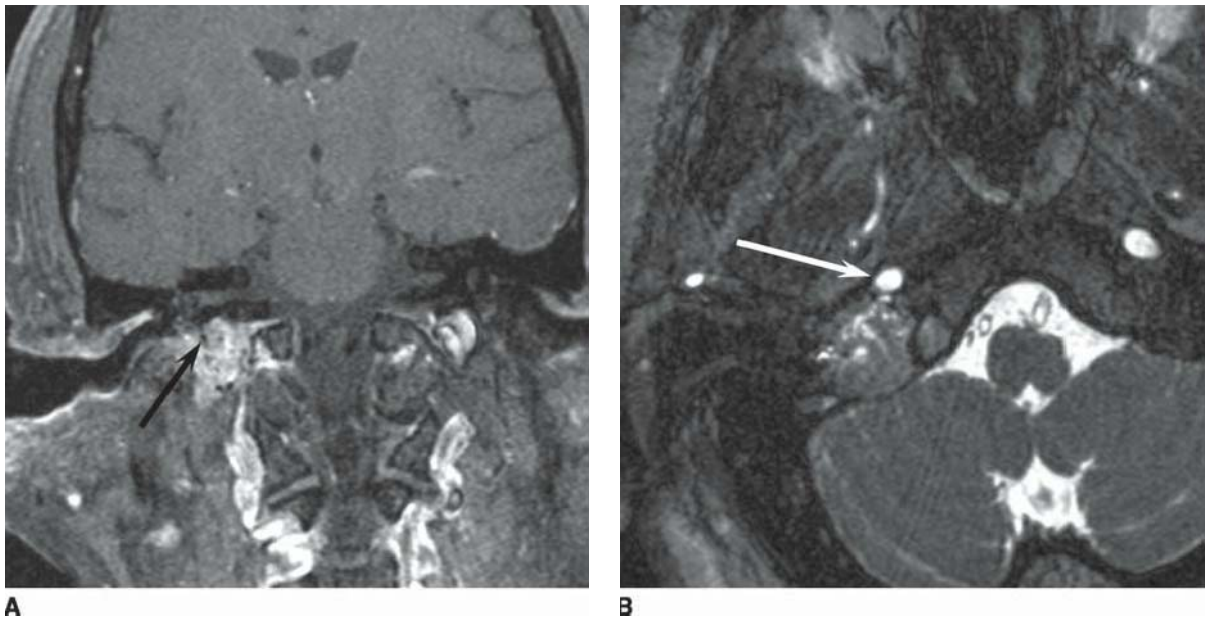

Figure 127.9 Jugular paraganglioma. **A:** Coronal enhanced fat-suppressed T1-weighted image shows avid enhancement with focal round flow voids (*arrow*) indicating large feeding vessels. **B:** Axial fat-suppressed T2-weighted image demonstrates the proximity of the tumor to the vertical portion of the petrous internal carotid artery (*arrow*) as well as the intracranial but extradural component of the tumor in the jugular foramen posteriorly.

or where a planned internal carotid resection is contemplated. An angiographic balloon occlusion test involves the threading of a transfemoral catheter to the internal carotid and involves temporarily occluding the internal carotid artery, usually at the carotid siphon within the cavernous sinus to determine whether there will be neurologic deficit (9,11). Several modalities for neurologic monitoring during balloon occlusion testing of the internal carotid artery are available. In order of decreasing sensitivity, they are clinical neurologic examination, electroencephalography (EEG), and quantitative blood flow examination through xenon CT concurrent examination. Xenon CT angiography is a precise quantitative study with the best sensitivity but is cumbersome and rarely available (37,38) (Fig. 127.11).

Radionuclide Imaging

Radionuclide imaging of paragangliomas targets the biochemical pathways of catecholamine synthesis, storage, and secretion by chromaffin tumor cells. A variety of different imaging techniques exist:

^{123}I-metaiodobenzylguanidine (MIBG), ^{18}F-3,4 dihydroxyphenylalanine–positron emission tomography (^{18}F-DOPA–PET), ^{18}F-fluorodopamine (^{18}F-FDA–PET), ^{18}F-fluoro-2-deoxyglucose (^{18}F-FDG–PET) and Indium octreotide scanning (^{111}In-octreoscan) (39,40).

Different functional imaging agents target paraganglioma tumor cells through different mechanisms. ^{123}I- and ^{131}I-labeled MIBG and ^{18}F-FDA are actively transported into neurosecretory granules of catecholamine-producing cells via the vesicular monoamine transporters after uptake into cells by the norepinephrine transporter. In contrast, ^{18}F-DOPA enters the cell via the amino acid transporter based on the capability of PGL and other neuroendocrine tumors to take up, decarboxylate, and store amino acids and their biogenic amines. Instead of targeting catecholamine pathways, ^{18}F-FDG enters the cell via the glucose transporter, and its accumulation is an index of increased glucose metabolism whereas ^{111}In-octreoscan images indicate somatostatin type 2 receptors that are expressed in paragangliomas (9,10).

^{111}In-octreoscan specificity and sensitivity is approximately 90% in head and neck paragangliomas, which makes it a very effective way to screen for secondary tumors and postoperatively screen for recurrent disease when structural studies like CT and MRI may be compromised postoperatively. ^{123}I-MIBG shows similar sensitivities and specificities. Malignant and metastatic paragangliomas are best imaged with ^{18}F-FDG–PET, which shows sensitivities of 74% to 88% (9,10).

It is increasingly understood that there is a link between genotype-specific tumor biology and imaging. For example, ^{18}F-FDG–PET has an excellent sensitivity for paragangliomas due to SDHB-associated mutation. The SDHB gene encodes for subunit B of the mitochondrial SDH complex II that catalyzes the oxidation of succinate to fumarate in the Krebs cycle and feeds electrons to the respiratory chain, which ultimately leads to the generation of ATP (oxidative phosphorylation). SDHB mutations can lead to complete loss of SDH enzymatic activity in malignant paragangliomas, with up-regulation of hypoxic-angiogenetic responsive genes (23). Impairment of mitochondrial function due to loss of SDHB function may cause tumor cells to shift from oxidative phosphorylation to aerobic glycolysis, a phenomenon known as the Warburg effect. Higher glucose requirements for anaerobic metabolism explain the increased ^{18}F-FDG uptake by malignant SDHB-related paragangliomas (40).

Figure 127.11 Balloon occlusion testing. **A:** Frontal angiographic image shows the inflated radiodense balloon in the proximal left internal carotid artery, occluding flow. **B:** Quantitative cerebral blood flow images created by inhaling xenon gas during dynamic CT. The color images reveal reduced flow (blue instead of red) in the left MCA distribution.

Treatment

Surgical resection has been the traditional treatment for paragangliomas of the head and neck. Microsurgical skull base techniques such as the Fisch infratemporal fossa approaches were developed to specifically resect temporal bone paragangliomas (Fig. 127.12). The refinement of these surgical techniques with the assistance of preoperative embolization has significantly reduced morbidity and has minimized mortality associated with surgery. However, when complete tumor extirpation is contemplated, lower cranial nerve resection or inadvertent injury to the lower cranial nerves can result in significant morbidity affecting phonation and deglutition with a risk for aspiration.

Radiation therapy, which was initially used for the treatment of unresectable tumors or for surgical treatment failures, has become an acceptable treatment modality and has been incorporated into the treatment algorithms for head and neck paragangliomas. External beam radiation, intensity-modulated radiation therapy (IMRT), and, more recently, stereotactic radiation have all been used with excellent results.

In deciding what modality of treatment to select, the following factors should be taken into account: the patient's age and medical comorbidities, the type of paraganglioma in question (vagal, tympanic, jugular, carotid body), the presence of concurrent paragangliomas, the extent of the tumor as well as any preoperative cranial nerve deficits, whether partial or complete. When surgery is contemplated, a surgical team with experience in lateral skull base surgery, head and neck surgery and interventional neuroradiology is a requisite.

Surgery

Preparation for surgery requires angiographic evaluation for most paragangliomas. Anesthesia requirements should take into consideration tumors that may be actively secreting catecholamines, which will require alpha and beta adrenergic blockade. Continuous arterial pressure monitoring is required and transfusions may be necessary. Central venous pressure monitoring may be required depending on the underlying comorbidities.

Angiographic Evaluation

Superselective angiography is an invaluable adjunct for planning surgery in paragangliomas by providing an arterial map that identifies the feeding blood vessels as well as providing the flow dynamics to the tumor. This is especially useful in larger tumors where multiple feeding vessels from both the internal and external circulation may be present with anastomoses between the external and internal carotid systems (41). Similarly, the internal carotid artery can be evaluated for structural integrity and areas of constriction or irregularity, which would imply involvement of the vessel and the potential need for sacrifice. The venous phase of angiography is equally important in identifying the draining vessels and, in jugulotympanic paragangliomas, the degree of occlusion of the jugular bulb, sigmoid sinus, and jugular vein.

Equally important is the angiographic evaluation of adequate cerebral circulation in the event of internal carotid artery disruption or sacrifice. There are many methods

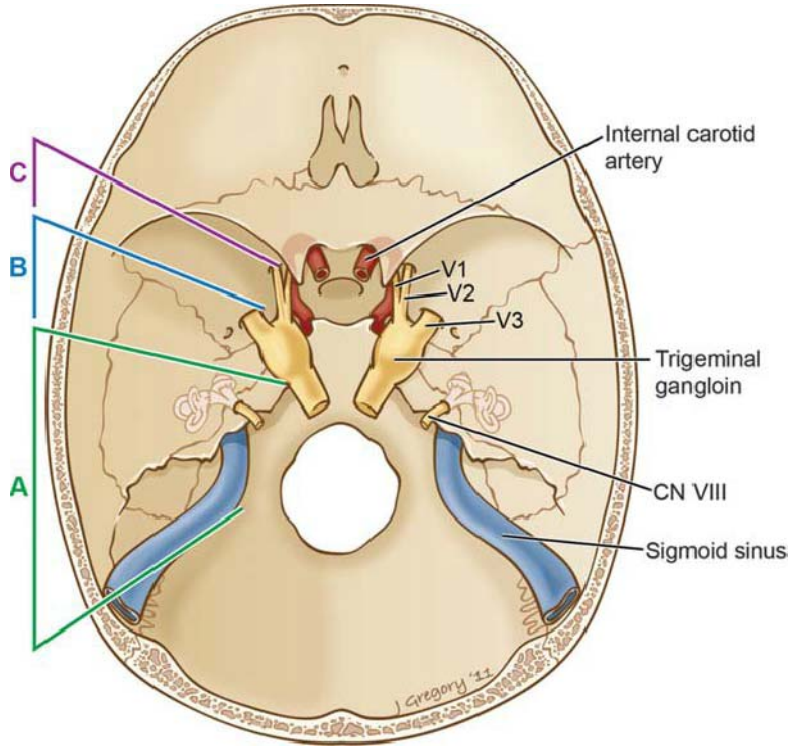

Figure 127.12 Fisch classification of infratemporal fossa approaches. Type A, exposure to the level of the anterior eustachian tube, middle meningeal artery/foramen spinosum. Type B, exposure to the foramen ovale, V3. Type C, exposure to the foramen rotundum, V2.

for assessing adequate contralateral cerebral circulation. Xenon CT scanning with concurrent balloon occlusion is a quantitative analysis of cerebral flow and is the most precise method of cerebral circulation evaluation, though it is cumbersome and not readily available (37,38). Temporary balloon occlusion of the carotid with monitoring of the clinical neurologic examination in the presence of a patent circle of Willis is easier to perform and also very reliable. EEG monitoring can be performed during balloon occlusion as well as hypotensive challenge during the period of balloon occlusion. Approximately 93% of patients can tolerate sacrifice of the carotid artery based on angiographic evaluation. It should be noted that intraoperative conditions may be different in terms of cerebral delivery of oxygen than those in the angiographic suite (11). Tolerance of temporary internal carotid occlusion does not predictably avoid the possibility of a delayed postoperative cerebrovascular ischemic event. The venous outflow of the ipsilateral and contralateral sigmoid and jugular systems should be noted, especially in jugulotympanic paragangliomas. Since there are anatomic variants, a contralateral hypoplastic or absent jugular system would be a contraindication for surgery as this would raise the possibility of a postoperative venous stroke unacceptably (42–44) (Fig. 127.13).

Embolization

Embolization is an exceptionally useful adjunct in the surgery of large paragangliomas. In experienced hands, it carries very low morbidity. The risk of embolization is the escape of embolizing particles into the cerebral circulation thus causing a stroke. This can occur through external–internal carotid circulation anastomoses or flow reversal from the arterial supply of the tumor. The advantages of embolization are tumor shrinkage and decreased blood flow with profound surgical benefits. Less intraoperative bleeding diminishes the requirement of potential transfusions and provides for a much easier dissection with better-defined tissue planes leading to less risk to normal anatomic structures, including cranial nerves. Larger paragangliomas have multiple arterial feeding vessels that need to be individually addressed through superselective angiography. In doing so, with each successive embolization of these vessels, additional compartments of the tumor are devascularized until finally with further injection of contrast in the arterial circulation, there is absence of a tumor "blush." Surgery should be performed within 48 hours of embolization to avoid recruitment of collateral circulation, and administration of steroids is useful in reducing the post-embolization inflammatory response (41,45) (Figs. 127.5 and 127.14).

Surgery

Carotid Body Tumors

Smaller carotid body tumors can be approached through a transverse neck incision, larger ones through an oblique vertical incision along the anterior border of the sternocleidomastoid muscle. Proximal and distal dissection to

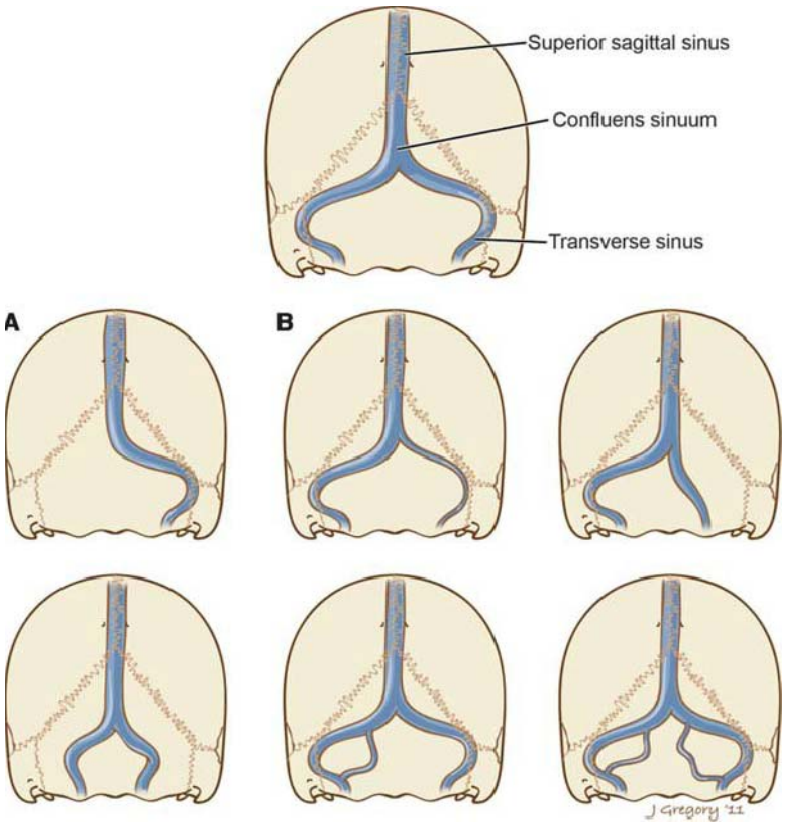

Figure 127.13 Variations of the intracranial posterior venous outflow system at the level of the transverse sinus, sigmoid sinus, and jugular bulb. Variations **A** and **B** would have a high surgical significance if a lesion were to involve the dominant side.

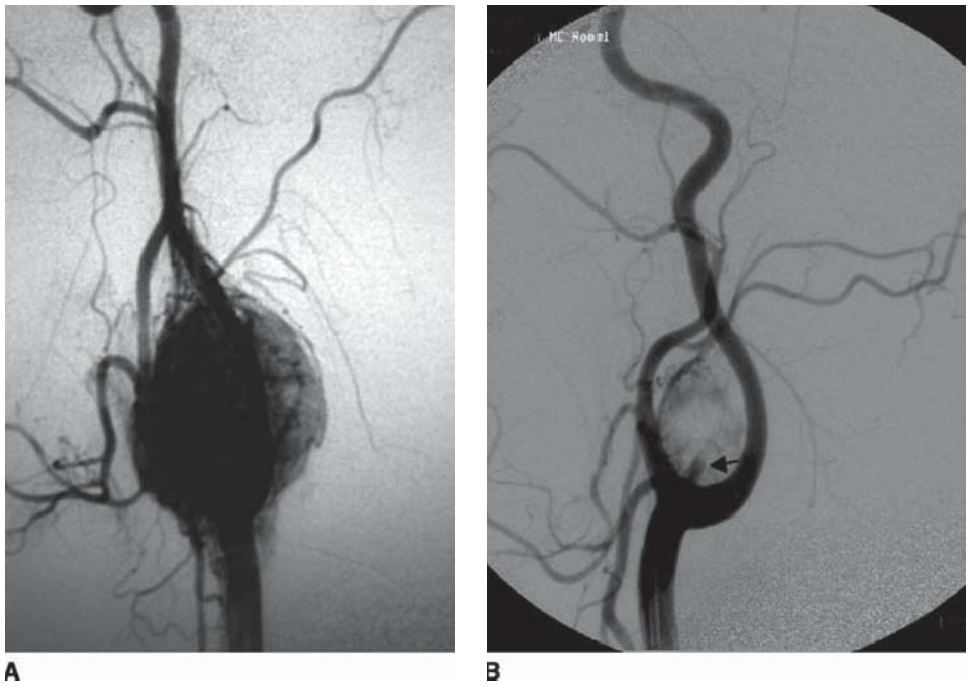

Figure 127.14 Preoperative embolization of a carotid body tumor. **A:** Pre-embolization lateral angiogram shows early, intense blush reflecting high vascular flow with multiple collateral feeding vessels. **B:** Postembolization frontal angiogram shows marked reduction in vascularity. The primary feeding vessel (*arrow*) terminates abruptly.

the tumor identifies the common carotid artery, internal and external carotid arteries, and jugular vein. Vessel loop control is applied. Carotid bypass precautions should be available. The entire course of the internal carotid artery is then exposed with the vessel being typically displaced posterolaterally. The dissection of the tumor is in the subadventitial plane and must be done with extreme care. The tumor may have to be split as it encases the internal carotid artery. In a similar fashion, the external carotid artery is then addressed. Encasement and infiltration of the external carotid artery may necessitate its sacrifice, though this should be avoided if possible. The dissection of the tumor at the bifurcation of the carotid is left last since this is the most vulnerable point for breaching the artery as it is intimately associated with the arterial wall where the tumor originates from the carotid body. The surrounding cranial nerves in carotid body tumors show marked hyperemia of their vasa nervosum of the nerve sheath. In larger tumors, these nerves may be intimately involved and their dissection may cause dysfunction of the vagus, hypoglossal, and glossopharyngeal nerves. Ligation of the external carotid artery as a means to control blood flow to the tumor should be avoided as this maneuver does not affect tumor blood flow since collateral circulation may be profuse (Figs. 127.15 and 127.16).

Jugulotympanic Paragangliomas

Small tympanic paragangliomas (Glascock-Jackson type I, Fisch class A) can be approached through a transcanal/inferiorly based tympanomeatal flap. Embolization of these tumors is not required. Bipolar electrocautery microforceps can be used to shrink the tumor and resect it. Larger tympanic paragangliomas confined to the middle ear and/or mastoid without breaching the bone overlying the jugular bulb or the jugulocarotid spine can be exposed through a combined postauricular/endaural approach with a canal wall up mastoidectomy and extended facial recess approach inferiorly that sacrifices the chorda tympani and removes the vaginal process of the tympanic bone to expose the hypotympanum.

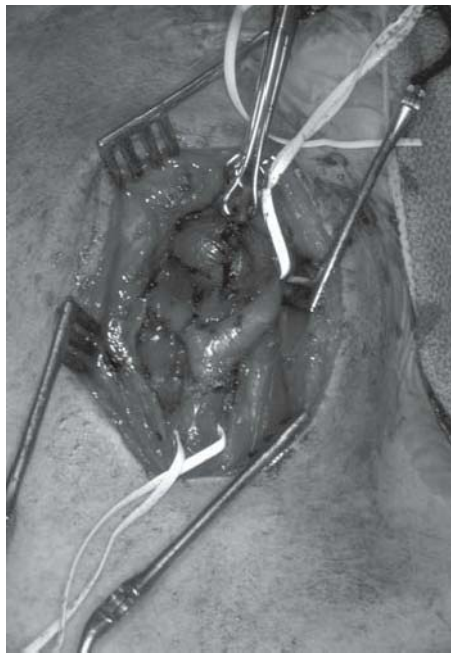

Figure 127.15 Intraoperative picture of a carotid body tumor. Tenaculum is on the lateral tumor surface. Vessel loops are around the common carotid artery (inferiorly) and internal carotid artery (superiorly).

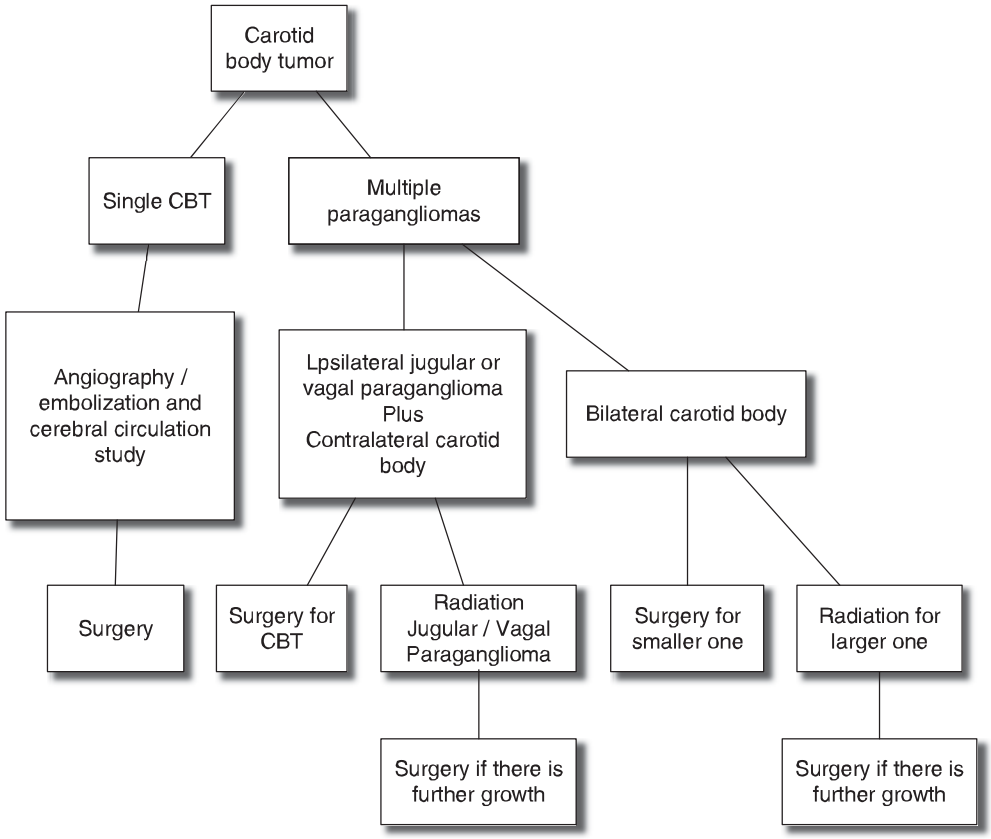

Figure 127.16 Decision analysis tree for the treatment of carotid body tumors.

When the jugular bulb is involved, a combined temporal/cervical approach is required. An extended mastoidectomy and extended facial recess approach is performed with skeletonization of the sigmoid sinus and exposure of the jugular bulb through the retrofacial air cells. The internal carotid artery is dissected superiorly and controlled. Cranial nerves 9, 10, and 11 are identified and traced proximally and distally. The internal jugular vein is then ligated superiorly and dissected toward the jugular bulb in the neck. The sigmoid sinus is occluded and ligated above the tumor extension. Contralateral venous outflow should be verified through preoperative studies. When occlusion of the sigmoid sinus is performed, this should be done in a manner that avoids interfering with the outflow from the anastomotic vein of Labbe that drains the temporoparietal cortex, thereby avoiding the risk of a venous stroke (46). Once the sigmoid sinus is opened and the jugular vein is ligated inferiorly, hemostatic agents can be injected to gently occlude the inferior petrosal veins. Dissection of the tumor should proceed with irrigating bipolar electrocautery. At the level of the jugular bulb, the dissection should proceed with extreme caution since the cranial nerve rootlets of the glossopharyngeal and vagus are at their most vulnerable. In jugulotympanic paragangliomas, these rootlets are displaced medially and are thus in a favorable position. If the tumor does not extend into the pars nervosa/medial jugular bulb compartment, preservation of the cranial nerves is feasible and desirable (47).

More advanced tumors that involve the vertical and/or horizontal petrous carotid artery with possible intracranial extension require a postauricular infratemporal fossa approach. These approaches begin with an extended mastoidectomy, removal of the external auditory canal, tympanic membrane, malleus, and incus. The external canal is permanently oversewn, which commits the patient to ipsilateral conductive hearing loss. The peritubal and pericarotid air cells are removed and the intrapetrous carotid artery is skeletonized proximal to the tumor extent. This may involve sacrifice of the middle meningeal artery and removal of the foramen spinosum as well as the foramen ovale if the tumor has extended toward the cavernous sinus. The tumor is removed from the carotid, middle ear, and sigmoid/jugular bulb/jugular vein (Fig. 127.17). Extension of the tumor to the medial jugular bulb compartment or intracranially places the nerve rootlets of cranial nerves 9, 10, and 11 in an unfavorable position, and more frequently than not these need to be sacrificed. If there is no such extension, an effort is made to gently dissect the tumor away from the nerves. The eustachian tube should be permanently occluded to avoid postoperative cerebrospinal fluid rhinorrhea. Intracranial extension is addressed by opening the dura in the presigmoid area down to the tumor extension at the level of the jugular bulb. Tumor extension

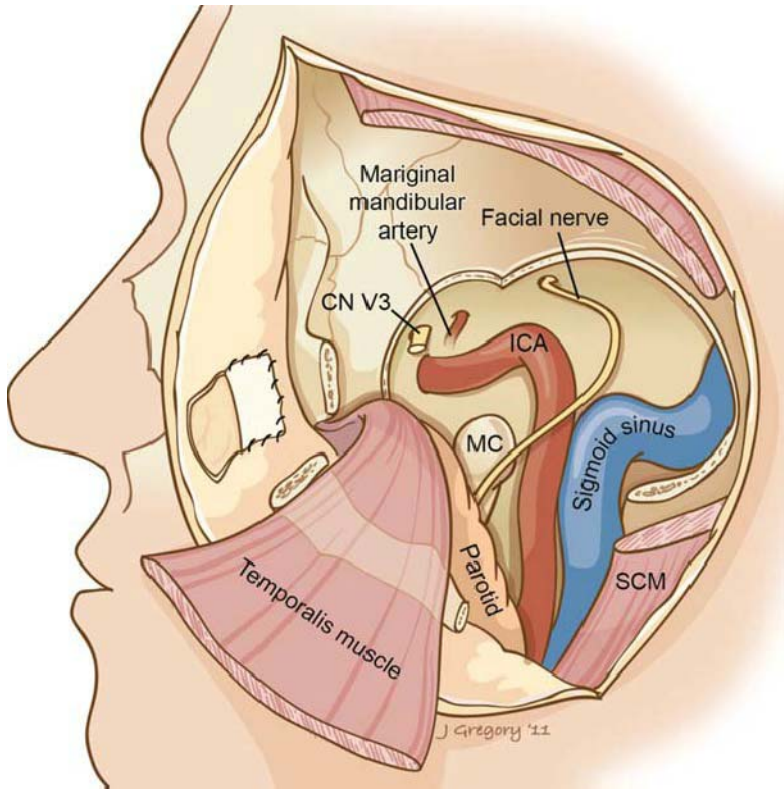

Figure 127.17 Schematic representation of a type B infratemporal fossa approach. Lateral temporal bone has been removed exposing the petrous carotid artery, jugular vein, jugular bulb, and sigmoid sinus. Facial nerve has been mobilized in its horizontal and vertical portions. The third division of the trigeminal nerve (V3) has been divided as well as the middle meningeal artery right behind it. MC, mandibular condyle; SCM, sternocleidomastoid muscle; ICA, internal carotid artery.

toward the petrous apex and clivus may necessitate a translabyrinthine/transcochlear approach. In these approaches, the facial nerve is mobilized out of the fallopian canal in its vertical and horizontal portion to the geniculate ganglion. This will result in temporary facial paralysis due to interruption of the blood supply to the nerve as well as the retraction anterosuperiorly (15,28,48). Incomplete recovery of facial nerve function is a possible outcome. Reconstruction with temporoparietal fascia flap or temporalis muscle is done at the conclusion to assist healing and prevent a cerebrospinal fluid leak. Lumbar drainage for a limited period of time in the immediate postoperative recovery may be indicated for the prevention of a cerebrospinal fluid leak. When cranial nerves have been sacrificed, immediate surgical amelioration with a concurrent vocal cord medialization and a pharyngoplasty with cricoesophageal myotomy at the same sitting have been recommended.

Refinement of these surgical techniques includes the juxtacondylar approach as well as the transjugular craniotomy (47). These modifications have in common the shifting of the surgical angle of approach more posteriorly. The advantages are that they obviate the need for facial nerve transposition and improve the control and preservation of the lower cranial nerves in the jugular foramen. The limitation is that they cannot address tumors that involve the petrous carotid artery.

Vagal Paragangliomas

Most vagal paragangliomas originate in the nodose (inferior) vagal ganglion, which is situated 2 cm below the jugular foramen. Their bidirectional growth along the vagus results in involvement of the jugular bulb superiorly and poststyloid parapharyngeal space inferiorly. The internal carotid artery is displaced anteriorly (30). Vagal paragangliomas originating in the superior and middle ganglia, which are situated within the jugular foramen, cause early skull base invasion with intracranial extension. The surgical techniques to approach these tumors are identical to those for jugulotympanic paragangliomas when the skull base is involved. The inferior extent of vagal paragangliomas require detaching the digastric muscle from its origin and removing the styloid process to access the parapharyngeal space extension. Sacrifice of the vagus nerve in these tumors is inevitable. With involvement of the jugular foramen and skull base, additional cranial nerve deficits are to be expected as these tumors extend medial to the cranial nerve rootlets, within the pars nervosa of the jugular foramen.

Complications

Vascular Injury

Early surgical series for paraganglioma surgery reported a stroke rate of 10% to 20%. More recent series report a stroke rate of 0% to 2%. With more recent diagnostic evaluations, preoperative planning, and microsurgical techniques, the risk of injury or need for internal carotid sacrifice is minimal. For carotid body tumors, the risk of injury and need for vessel sacrifice is size specific, with tumors larger than 5 cm likely requiring carotid reconstruction. In addition,

preoperative findings of stenosis and irregularity on angiography and/or circumferential involvement on MRI with loss of the pericarotid advential plane should dictate preoperative preparation for carotid resection and reconstruction (49–52).

Vagal paragangliomas differ from carotid body tumors and jugulotympanic paragangliomas as they are not intimately associated with the carotid artery. In advanced tumors, both vagal and jugulotympanic, the internal carotid artery can be completely encased in its petrous portion. With adequate surgical exposure and microsurgical technique, injury should be infrequent in experienced hands. Internal carotid sacrifice in this location is fraught with problems, and therefore if sacrifice is contemplated, consideration for alternate treatment in these instances is important. If the vessel is at high risk for injury within the petrous carotid portion and the patient has safely passed balloon occlusion testing, permanent preoperative occlusion of the carotid distal to the tumor should be considered.

More recently, a novel approach to the artery at risk is to place a vascular endoprosthesis and then perform the surgery several weeks later. Fibrosis around the self-expanding stent creates a leak-proof artery. This has the advantage of reducing blood flow to the tumor as well as preventing vascular injury (53).

Baroreflex Failure

Surgery for removal of bilateral carotid body tumors results in loss of the baroreceptor reflex with bilateral denervation of the carotid sinus. In the immediate postoperative period, this results in labile refractory hypertension, tachycardia, diaphoresis, and headache, which may be managed with sodium nitroprusside. The long-term treatment is controlled with clonidine (54). Alternative therapy may be considered on one of the tumors to avoid long-term blood pressure lability.

Cranial Nerve Injury

The risk to the lower cranial nerves in surgery for paragangliomas is location specific and tumor size specific. The surgical treatment of the following tumors, in decreasing order, pose risk to the cranial nerves: vagal, jugulotympanic, and lastly carotid body paragangliomas. Size of lesion is especially important in vagal and jugulotympanic paragangliomas. Tumors with extensive skull base involvement, intracranial, and/or infratemporal fossa extension are likely to have extensive involvement of the lower cranial nerves with at least one lower cranial nerve involved and often times multiple cranial nerve deficits preoperatively. Involvement of the facial nerve with preoperative paralysis is a sign of such extensive involvement (15,28,29,55,56).

Postoperative individual cranial nerve deficits most often result in a temporary deglutition, phonation, tongue motion, and/or aspiration problem. Multiple cranial nerve deficits have additive effects and are poorly tolerated. In older patients, recovery is often very difficult and permanent aspiration requiring management with a gastrostomy and tracheostomy is a possibility, especially in high vagal nerve injuries. Bilateral lower cranial nerve paralysis, especially of the vagus nerve as a result of therapy or progression of tumor in bilateral disease is a devastating injury that results in inability to swallow and phonate.

The deficit in vagal nerve injuries is proportionate to the level of the injury. Low vagal nerve injuries distal to the origin of the superior laryngeal nerve will result in vocal cord paralysis that can be mitigated relatively easily. Injury to the vagus at the nodose ganglion or at the level of the jugular foramen results in vocal cord paralysis, anesthesia of the ipsilateral hemilarynx, supraglottic structures, and paralysis of the ipsilateral soft palate. The deficit results in aspiration due to lack of sensory input from the larynx with paralysis of the pharyngeal musculature and the vocal cord. In addition, there is air and food escape into the nasopharynx due to the paralysis of the soft palate. Vagal nerve injuries at the jugular foramen are often associated with glossopharyngeal nerve injuries, which add ipsilateral pharyngeal anesthesia, further compromising swallowing function. Superior vagal injuries require immediate and intensive swallowing therapy with surgical management of the vocal cord paralysis (Fig. 127.18). Most injuries at the level of the jugular foramen are permanent, and immediate surgical management to mitigate deficits is indicated. Vocal cord medialization with a thyroplasty combined with cricopharyngeal myotomy will improve phonation and deglutition as well as minimize the risk of aspiration. An ipsilateral palatal adhesion procedure can mitigate the hypernasality in speech and nasal bolus escape during deglutition. Additional lower cranial nerve injuries are seen in 30% to 50% of patients with a vagal nerve injury significantly complicating recovery (57–60).

Accessory nerve injury results in loss of trapezius and sternocleidomastoid muscle function. Physical therapy is required to avoid should pain secondary to shoulder "drop" and limitation of motion. If the nerve is injured below the jugular foramen it may be amenable to primary repair either directly or through a nerve graft (59).

Injury to the hypoglossal nerve results in ipsilateral tongue paralysis. Hemiatrophy of the tongue is the eventual outcome within a few months. When this is in combination with additional cranial nerve injuries swallowing therapy is of paramount importance in preventing aspiration. Swallowing therapy is directed at teaching the patient to move the bolus to the functioning side (59).

Injury to the sympathetic chain is seen in approximately 25% of patients postoperatively as a result of interruption of the sympathetic ganglia. This results in partial or complete Horner syndrome. The resultant ptosis can be easily rectified through a Müller muscle eyelid-tightening procedure. "First bite syndrome," which is intense pain with the first bite, can develop as a result of denervation hypersensitivity of the myoepithelial cells of the parotid gland. This problem improves gradually and spontaneously in most patients.

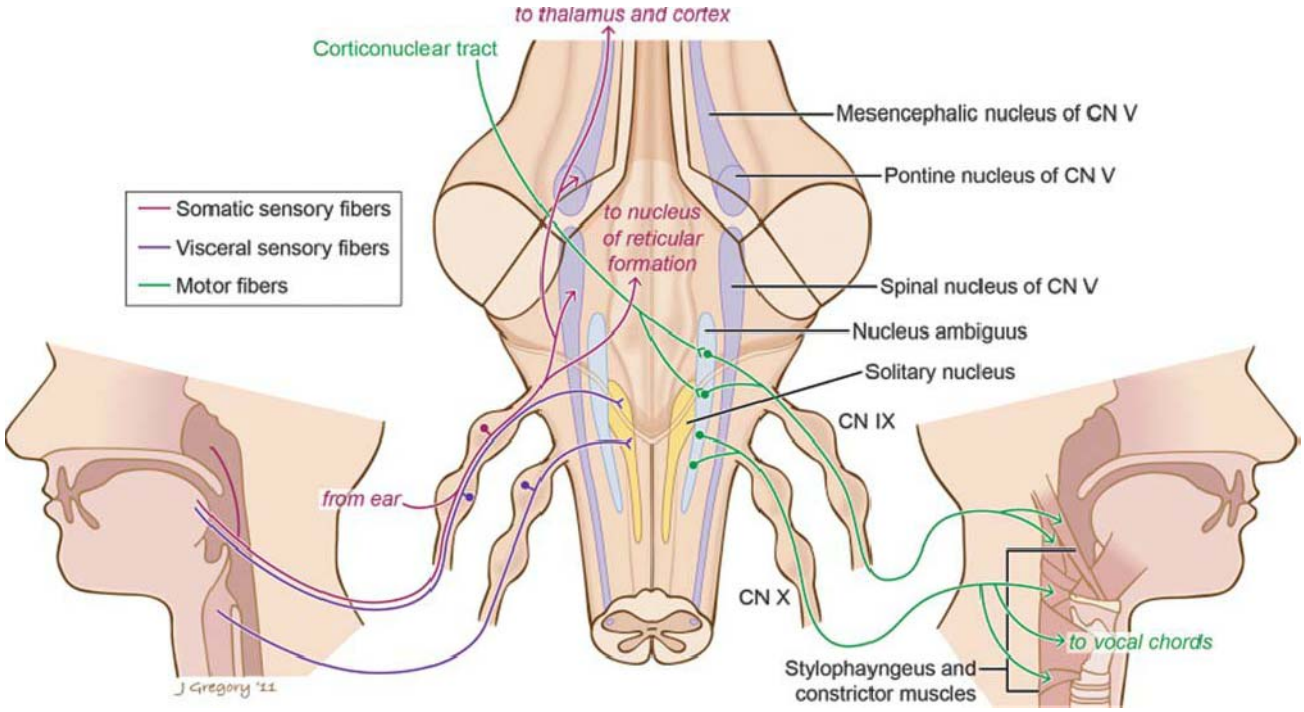

Figure 127.18 Schematic representation of the afferent and efferent swallowing reflex.

Postoperative cranial nerve deficits in carotid body tumor surgery are seen in up to 40% of patients and are associated with large tumor size. The majority of these deficits are transient and related to the manipulation of cranial nerves during dissection. Vagal nerve injury is most common. In jugulotympanic paragangliomas, the most common nerve deficit is also vagal (27%), followed by the glossopharyngeal (18%), the accessory, and hypoglossal (8%) (9–11,29,59).

External Beam Radiation

Paragangliomas are responsive to radiation treatment. On the basis of histologic studies, the primary effect of radiation is obliterative endarteritis at the capillary level, followed by fibrosis within several months. However, chief cells remain viable in the specimens studied following radiation. It is difficult to state whether these cells retain their capacity to proliferate. Traditionally, radiation was relegated for tumors that were deemed unresectable or tumors in elderly and medically infirm patients deemed not able to tolerate surgical resection. The optimal dose appears to be 45 Gy/over 5 weeks.

Local control with radiation therapy is defined as tumor shrinkage or nonprogression. An analysis of 36 series with over 1,000 tumors treated spanning the period of 1964 to 2001 shows an average local control of 90% with a range of 65% to 100%. Other reviews of the radiation therapy literature provide similar control rates of 90% and 91%, respectively. Follow-up in these series is wide, ranging from 1.5 to 30 years. The intriguing aspect of radiation is the minimal additional damage to cranial nerves. New cranial neuropathies range from 1% to 4% with existing cranial neuropathies improving in an average 35%. The incidence of severe complications is 6% with a mortality of 0.6%. These include radiation osteoradionecrosis, temporal bone complications, and brain complications and are associated with older radiation techniques or higher radiation dosages. In addition, there are well recognized and reported cases of secondary malignancy from radiation to the temporal bone (61).

Stereotactic Radiation

The principle of stereotactic radiation is to deliver a one-time high dose of radiation to the target in question, which is highly focused and has a sharp drop off to spare surrounding normal tissue. This can be achieved through the Gamma Knife that utilizes cobalt as a source of radiation or radiation generated in a linear accelerator—LINAC. The advantages are similar to those of external beam therapy with preservation of cranial nerve function and minimal significant complications, in addition to the therapy being delivered in one sitting. This modality cannot be used for tumors larger than 4 cm and cannot be used for carotid body tumors as well as tumors that extend caudal to the skull base as they are out of the stereotactic frame field. Local control rates for stereotactic radiation range from 82% to 100% albeit with limited follow-up ranging from 19 months to 4.2 years (62–66).

Treatment Comparisons

The results of surgery, external beam radiation, and stereotactic radiation show similar efficacy in affecting cure:

approximately 90%. The definition of cure is different for surgery and radiation. Surgical cure is total resection with no evidence of tumor regrowth by serial radiologic imaging. With radiation, a fraction of tumors show some reduction in size and the majority remain stable in size. Two more factors are important in interpreting results: recurrences and disease progression. Tumor growth for paragangliomas is very slow with a mean growth rate of 1 mm/y and an average tumor doubling time of 4.2 years. In comparing external beam radiation to surgery, the recurrence rates are similar at 7% to 8%, respectively. Salvage therapy for recurrent disease is effective in 88% of patients. Disease progression and death from paraganglioma tumor occurs in 2.5% of those treated by surgery and 6% of those treated by radiation (disease specific mortality). In comparing surgery versus stereotactic radiation, the control rate was 86% for surgery with an 88-month average follow-up versus a 95% control rate for stereotactic radiation with a 71-month follow-up. Others have found a control rate of 92% versus 97% for surgery versus stereotactic radiation, albeit with a shorter follow-up period (61).

Treatment Strategies

Patients presenting with signs and symptoms consistent with paraganglioma and patients referred for treatment with a radiographically confirmed paraganglioma should undergo a thorough history and examination. Attention should be focused on signs and symptoms of a secreting tumor, a familial history of paragangliomas, MEN type 2, and von Hippel-Lindau syndromes. Examination should focus on cranial nerve function, and any dysfunction should be documented thoroughly. Genetic testing for PGL gene should be done if there is a positive family history and other members of the family should be screened for paragangliomas. Multiple paragangliomas can be screened by ^{123}I-MIBG or ^{111}In-octreotide scans as well as (18)F-DOPA PET scans. If malignant paraganglioma is suspected, (18) F-FDG PET scan should be the modality of choice. Twenty-four–hour urine as well as serum catecholamine screening for norepinephrine, epinephrine, and their metabolites should be performed to exclude a functioning tumor. Contrast-enhanced CT scans with thin cuts as well as MRI scans should be done for pretreatment evaluation. If surgery is contemplated, angiographic evaluation with superselective embolization in preparation for surgery should be performed for the appropriately selected tumors. Similarly, cerebral angiography for adequacy of collateral blood flow and temporary balloon occlusion studies will be required in selected patients. A fine needle biopsy is not indicated in most instances as the radiographic studies are pathognomonic (9,10,15,61).

Noting that the definition of cure is different for surgery than radiation and assuming that the two are equal concerning "cure," treatment algorithms can be constructed for paragangliomas that maximize the long-term control and minimize the potential morbidities of each modality. Therefore, for unilateral small- to moderate-sized carotid body tumors as well as tympanic paragangliomas without cranial nerve dysfunction, primary surgery is the first line of choice. In bilateral carotid body tumors, surgery on both sides should be avoided because of labile hypertension. However, this needs to be weighed against radiation risks for accelerated atherosclerosis and radiation-induced malignancy risk especially in young patients. Radiation therapy is a highly effective treatment for jugulotympanic and vagal paragangliomas without cranial nerve dysfunction. For patients with jugulotympanic as well as vagal paragangliomas, surgery should be the primary modality when lower cranial nerve dysfunction is present, especially vagal paralysis. Radiation therapy as a primary modality is best suited for those who have medical comorbidities and those who have no lower cranial deficits at presentation. Elderly patients can either be observed or treated with radiation as the primary treatment. Salvage therapy for recurrent tumors should be offered (Figs. 127.16 and 127.19).

Catecholamine-secreting tumors should be managed by surgery as primary treatment as these tumors continue to secrete after radiation despite radiographic evidence of arrest of growth (61).

Paragangliomas suspected or proved to be malignant, either by fine needle biopsy of suspicious lymph nodes and/or positive PET–FDG scans, should also be managed by surgery as the primary modality, given the unknown response rate to radiation alone as well as the frequent need to perform neck dissection for staging and comprehensive treatment. Additionally, in patients who have been genetically screened and found to have a PGL4 mutation, because of the marked increase in incidence of malignant paragangliomas, surgery should be considered as the first line of treatment.

Finally, despite advances in surgical treatment as well as radiation techniques, these tumors have the potential for significant morbidity. Overriding factors such as the patient's wishes, the patient's lifestyle, and family support structure may alter the treatment choices. Regardless of the modality of treatment, long-term follow-up with serial scanning is indicated.

HEMANGIOPERICYTOMA

Hemangiopericytoma (HPC) is an uncommon tumor that arises from the pericytes of Zimmerman that are found spiraling around capillaries and postcapillary venules. The function of the cell is to control vascular tone in these capillary beds and this tumor can theoretically arise wherever capillary beds are found. HPC was first described by Stout and Murray in 1942. The pathologic diagnosis is vexing and frequently confused with synovial cell sarcoma, epithelioid hemangioendothelioma and solitary fibrous tumor (SFT). The architectural pattern of HPC is similar to that of other mesenchymal neoplasms, for example, sarcomas (67).

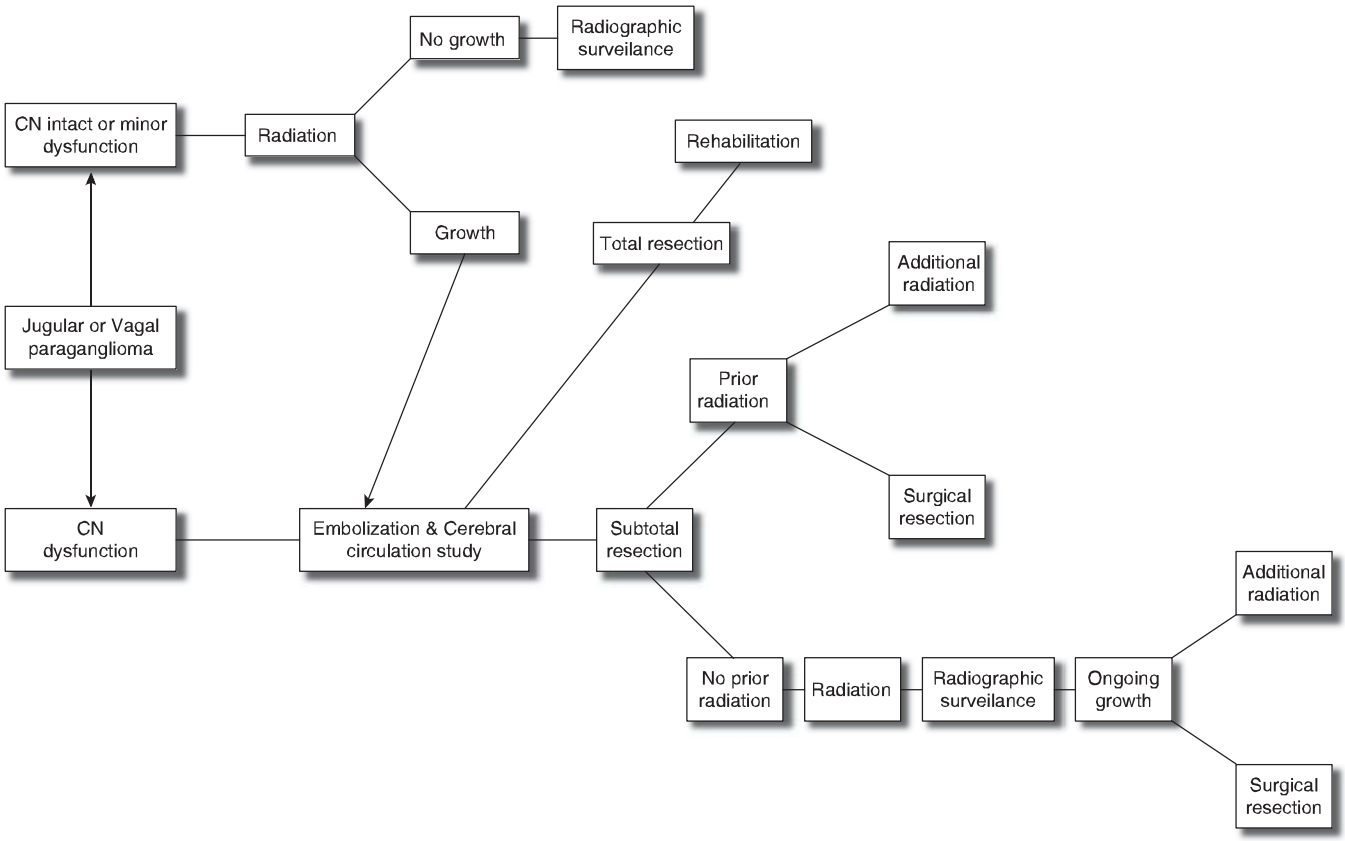

Figure 127.19 Decision analysis tree for the treatment of vagal and/or jugular paragangliomas.

An ongoing debate currently exists among sarcoma experts as to how best to classify HPC and SFT. Because of the large overlap of morphologic and clinical features between HPC and SFT and a lack of clear diagnostic criteria, the two entities have been frequently misdiagnosed for each other. In the most recent WHO classification of soft tissue sarcomas, the concept of HPC as a vascular, pericyte-derived tumor was abandoned in favor of a fibroblastic cell of origin, thus aligning HPC more closely with SFT. SFT in particular displays two different types: a fibrous variant and a cellular variant. The latter is virtually indistinguishable from HPC. The current paradigm tends to view HPC and SFT as a spectrum of a single entity (68).

The diagnosis of HPC is one of exclusion and relies on the presence of characteristic histologic features. Older studies have characterized a low-grade versus a high-grade variant of this tumor based on the presence and number of mitoses, presence of necrosis, and cellular anaplasia. Ten-year survival was markedly different between the two groups: 77% for those with low grade, versus 29% for those with high-grade tumors. More recently, reverse transcriptase polymerase chain reaction has helped distinguish HPC variants such as lipomatous HPC, glomangiopericytoma, and myopericytoma, which have a much more benign course and require much less aggressive therapy than HPC (68).

Of interest is that an infantile or congenital HPC exists that differs substantially clinically and pathologically from the adult form. Congenital HPCs are predominantly subcutaneous head and neck lesions that display an indolent behavior despite worrisome histologic features such as extensive necrosis and hemorrhage, hypercellularity, and increased mitotic figures. These tumors spontaneously regress and behave biologically in a much more benign fashion despite their aggressive histologic features (69). Similarly, sinonasal HPCs behave biologically in a more benign fashion than other head and neck sites (70,71).

Overall, it is difficult to predict biologic behavior of the HPC on conventional histopathologic parameters.

Clinical Behavior

In descending order of frequency, these tumors occur in the extremities, particularly the lower extremity, the pelvis and retroperitoneum, the head and neck as well as the meninges. Fifteen percent to twenty-five percent of these tumors occur in the head and neck. Meningeal HPCs were initially thought to be variants of meningioma (hemangioblastic meningioma) and were reclassified by the WHO in 1993. In the head and neck, they can be mucosal, arising in the sinonasal tract as well as the oral cavity or in the soft tissues of the neck, particularly of the scalp. Orbital HPC tumors have also been described. Sinonasal HPCs behave clinically in a less aggressive fashion with lower rates of metastases (72,73).

Overall, the clinical course of HPC may vary from indolent, with a low rate of local recurrence, to aggressive, with rapid development of metastases.

The tumor presents most frequently as a painless mass, predominantly in the sixth and seventh decades with a median age of 45 at presentation and no sex predilection. Pain is associated with advanced presentation. Satellite nodules around the primary tumor can be frequently seen, though they are not specific for this lesion. The etiology of HPC is unknown, although the presence of HPC has been linked to trauma, prolonged steroid use, and hormonal imbalance.

Treatment

No treatment modality for HPC/SFT has been evaluated prospectively, but several retrospective analyses suggest that complete surgical resection of the tumor, whenever possible, should be the treatment of choice. Earlier studies have demonstrated an overall 10-year survival of 54% to 89% after complete surgical resection. However, it is worth noting that earlier series may include patients who were histologically classified as an HPC when in fact these tumors were sarcomas. The rate of regional metastasis from HPC is low, and most patients fail at a local or distant site. Local recurrence and distant metastases are often noted after a significant disease-free period, which necessitates continuous surveillance. Series have shown that over 80% survival rates have been faulted by limited follow-up, especially for a tumor that has indolent and unpredictable behavior (72,74–76).

In comparison with other soft tissue sarcomas, HPCs fare much better in terms of recurrence and overall survival. Development of distant metastatic disease is a poor predictor of survival.

Management of HPC/SFT patients who develop locally recurrent or metastatic disease has been challenging, for no clearly effective therapy exists. Re-resection and/or metastasectomy can lead to improvement in tumor-free survival and should be considered if technically feasible.

Radiation Therapy

Radiation therapy has been used, both as adjuvant therapy in patients considered at risk for local recurrence and as primary therapy in unresectable cases. The best evidence for effectiveness of external beam radiation is for meningeal HPCs. In one study with long follow-up, adjuvant external beam radiation extended the disease-free interval from 154 months to 254 months, providing patients with an increased recurrence-free interval and overall survival (72).

Chemotherapy

Conventional chemotherapy for HPC is based on anthracycline agents that involve significant toxicity. Limited data are available for the effectiveness of systemic chemotherapy in advanced HPC. Although a few responses have been reported, systemic chemotherapy has not shown significant clinical response, and its effects on disease progression and/or survival advantage are difficult to prove (77,78).

More recently, inhibition of angiogenesis pathways with monoclonal antibodies has provided a target for this tumor with limited but promising data for disease stabilization. In a study of temozolomide and bevacizumab for both HPCs and SFTs considered unresectable, disease stabilization was demonstrated. These agents had a 10% mortality in this cohort of medically compromised patients. Bevacizumab is a recombinant monoclonal antibody that targets VEGF, a key mediator of a signaling pathway that affects many vital cellular processes, including angiogenesis and vascular permeability. Bevacizumab has shown antitumor activity when combined with a number of cytotoxic chemotherapeutic agents. Other specific target agents that have been used are sunitinib, sorafenib, and pazopanib, which target broadly the tyrosine kinase receptors and block multiple pathways of tumorigenesis. The results of these studies are difficult to extrapolate to this specific tumor because of its rarity and the fact that it is included in studies that include multiple soft tumor types (79).

ANGIOSARCOMA

Epidemiology

Angiosarcomas are a subtype of soft tissue sarcoma and are aggressive malignancies arising from the vascular endothelium of blood vessels or lymphatics. Fewer than 5% of all soft tissue sarcomas occur in the head and neck, and approximately 10% of these head and neck soft tissue sarcomas are angiosarcomas (80). Angiosarcomas are the fourth most frequent sarcoma of the skin, after Kaposi sarcoma, dermatofibrosarcoma protuberans, and leiomyosarcoma. The incidence of angiosarcoma has risen over the past 30 years, but whether this is a true increase is unclear. The rise could be related to greater use of radiotherapy and improved diagnosis. Angiosarcomas have a similar distribution between sexes, can develop at any age, and are more common in older patients. Angiosarcoma can arise in any soft tissue structure or viscera, and cutaneous angiosarcomas typically involve the head and neck, particularly the scalp. Cutaneous head and neck angiosarcomas account for 62% of all angiosarcomas, have a male predilection, and 88% occur in the Caucasian population (81).

Treatment Is Challenging and Prognosis Is Poor

Angiosarcomas of the face and scalp are insidious, and their clinical presentation varies widely. In their early stages, they frequently appear clinically innocent and may even show benign capillary hemangioma-like structures histologically. There is a frequent delay in clinical diagnosis. This pattern, however, is deceiving because angiosarcomas usually have an aggressive course. Tumor cells are located mainly in the dermis and may extend into the subcutaneous tissue.

Results of treatment are difficult to interpret due to the rarity of the tumor and paucity of adequate studies. There have been no phase-3 and few phase-2 treatment trials in angiosarcomas. In the past, the prognosis of cutaneous angiosarcoma was considered extremely poor, with an overall 5-year survival rate less than 20%. Age, (less than 50 years), tumor stage (localized), and anatomical site (trunk) confer a favorable prognosis. Locations other than the head and neck (i.e., trunk and extremities) confer a better survival prognosis, which is similar to Merkel cell carcinomas. The tendency of angiosarcoma for early regional and distant metastases, as well as local recurrences after years of apparent remission, is well recognized (81,82).

Etiologic Factors

Most angiosarcomas arise spontaneously, but there are a few reports of malignant transformation within preexisting benign vascular lesions. Several well-described risk factors exist (Table 127.5).

Chronic lymphoedema of any origin is associated with the development of angiosarcoma, (Stewart-Treves syndrome). Lymphoedema caused by Milroy disease and chronic infections, such as filariasis, have been linked to the development of angiosarcomas.

Radiotherapy is an independent risk factor. Although the association between radiotherapy and subsequent angiosarcoma is best described for breast cancer therapy, it is not exclusive to breast lesions (82). In a review of the Surveillance of Epidemiology and End Results (SEER), data showed an increased risk of soft tissue sarcomas (particularly angiosarcomas) after adjuvant radiotherapy, with a peak incidence 5 to 10 years after treatment. Angiosarcoma of the breast is associated with previous treatment by radiation with subsequent lymphoedema as well as treated breast cancers with mutations in the DNA repair genes, BRCA1 and BRCA2. Other familial syndromes such as Maffucci syndrome and Klippel-Trenaunay have been associated with increased incidences of angiosarcoma (81,82).

Various chemicals are associated with the development of angiosarcomas, particularly within the liver. Occupational exposure to vinyl chloride as well as thorium dioxide is associated with hepatic angiosarcomas. Exposure to arsenic, radium, and anabolic steroids is also associated with angiosarcomas. Reports of angiosarcoma associated with foreign bodies include accidentally retained surgical gauzes as well as surgical prostheses (82).

Filariasis (parasitic lymphoedema)
Carcinogens
Vinyl chloride
Thorium dioxide
Arsenic
Anabolic steroids
Foreign bodies
Syndromes
Neurofibromatosis type 1
Maffucci syndrome
Klippel-Trenaunay syndrome
BRCA-1 or BRCA-2 mutations

Pathology

Angiosarcomas are infiltrative and do not have a capsule or a clear border.

Abnormal, pleomorphic, malignant endothelial cells are the hallmark of angiosarcoma and can have an epithelioid appearance. In well-differentiated tumors, abnormal endothelial cells retain vascular structures with functioning vascular channels. With increasing dedifferentiation, the vascular architecture disappears with abnormal cells becoming multilayered and forming papillary-like projections. In poorly differentiated areas, the malignant endothelial cells form continuous sheets with areas of necrosis, which can make differentiation from anaplastic carcinoma or melanoma difficult (82).

Angiosarcomas typically express endothelial markers including von Willebrand factor, CD34, CD31, Ulex europaeus agglutinin 1, and VEGF. Immunohistochemistry is therefore important in confirming the diagnosis. von Willebrand factor, U europaeus agglutinin 1, and CD31 are the most useful markers in poorly differentiated cases. However, progressive tumor dedifferentiation can lead to a loss of these markers. The absence of melanocytic markers (S100), human melanoma black-45, and melanoma antigen can help distinguish angiosarcoma from melanoma. Additionally, epithelioid angiosarcomas can express cytokeratins, leading to confusion with poorly differentiated carcinomas (82,83).

Molecular Studies

Because angiosarcomas are endothelial-cell tumors, there is great interest in the role of angiogenesis and the angiogenic factors associated with their pathogenesis, and how they might be used as targets for treatment. VEGF and its receptors can be overexpressed in angiosarcomas. VEGF-A is the most studied cytokine and is consistently expressed at higher concentrations in angiosarcomas than in benign vascular or normal-tissue controls (82).

All three subtypes of VEGF receptors (VEGFRs) have been detected in angiosarcomas. VEGF-A expression is correlated with VEGFR-1 expression, VEGFR-2 is correlated with prognosis, and the loss of expression of VEGFR-2 is associated with a significantly poorer prognosis (84,85).

Activation of the RAS pathway is often tumorigenic. Although immortalized murine endothelial cells form benign hemangiomas *in vivo*, the addition of activated HRAS produces rapidly growing, poorly differentiated angiosarcomas. In clinical cases, KRAS mutations have been reported in liver and cardiac angiosarcomas.

Consistent with the invasive and metastatic potential of angiosarcoma, overexpression of the transcription factor ETS1 results in increased production of metalloproteinases (particularly MMP1, MMP3, and uPA), resulting in increased extracellular proteolysis and decreased amounts of the major basement membrane components. Angiosarcomas recruit inflammatory cells, particularly mast cells, that drive positive feedback loops by causing further release of cytokine growth signals, including basic fibroblast growth factor (bFGF) and VEGF (79,85,86).

Because of the success of KIT–tyrosine-kinase inhibitors in treating some other sarcomas, investigators have studied KIT expression in various forms of angiosarcoma. Results pooled from three separate series showed KIT positivity in 50% of the samples examined. KIT-mutation analysis has been done for a handful of angiosarcomas; however, no unique abnormalities to angiosarcomas have been to date identified. Conversely, although angiosarcomas are tumors of malignant endothelial cells, increased expression of angiogenic cytokines, including VEGF and its receptors, bFGF, platelet-derived growth factor (PDGF), and the angiopoietin system, have been reported in other cancers including soft tissue sarcomas of nonendothelial vascular origin (79,85,86).

Pathologically, the distinction between angiosarcoma and a benign capillary lesion or an HPC or Kaposi sarcoma is difficult and fraught with error on routine light microscopy.

Staging

Soft tissue sarcomas are staged using the International Union Against Cancer and American Joint Committee on Cancer (UICC/AJCC) system. This is based on the TNM (tumor–node–metastasis) staging system (Table 127.6). Angiosarcomas are not graded according to histology as they all are considered high grade. Various authors have tried staging angiosarcomas, and in a review of the SEER data, three stages were identified: local, regional, and distant disease.

Approximately 10% of patients with head and neck angiosarcoma will show regional metastases at presentation. Eighty-two percent of primary tumors are larger than 5 cm at presentation. Satellite lesions are seen in 46% of patients and these are an ominous prognostic sign. Approximately 10% of patients will have distant metastases at presentation. The lungs followed by the liver and bones are the most common sites of distant metastatic disease (81).

Treatment

There are no randomized trials and few prospective studies; most published reports of angiosarcoma treatment are retrospective case series. Treatment guidelines for angiosarcoma have been included in guidelines for other soft tissue sarcomas. Such guidelines have been published by the European Society for Medical Oncology and the National Comprehensive Cancer Network.

TABLE 127.6 TNM SARCOMA STAGING

N0	No regional lymph-node involvement
N1	Regional lymph-node involvement
M stage	
Mx	Cannot be assessed
M0	No distant metastasis
M1	Distant metastasis

Radical surgery with complete (R0) resection is the primary treatment of choice. Involved margins (R1 or R2 resection) are common because of the invasive and often multifocal nature of angiosarcomas, which confer a worse prognosis.

Wide margins are recommended but are difficult to achieve in the head and neck and particularly the scalp because of extensive microscopic spread, surrounding function—critical structures, and cosmesis. Compounding this problem is the inability of intraoperative frozen section to evaluate correctly for microscopic margins. In one study, the negative predictive value of frozen section was 33.3% with 79% of patients having residual microscopic disease despite multiple attempts at achieving clear microscopic margins (80). Therefore, what appears to be a clinical T1 stage will be very frequently upstaged to a pathologic T2 stage in angiosarcoma. Because of these limitations, the use of Mohs surgery does not confer an advantage in treatment.

Some have argued that since an R0 resection rarely results in clear margins of resection, the goal should be an R1 or R2 resection with rapid wound closure to expedite adjuvant therapy. However, with the availability of reliable free tissue transfer to close large wound defects, margins need not be compromised for prompt delivery of adjuvant therapy (Figs. 127.20 to 127.22).

Additional surgery in locally recurrent disease to achieve a pathologic complete resection may improve survival. Because of the high risk of local recurrence, adjuvant radiotherapy, with large doses (greater than 50 Gy) and wide treatment fields, is recommended. Radiation treatment alone is generally thought to be inadequate treatment for angiosarcoma and further radiotherapy is usually avoided for radiation-induced angiosarcomas (84).

Figure 127.20 Extensive recurrent angiosarcoma of the scalp.

Figure 127.22 Same patient as in Figures 127.20 and 127.21 after reconstruction with a latissimus dorsi free flap.

Chemotherapy has not been shown to improve either overall or disease-specific survival in large series and there is no convincing evidence to support the use of chemotherapy in the neoadjuvant or adjuvant setting after definitive surgery and radiotherapy for angiosarcoma. However, in view of the risk of distant metastasis, in the setting of local failure, a compelling argument can be made for adjuvant chemotherapy.

Chemotherapy is the primary treatment option for metastatic angiosarcoma, although the evidence base for this is limited. Drugs that have been used include: doxorubicin, ifosfamide, and taxanes. Many angiosarcoma patients are elderly, so comorbidities and the risk of treatment-related toxicity can limit the use of chemotherapy.

Figure 127.21 Same patient as in Figure 127.20 after resection including sagittal craniectomy.

In soft tissue sarcomas, doxorubicin and ifosfamide as single drugs show response rates of 16% to 36% (87,88). Combination chemotherapy is associated with increased toxicity but not necessarily with better outcomes. The addition of cisplatin, vinorelbine, and gemcitabine to doxorubicin and ifosfamide has shown no proven benefit to the treatment of angiosarcoma. Liposomal doxorubicin has the theoretic advantage of higher vascular tissue accumulation of the drug (89).

Response rates for taxane-based drugs in other soft tissue sarcomas have been disappointing, but taxanes have antiangiogenic activity and are therefore of particular interest in the management of angiosarcomas. The results have been mixed with studies reporting short-lived response rates of 63% to 75% and small gains in progression-free intervals (90). In one study, though the response rate was low at 17%, three patients with otherwise unresectable disease went subsequently to surgery with complete pathologic response (91).

Biologic Molecules

Although the pathogenic pathways underlying angiosarcoma are not fully understood, there is interest in exploring the potential of antiangiogenic molecules in the treatment of angiosarcomas. Encouraging reports on the use of the VEGF-A monoclonal antibody, bevacizumab, include one of two patients with nasal angiosarcomas who achieved pathologic-complete responses to treatment with bevacizumab and radiotherapy (92,93). A phase 1/2 study of bevacizumab, in combination with docetaxel and gemcitabine chemotherapy in advanced and recurrent soft tissue sarcomas, included three angiosarcomas, with complete responses reported in two of them (87).

There is evidence to suggest activity of the targeted treatments, bevacizumab and sorafenib, in angiosarcoma; however, biologic agents are not recommended,

either as monotherapy or in combination with cytotoxic chemotherapy, outside of clinical trials.

Results

Disease variables that affect survival in angiosarcoma of the head and neck include: anatomic location, size of tumor at presentation, presence of regional or distant metastatic disease, presence of satellite lesions as well as age at presentation.

In the SEER study, head and neck angiosarcomas had a 13.8% 10-year relative survival rate, whereas tumors arising in the trunk resulted in a 75.3% 10-year survival rate. Angiosarcomas of the scalp are particularly problematic. Patients with scalp angiosarcoma show significantly poorer prognosis than patients with angiosarcoma of the face. Size of lesion at presentation shows significant difference in survival and this is more pronounced for the scalp. Patients with T1 lesions have a 71.4% disease survival rate versus those with T2 lesions who show a 9.5% survival rate (81).

Overall patients with angiosarcomas localized to the skin show a 54% 10-year relative survival rate, those with regional metastases a 19% 10-year relative survival rate, and those with distant metastases a 6.1% survival rate (81).

The vast majority (85%) of patients with angiosarcomas of the skin are older than 60 years. The SEER epidemiologic data show that patients younger than 50 years have a 10-year relative survival rate of 71.7%, whereas patients 50 years and older have a 36.8% 10-year survival rate (81).

Disease relapse occurs frequently, and in one large series, 53% developed local recurrence, 36% developed distant metastases, and 21% developed regional metastases. Overall, almost two-thirds of patients experienced local recurrence of their disease, and 36% developed distant metastases. Isolated local recurrence portends a poor prognosis that leads to the development of distant metastases. This highlights the critical role definitive local management plays in controlling this disease. Most local relapses occur in the first 5 years (92%), but local relapses up to 10 years after successful initial treatment have also been reported. Similarly, the interval for distant metastases after successful treatment spans to 10 years (80,82,94,95).

JUVENILE NASOPHARYNGEAL ANGIOFIBROMA

Epidemiology and Pathogenesis

Juvenile nasopharyngeal angiofibromas (JNAs) are rare fibrovascular tumors that account for less than 0.5% of all head and neck tumors. The incidence of JNA is approximately 1:150,000, and it affects adolescent boys and men between the ages of 14 and 25 years. Rare cases have been reported in men over 25 years old and in adolescent girls. Although benign, they are locally invasive with a capacity for extensive bone destruction and remodeling (96,97).

The most widely accepted theory of formation of JNA is that the tumor originates from embryologic chondrocartilage during the development of the cranial bones. The site of origin is the superior margin of the sphenopalatine foramen, which is formed by the junction of the palatine bone, horizontal ala of the vomer, and the root of the pterygoid process (98).

Histologically, JNA shows a biphasic pattern. There is a component of fibrous stroma of spindle cells in a dense collagen matrix and a component of a rich network of vascular channels of varying sizes in clusters. These vascular channels lack the surrounding smooth muscle of normal blood vessels and it has been theorized that this is related to their capacity to profusely bleed when surgically manipulated. JNAs are nonencapsulated and are mucosa covered on their nasal and nasopharyngeal aspect (99,100).

Because of this tumor's sex selectivity and young age at diagnosis, early research focused on steroid hormones. Trials of estrogen treatment showed variable response of JNAs to this therapy and have been largely abandoned. Accelerated tumor growth was described with testosterone treatment that led to studies of flutamide (antiandrogen) treatment preoperatively that showed minimal tumor reduction. More recently, androgen receptors have been identified suggesting that JNA may be androgen dependent (101). Angiogenic and growth factors have also been studied, and bFGF and transforming growth factor-beta 1 have been found in the stromal component of JNAs implicating these growth factors in tumorigenesis. VEGF, as well as VEGFR-2, and PDGF have been found in the vascular component of JNAs (102). Chromosomal studies of JNA show that DNA gains are remarkably more common than DNA losses, with loss of chromosome Y reported in all these studies. The association of JNA with familial adenomatous polyposis has been a focus of studies on the adenomatous polyposis coli tumor suppressor gene (APC) located on chromosome 5q21. The APC gene regulates the level of beta-catenin, which in turn regulates cell–cell adhesion as well as an activator of the Wnt signaling pathway implicated in carcinogenesis (97,103). Beta-catenin products are found in the majority of JNAs in the stromal but not vascular component of the tumor. Furthermore, beta-catenin functions as a coactivator of androgen receptor that may possibly increase tumor androgen sensitivity. Other studies have focused on the oncogenes C-KIT and C-MYC that regulate cell differentiation, cell proliferation, and apoptosis among numerous other functions (100). JNAs are positive for these oncogenes again in the stromal compartment. Though the molecular tumorigenesis of JNAs remains elusive, these studies collectively suggest that the stromal component of the tumor is the neoplastic element of JNAs and that deregulated vessel growth is driven by stromal growth factors. Furthermore, the loss of chromosome Y and the presence of androgen receptors and beta-catenin suggest an androgen-related pathophysiologic response of these tumors (97).

Patterns of Growth

Although histologically benign, the tumor exhibits aggressive local behavior with extensive bone erosion and remodeling and extensive invasion of adjacent structures. The location of origin of JNAs allows these tumors to spread simultaneously toward multiple locations that can involve the nasopharynx, nasal cavity and paranasal sinuses, the infratemporal fossa, and inferior orbital fissure via the pterygomaxillary fissure as well as the skull base and splanchnocranium. However, the early stages are characterized by an indolent growth phase with minimal symptoms. These include unilateral nasal obstruction and epistaxis that tend to be ignored for prolonged periods of time. This is why the majority of patients present with advanced disease. Significant morbidity can occur in the later stages of growth, and even death from hemorrhage and/or intracranial extension (Fig. 127.23).

Medial growth of the tumor fills the nasopharynx and ipsilateral nasal cavity. Anterior growth invades the posterior aspect of the maxillary sinus and more superiorly the ethmoid air cells. With lateral growth, the pterygoid plates are eroded, and the tumor extends into the pterygomaxillary fissure. From here it invades the infratemporal fossa and gains access to the inferior orbital fissure with erosion of the greater wing of sphenoid. The orbit is frequently involved through the inferior orbital fissure as well as through the lamina papyracea from the ethmoid tumor component. When the orbit is involved, additional symptoms of diplopia, visual loss, and proptosis may develop. Proptosis may be due to increased orbital volume from

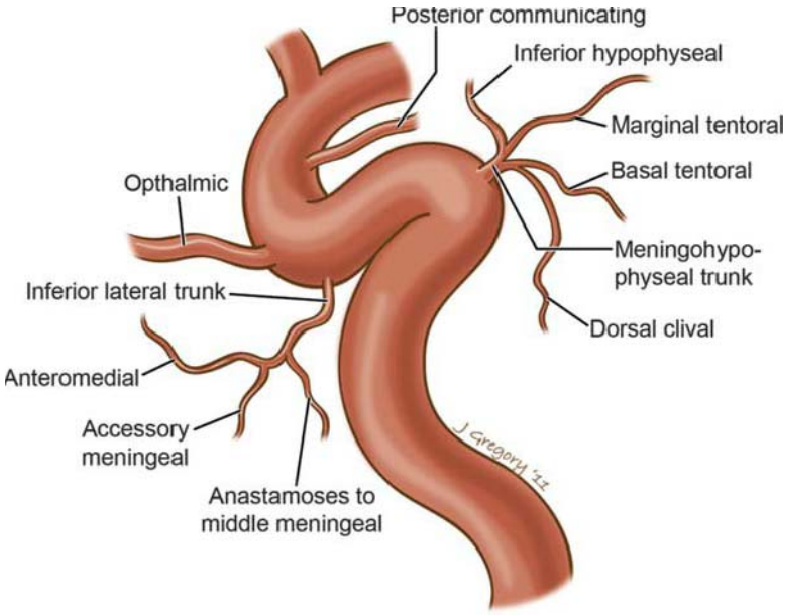

Figure 127.24 Schematic representation of the cavernous carotid artery with hypophyseal and meningeal branches.

tumor growth or increased venous pressure with involvement of the orbital apex.

Superior growth of the tumor involves the base of the pterygoid plates and the body of the sphenoid. Intracranial involvement has been reported to occur in 10% to 36% of all cases in western series. In published data from India, intracranial involvement is as high as 90% (104–106).

Four routes of intracranial invasion have been described: direct extension through the foramen rotundum, ovale, and lacerum; from the infratemporal fossa directly into the middle cranial fossa; from the pterygomaxillary fissure through the inferior and superior orbital fissures into the middle cranial fossa; rarely through the ethmoid lamina and cribriform plate into the anterior cranial fossa with ethmoid air cell involvement; and finally a particularly vexing intracranial extension through the roof of the sphenoid sinus into the sella and medial to the cavernous sinus. With intracranial extension, JNAs recruit blood supply from the internal circulation through the hypophyseal plexus (Fig. 127.24). Invasion of the cavernous sinus and sella will threaten the pituitary, the optic chiasm, optic nerve as well as cranial nerves 3, 4, and 6.

Diagnostic Studies

The diagnosis of a JNA is usually made by nasal endoscopy based on suspected presenting symptomatology. Histopathologic confirmation is not necessary as subsequent radiographic studies are virtually pathognomonic. Biopsy of a suspected JNA prior to imaging may lead to severe epistaxis and blood loss.

Both CT and MRI are essential for the assessment of JNAs. CT is invaluable for providing bony anatomy reference points as well as degree of erosion and remodeling of the sphenopalatine area and the skull base. MRI with gadolinium contrast is essential in determining the difference between tumor and surrounding soft tissues, the delineation between tumor and obstructive sinus disease as well as the interface between tumor and intracranial structures. The determination of dural invasion by MRI is not precise and caution should be exercised when interpreting MRIs for dural invasion. When surgery is planned, specialized CT scanning for intraoperative navigation is essential for tumors that have intracranial invasion (106).

Angiography and embolization should be performed in patients when surgery is contemplated. The vascular anatomy of JNA is important in the planning of surgical resection. Blood supply is determined by the size and extension of the tumor. In the initial stages, there is a consistent vascular supply from the branches of the internal maxillary artery via the sphenopalatine branches. In advanced stage with intracranial extension, blood supply may be through both the internal and external carotid circulation, especially the ophthalmic artery, the ethmoid arteries, and branches of the cavernous carotid. In recurrent or residual JNAs, this vascular supply may become even more complex. Residual tumor blush after angiographic embolization may necessitate further angiographic procedures for control. These should be performed by an experienced interventional neuroradiology team (107,108) (Fig. 127.25).

Balloon occlusion of the internal carotid artery should be done in patients in whom intracranial extension encroaches the cavernous carotid or the horizontal petrous carotid.

Staging

Multiple staging systems have been elaborated for JNAs. The most commonly used system is that of Radkowski

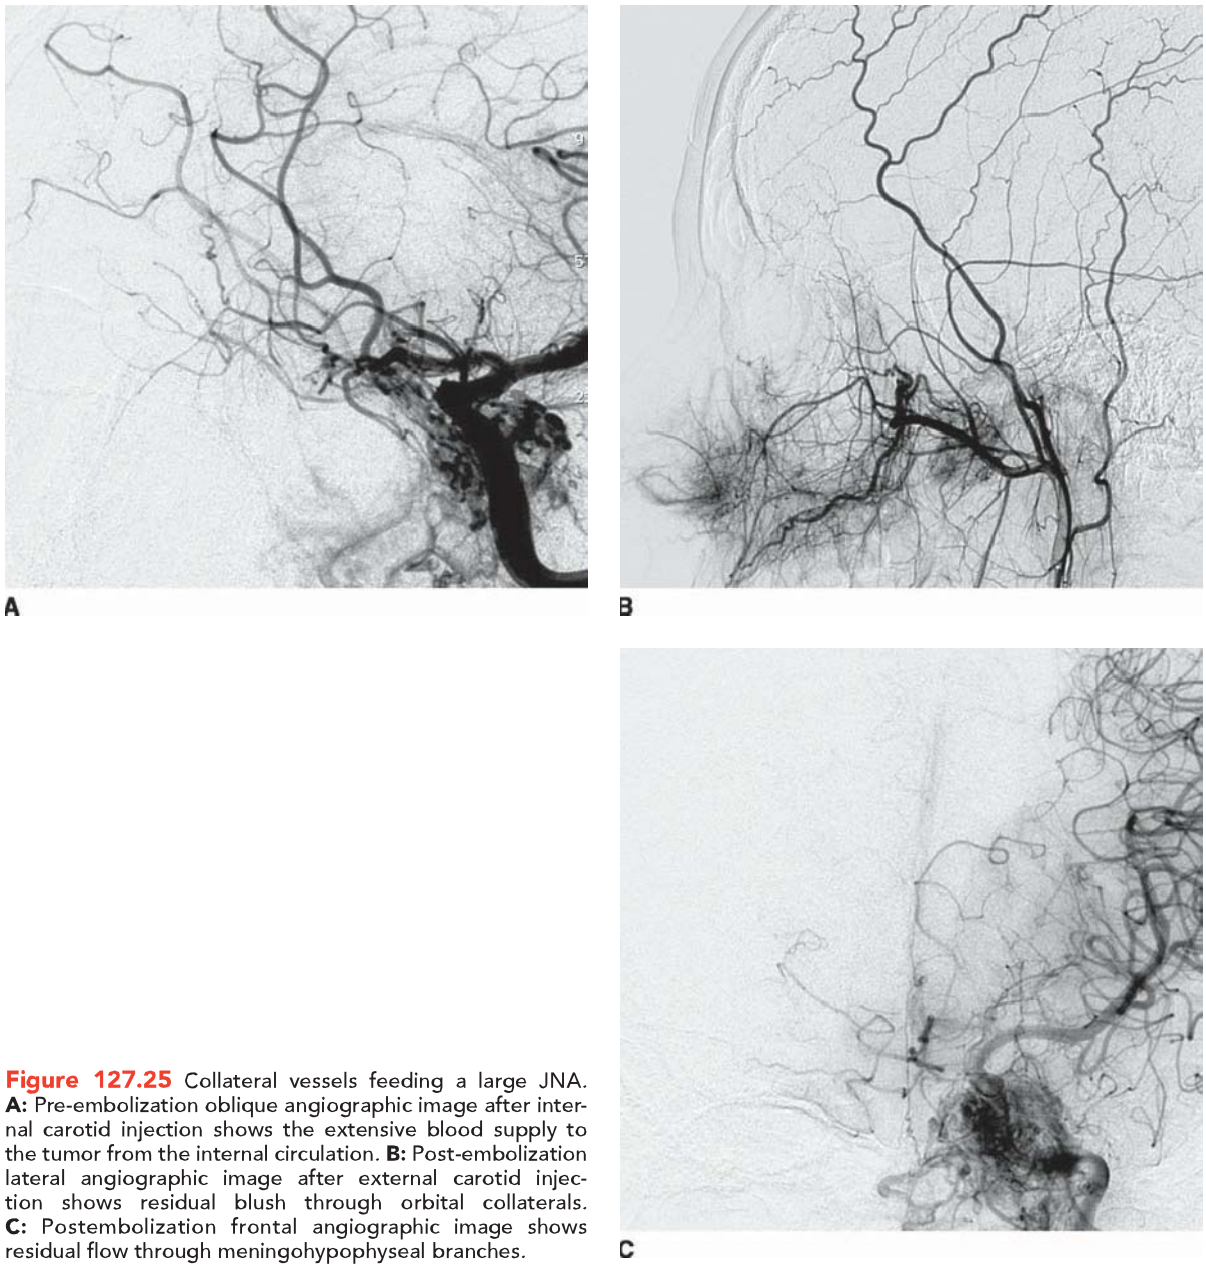

Figure 127.25 Collateral vessels feeding a large JNA. **A:** Pre-embolization oblique angiographic image after internal carotid injection shows the extensive blood supply to the tumor from the internal circulation. **B:** Post-embolization lateral angiographic image after external carotid injection shows residual blush through orbital collaterals. **C:** Postembolization frontal angiographic image shows residual flow through meningohypophyseal branches.

et al. (109). Variations of these systems have been used recently such as the modified Fisch system and the system proposed by Snyderman for endoscopic resection of tumors (110,111) (Table 127.7).

Treatment Options

The treatment of choice for JNAs is surgical excision. Smaller tumors without intracranial extension can be effectively removed through endoscopic approaches. More extensive tumors are now also amenable to endoscopic approaches due to intraoperative navigation, improved surgical tools, and surgical experience. Extensive intracranial involvement of JNA requires an open approach of which there is a wide variety. However, even extensive JNAs with intracranial involvement can be approached through an extracranial approach. These tumors do not tend to invade or adhere to the adjacent dura. Previous surgery and radiation limit the utility of extracranial approaches for intracranial invasion (Table 127.8).

Open Surgery

Tumors that infiltrate the infratemporal fossa, the sphenoid sinus, the base of the pterygoids, the cavernous sinus, the foramen lacerum, and the anterior fossa are at higher risk for recurrence. With the refinement of surgical approaches and skull-base techniques, these lesions can routinely undergo total resection.

Choice of Surgical Approach

Combined intracranial and extracranial approaches may be necessary. Surgical approaches can be modified according to the extent of the tumor. The selection of the surgical approach is dictated by the ability to expose the tumor and

TABLE 127.7 RADOWSKI CLASSIFICATION OF JNA

Stage	Tumor Extent
Ia	Limited to the posterior nares and/or nasopharyngeal vault
Ib	Involving the posterior nares and/or nasopharyngeal vault with involvement of at least one paranasal sinus
IIa	Minimal lateral extension to the pterygomaxillary fossa
IIb	Full occupation of the pterygomaxillary fossa with or without erosion of orbital bones
IIc	Extension into the infratemporal fossa or extension posterior to the pterygoid plates
IIIa	Erosion of the base of skull (middle cranial fossa/base of pterygoids)—minimal intracranial extension
IIIb	Extensive intracranial extension with or without extension into the cavernous sinus.

critical structures, control bleeding, avoid growth centers in the craniofacial skeleton of young patients and finally avoid facial scars if possible.

Open Surgery

Open surgical techniques can be classified according to the following scheme (Table 127.8).

These approaches can be classified according to the incision placement and the type of bone work required. Thus, the anterior approaches can be intraoral without external incisions or extraoral anterior with facial incisions

TABLE 127.8 OPEN APPROACHES FOR JNA SURGICAL RESECTION

Open anterior approaches Intraoral	Degloving-Le fort-I osteotomy and downward palatal translocation
	Degloving, transantral approach
	Degloving modified transantral approach with medial maxillectomy and lateral buttress removal
	Degloving, maxillary/zygomatic removal and re–insertion
	Transpalatal and modified transpalatal approach
Open anterior approaches Facial incision	Weber-Ferguson and extended WF incision with facial translocation (removal and reinsertion of zygomatic bone including orbit floor and lateral wall)
Open lateral approaches	Fisch type D transtemporal approach with facial nerve mobilization
	Preauricular infratemporal fossa approach with zygomatic arch displacement and pterional craniectomy extradural approach

or lateral with coronal/hemicoronal incision. In terms of bone work, these can be broadly categorized as those that remove bone and those that displace bone (bone is temporarily translocated and placed back at closure), or a combination of the two.

The choice of approach is largely dependent on tumor extent and the facility of the surgical team.

With the transpalatal approach, the soft palate is mobilized and retracted to the opposite side of the tumor once the greater and lesser palatine vessels and nerves on the ipsilateral side have been sacrificed. The posterior hard palate along with the posterior upper molars may be resected and the corresponding alveolus drilled down along with the hard palate, the pterygoid plates leading to the base of the sphenoid. Once in this location, using as landmarks the dura of middle cranial fossa, V2 and V3 and their bony foramina and the sphenoid sinus, the skull base can be widely exposed and the tumor removed. A facial degloving with Le Fort-I achieves a very similar result in terms of exposure. A facial degloving with a medial maxillectomy and resection of the posterior lateral walls of the maxilla can effectively expose the nasal cavity, nasopharynx, pterygomaxillary space, and infratemporal fossa with excellent tumor exposure and removal. An anterior approach with a Weber-Ferguson facial incision can be combined with the removal of the zygomatic bone (including the orbital floor and lateral wall) possibly with a Le Fort-I osteotomy to provide wide access. This bone is removed, the tumor is removed, and then the bone segment is replaced and fixed with osteosynthesis plates.

With the preauricular infratemporal fossa approach, an extended hemicoronal incision is made, the zygomatic arch is transected and the temporalis muscle is inferiorly displaced from the temporal fossa. Soft tissue elevation exposes the body of the sphenoid and base of pterygoid plates. After a pterional craniectomy, the sphenoid wing and middle cranial fossa floor are removed, which provides contiguous access along the middle cranial fossa up to the cavernous sinus. The limits of this are the superior orbital fissure, optic canal, and horizontal petrous carotid artery. The lateral preauricular approaches are largely reserved for intracranial extension and can be combined in the same sitting as an anterior approach or as a separate procedure.

The postauricular transtemporal approach requires sacrifice of the middle ear structures and mobilization of the facial nerve. This indirect approach is used for more extensive petrous involvement.

The concerns with open approaches, especially those that involve bone displacement or resection in children and adolescents, are that bone growth may be affected with resultant facial symmetry and malocclusion. None of these concerns have been substantiated to date. Facial incisions, which are ideally placed correctly at the border of adjacent facial aesthetic units and closed meticulously, will leave almost imperceptible scarring (112).

Open approaches will achieve approximately 80% complete resection avoiding tumor recurrence even in advanced and salvage cases (96,106,109).

Endoscopic and Endoscopic-Assisted Approaches

There are increasing numbers of endoscopic and endoscopic-assisted approaches for JNA. Few authors have considerable experience with very advanced disease. Previous limitations of endoscopic approaches include extensive intracranial extension, tumor extension lateral to the cavernous sinus or posterior to the pterygoid plates.

Improved technique and intraoperative navigation have extended the successful endoscopic approach for these extensive tumors. Patient selection and the experience of the endoscopic surgeons are of paramount importance (111,113).

Radiotherapy

Radiation therapy is effective at controlling JNA. Rates of control of over 80% have been reported. Conventional radiation therapy of 30 to 35 Gy can achieve these results. IMRT can also be used, and excellent control has been reported. The advantage of IMRT is the precise computer-controlled dosing, which can potentially eliminate significant complications. Stereotactic radiation has also been used, especially in the setting of residual small volume tumor remnants after surgery (114–116).

Complications from radiation have included well-documented secondary malignancies, cataracts, CNS complications as well as panhypopituitarism. The risks of radiation should be carefully weighed against other available modalities especially in these young patients.

Surveillance

Symptoms and physical examination, including serial endoscopic examinations are unreliable for the detection of recurrent JNA, especially in previously treated advanced tumors. Serial radiographic imaging by contrast-enhanced CT and/or MRI is the choice of follow-up. Gadolinium-enhanced MRI is particularly sensitive for residual disease. Findings consistent with residual disease should be followed for at least 2 years before a decision for additional treatment is made.

HIGHLIGHTS

- Paraganglia facilitate the baroreceptive and chemoreceptive reflexes of the vascular system. In the head and neck, the carotid body only facilities the chemoreceptive reflex.
- The carotid body is a separate structure that lies at the carotid bifurcation. The jugulotympanic paraganglia are distributed in the temporal bone along Jacobson nerve while the vagal paraganglia are found within the vagus nerve at the level of the jugular foramen.
- Genetics and hypoxemia, such as high-altitude living, predispose to the paragangliomas.
- Mutations in the gene encoding for the mitochondrial enzyme SDH, a key enzyme in the Krebs cycle, are responsible for the genetic etiology of paraganglioma formation. PGL1 and PGL4 mutations show multicentricity and pheochromocytomas. PGL4 is associated with higher rate of malignant paraganglioma.
- Both radiation and surgery are effective treatments for paragangliomas. Selection of treatment depends on existing cranial nerve deficits, bilateral and/or multicentric tumors as well as age of patient.
- Surgery for paragangliomas requires extensive preparation including serum and urine catecholamine screening for functioning tumors, detailed radiographic investigations as well as superselective angiography with preoperative embolization. Jugulotympanic and vagal paragangliomas require an infratemporal fossa approach tailored to the size and extent of the lesion.
- HPCs are rare tumors. Twenty-five percent of them occur in the head and neck including the meninges. Ten-year survivals of 54% to 89% can be achieved with complete surgical resection, which is the primary mode of treatment.
- Angiosarcomas account of 10% of all head and neck sarcomas; they are much more aggressive than other body sites. They are difficult to distinguish pathologically from other vascular lesions.
- The treatment of angiosarcoma is wide resection with the goal of negative margins, which are difficult to achieve. Adjuvant therapy in the form or radiation and chemotherapy should be considered, but there is little evidence for their efficacy. Ten-year survival is approximately 14%.
- JNAs are highly vascular tumors that occur exclusively in adolescent and young adult males. They express indolent behavior with continued growth, which frequently extends to involve the skull base.
- The management of JNAs is surgical. Endoscopic techniques are indicated for early-stage tumors while a variety of open approaches are applicable to advanced disease.

128 Lymphomas of the Head and Neck

Raymond L. Chai *Andrew B. Tassler* *Seungwon Kim*

Lymphoma, a malignancy of lymphoid tissue characterized by the proliferation of lymphoid cells or their precursors, is the most common nonepithelial malignancy of the head and neck. Because lymphoma typically manifests as a neck mass, otolaryngologists are frequently involved in diagnosis. However, as it is a disease treated primarily by radiation and medical oncologists, the role of the otolaryngologist generally diminishes once a diagnosis is obtained. Nonetheless, as a participant of a multidisciplinary team, it is imperative for the otolaryngologist to be well versed in not only comprehensive management of the disease but also the controversies of classification and treatment. Moreover, the otolaryngologist will often be the diagnosing physician for lymphomas that present in the head and neck, and thus a high index of suspicion must be maintained, especially for lymphomas occurring at extranodal sites.

There are two main types of lymphoma: Hodgkin lymphoma (HL) and non-Hodgkin lymphoma (NHL). HL is typically characterized by the orderly spread of disease through contiguous groups of lymph nodes. In contrast, NHL can manifest in extranodal sites such as Waldeyer ring, salivary glands, and thyroid in addition to occurring in the nodal basins of the head and neck.

EPIDEMIOLOGY

NHL accounts for 86% of all lymphoma cases and is the fifth most common malignancy in the United States, excluding skin cancers (1). It is primarily a disease of adults, with less than 10% of overall cases occurring in children (2). NHL results from chromosomal translocations in B or T/natural killer (NK) cells that lead to either the inactivation of tumor suppressor genes or activation of oncogenes (3). B-cell lymphomas compromise roughly 90% of all NHLs; the two most common histologic subtypes are follicular lymphoma and the more aggressive diffuse large B-cell lymphoma (DLBCL) (4). Risk factors include male gender, long-term immunosuppression, exposure to radiation or pesticides, and autoimmune diseases such as systemic lupus erythematous (5). Infections including human immunodeficiency virus (HIV), human T-cell lymphotropic virus 1 (HTLV-1), human herpesvirus-8 (HHV-8), and Epstein-Barr virus (EBV) have also been associated with the development of lymphoma (6).

The less common HL is a highly curable disease with an estimated 5-year relative survival of 86% (2). The incidence of HL has a bimodal distribution, with the disease primarily occurring in young adults and patients 55 years and older (7). Much like in NHL, risk factors for the development of HL include viral exposure, immune suppression, and familial factors (8). Although HL originally had been subdivided into four categories, the most recent World Health Organization (WHO) classification has separated the disease into the more common classical HL and the rare nodular lymphocyte-predominant HL (9). The diagnosis of HL is made with the identification of Reed-Sternberg cells, a binucleated or multinucleated giant cell of germinal center B-cell origin (Fig. 128.1) (10). HL is unique in that malignant cells compromise the minority (estimated at 0.1% to 10%) of the cellular population of the tumor (11). Thus, obtaining ample biopsy specimen is critical for accurate diagnosis of the disease.

In 2010, the American Cancer Society estimates that 74,030 new lymphoma cases will be diagnosed and 21,530 deaths due to lymphoma will occur in the United States (2). An analysis of the National Cancer Data Base (NCDB) revealed that the proportion of lymphoma cases among all head and neck tumors increased from 14.7% between 1985 and 1989 to 15.4% between 1990 and 1994 (12). This increase has been postulated to be attributable to an increase in immunodeficiency secondary to both HIV and patients receiving organ transplants. Interestingly, more recent data from the NCDB suggest both an absolute and proportionate decrease (to 12.4%) in the prevalence of lymphoma from 2000 to 2004, perhaps reflecting the use

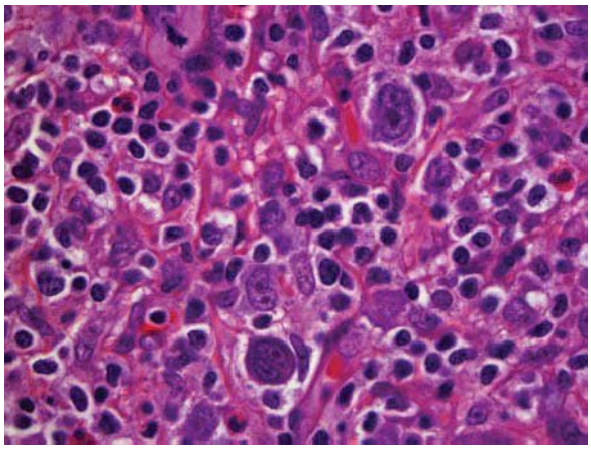

Figure 128.1 Reed-Sternberg cell in a lymph node involved by HL.

of combination antiretroviral therapy for patients with acquired immune deficiency syndrome (AIDS) (13).

CLINICAL DIAGNOSIS AND IMAGING

The majority of lymphoma cases present with nontender lymphadenopathy of greater than 2 weeks duration, usually in the neck or supraclavicular area (14). Systemic symptoms including fever greater than 38°C, drenching night sweats, and unintentional weight loss of greater than 10% of body weight over a period of 6 months or less are known collectively as B symptoms. B symptoms are established negative prognostic factors in both HL and NHL and predict worse treatment response and survival. Recently, B symptoms, a marker of systemic inflammation, have been established as an independent predictor of increased toxicity from chemotherapy in NHL patients (15).

Although HL is primarily a disease confined to lymph nodes, primary extranodal involvement occurs in 25% to 40% of NHL patients at initial diagnosis (16). Roughly a third of all primary extranodal lymphomas occur in Waldeyer ring, a circle of lymphoid tissue in the pharynx formed by the palatine and pharyngeal tonsils as well as the lymphatic follicles at the base of tongue (17). Several European studies have shown an even higher incidence of extranodal disease in Waldeyer ring, likely related to the routine biopsy of this area in all patients with NHL (18,19). Lymphomas in this region compromise greater than half of all primary extranodal lymphomas of the head and neck (20). Less commonly, primary lymphoma in the head and neck can manifest in salivary glands, the sinonasal region, the thyroid, and the larynx.

Diagnosis of lymphoma in the head and neck includes a combination of history and physical, including a full head and neck exam. Either mirror exam or flexible laryngoscopy should be performed to visualize Waldeyer ring, the larynx, and hypopharynx. Routine hematologic and biochemical profiles, renal and liver profiles, as well as imaging should be obtained as well. Cardiac assessment including clinical examination, electrocardiography (EKG), and echocardiogram should be performed for all patients greater than 65 years of age and when otherwise indicated.

Serum lactate dehydrogenase (LDH) level should be measured in all patients and is an important predictor of survival, with elevated levels indicating tissue damage, lymphoma relapse, or renewed growth. As a component of the International Prognostic Index (IPI), pretreatment LDH is used to stratify patient populations into appropriate treatment regimens (21). β-2 microglobulin testing, which has been shown to predict response rate and duration of remission, is also routinely performed in some centers (22). Bone marrow aspirate and biopsy, typically of the bilateral iliac crests, is also routinely performed to define the extent of disease in initial staging. Marrow involvement is found in 5% to 15% of HL patients at diagnosis and up to 30% of newly diagnosed NHL cases (23,24). Cerebrospinal fluid (CSF) evaluation should be performed in patients with paranasal sinus or nasopharyngeal involvement due to disease proximity to the skull base. CSF analysis should also be considered in patients with large cell lymphoma presenting with an elevated LDH and/or involvement of multiple extranodal sites (25).

Contrast-enhanced computerized tomography (CT) of the head, neck, chest, abdomen, and pelvis is routinely performed for evaluation of both nodal and nonnodal lymphoma involvement. CT of the head and neck is also useful for the assessment of any bony involvement or destruction of the mandible, maxilla, paranasal sinuses, and skull base. Although it is difficult to distinguish HL and NHL by CT alone, lymphoma is suspected when multiple, nonenhancing, large, homogeneous lymph nodes are present, particularly in unusual nodal chains such as the retropharyngeal, occipital, and parotid nodes (Fig. 128.2) (26). Because nodal necrosis is present in the majority of lymph nodes involved with squamous cell carcinoma (SCC) larger than 3 cm, lymphoma is implicated with the presence of large nonnecrotic nodes (27). Pretreatment nodal necrosis, when seen, is usually found in high-grade lymphomas (28).

Fluorine-18-fluorodeoxyglucose positron emission tomography-computed tomography (^{18}F-FDG-PET-CT) superimposes anatomic detail from CT images with functional imaging obtained by PET. ^{18}F-FDG-PET-CT is a good choice as the initial imaging study in patients with FDG avid lymphomas such as HL, B-cell lymphoma, or follicular lymphoma. A pretreatment ^{18}F-FDG-PET-CT is used in most centers for initial staging and allows for subsequent monitoring of response to treatment and assessment of recurrent or residual disease. Because it evaluates metabolic activity, ^{18}F-FDG-PET-CT can also help differentiate malignant and nonmalignant lymph nodes in small lymph nodes that are negative by CT size criteria. Improved accuracy in staging with ^{18}F-FDG-PET-CT may help avoid overtreatment and its associated toxicities.

Recent studies have shown upstaging of disease in up to 20% of cases using PET-CT with improved detection of

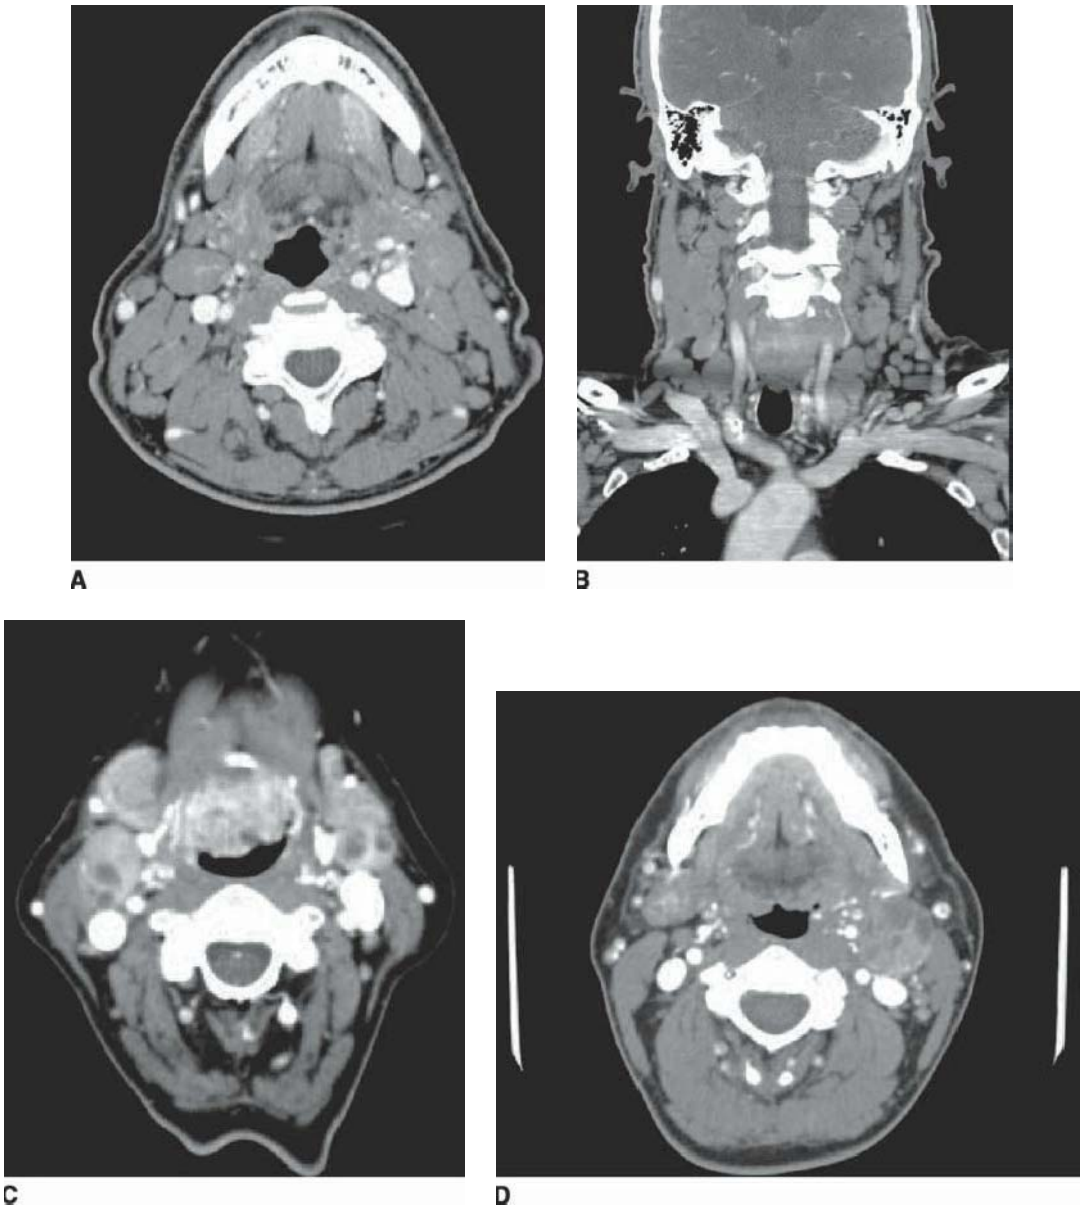

Figure 128.2 Contrast-enhanced (**A**) axial and (**B**) coronal CT images from patient with B-cell lymphoma, demonstrating multiple enlarged lymph nodes with poor contrast enhancement and uniform appearance. In contrast, lymph nodes with metastatic SCC demonstrate (**C**) heterogeneous enhancement as well as (**D**) central necrosis.

occult splenic involvement and exclusion of bone marrow involvement in aggressive B-cell NHL (29). A meta-analysis of 20 studies including seven prospective trials on the effectiveness of PET in lymphoma staging showed an overall change-in-management rate of 30% based on imaging findings (30). ^{18}F-FDG-PET-CT is less useful in low-grade NHL because of low metabolic uptake in malignant nodes (31).

TISSUE DIAGNOSIS

In order to institute appropriate therapy, adequate tissue sampling is needed for both diagnosis and definitive subclassification of lymphoma. As such, the gold standard for diagnosis of lymphoma in the head and neck is open excisional biopsy. However, with the advent of new classification schemes such as the Revised European-American Lymphoma classification (REAL) in the mid-1990s and more recently the WHO classification, new emphasis has been placed on immunophenotypic and cytogenetic characteristics rather than architectural features in the categorization of tumors. Thus, recent investigations have focused on the utility of both fine needle aspiration (FNA) and core needle biopsy (CNB) as independent diagnostic tools for lymphoma diagnosis.

FNA has become widely used in the head and neck in the evaluation of both lymphadenopathy as well as primary

lesions such as parotid and thyroid tumors. In comparison to surgical biopsy, FNA offers advantages in speed, cost, and minimal complications. Needle aspirates can provide material for both cytomorphology and flow cytometry, a technique that selects for specific surface antigens that determine lymphoid and/or myeloid cell lineages. It is possible to diagnose most lymphomas in general terms on the basis of characteristic cytologic morphology. FNA cytology has shown to have a high accuracy rate, ranging from 80% to 90%, in the diagnosis of both HL and NHL (32–36). Flow cytometry alone has also been shown to be an accurate independent ancillary test, with a large series from the University of Iowa demonstrating a sensitivity of 91.8% and a specificity of 95.5% in the diagnosis of B-cell NHL (37). Multiple studies have shown, however, that the malignant Reed-Sternberg cells that characterize HL are almost never detected by flow cytometry (38,39).

The primary limitation of FNA is the relatively small amount of material available for phenotyping. Although helpful in the diagnosis of lymphoma, flow cytometry has been shown to not aid in the subclassification of disease (40). A complete histologic diagnosis using the WHO classification is possible in only a minority of FNA specimens (41). FNA alone is thus clinically insufficient to design appropriate treatment plans for lymphoma patients. However, the utility of FNA has become widely accepted in certain clinical conditions, such as the documentation of recurrent lymphoma and the diagnosis of posttransplant lymphoproliferative disorder (PTLD) (42,43).

CNB is an intermediate step between FNA and open surgical biopsy. By using a larger sized needle (14 to 18 gauge), CNB provides sufficient sample for both immunohistochemistry and conventional histopathology. CNB is now commonly accepted as an initial procedure for patients with deep-seated lymph nodes, particularly in the mediastinum or abdomen (44). Two recent studies investigating ultrasound-guided CNB in cervical lymphadenopathy have shown full subclassification in 89.7% and 92.3% of lymphoma cases, respectively (45,46). Factors such as nodal necrosis or infarct significantly reduce the success of diagnosis, particularly for HL. Although promising, further investigation is needed in evaluating the full utility of this technique.

STAGING

First proposed in 1971 for HL and later adapted for NHL, the Ann Arbor staging system is the most widely used criterion for determining prognosis and treatment (Table 128.1) (47). This system is based on the region and number of affected lymph nodes as well as the presence of extranodal sites and constitutional symptoms. The Ann Arbor staging system that was originally developed for HL is currently used to stage both HL and NHL. In 1989, the Ann Arbor system was refined with the Cotswalds modification, which takes into account the importance of bulky disease as a negative prognostic factor (48).

TABLE 128.1 ANN ARBOR STAGING SYSTEM FOR LYMPHOMA

Stage I	Involvement of a single lymph node region (I) or of a single extralymphatic organ or site (IE)
Stage II	Involvement of two or more lymph node regions or lymphatic structures on the same side of the diaphragm alone (II) or with involvement of limited, contiguous extralymphatic organ or tissue (IIE)
Stage III	Involvement of lymph node regions on both sides of the diaphragm (III) that may include the spleen (IIIS) or limited, contiguous extralymphatic organ or site (IIIE) or both (IIIES)
Stage IV	Diffuse or disseminated foci of involvement of one or more extralymphatic organs or tissues, with or without associated lymphatic involvement

All cases are subclassified to indicate absence (A) or presence (B) or systemic symptoms of significant unexplained fever, night sweats, and unexplained weight loss exceeding 10% of body weight during the 6 mo prior to diagnosis.
The designation "S" refers to the involvement of the spleen.
The designation "E" refers to extranodal contiguous extension.

The Ann Arbor system does not, however, take into account the grade and biologic behavior of a given lymphoma and has been shown to be inadequate as a sole predictor of overall survival for patients with aggressive NHL (49). In 1993, the IPI was proposed. Based on a retrospective series of over 2,000 patients in an international multi-institutional study, this model uses age, Ann Arbor tumor stage, serum LDH, performance status, and number of extranodal disease sites to stratify patients into four risk groups (50). Because younger patients may tolerate more aggressive therapy and thus have different outcomes, an age-adjusted index was proposed in the same study for patients younger than 60. This simplified criteria use only stage, LDH, and performance status to predict outcomes. Similar to the IPI, the Follicular Lymphoma International Prognostic Index (FLIPI) was designed as a prognostic model for patients with indolent lymphoma (51). Factors in this index include age, stage, number of involved lymph node areas, serum hemoglobin level, and serum LDH.

These systems alone are not, however, sufficient for initiating treatment, as outcome is highly variable and dependent on tumor histology and morphology. In 1982, the Working Formulation, a now-obsolete classification of NHL tumors, subdivided lymphomas by morphology alone (52). The REAL and later the WHO classification groups differentiated NHLs by cell lineage and unique phenotypic, molecular, and cytogenetic characteristics. The fourth edition of the WHO classification, which is the most recent update, was introduced in 2008 and classifies NHL as indolent, aggressive, and highly aggressive tumors (9). However, it should be kept in mind that the WHO classification system is not a staging system. The Ann Arbor staging system, despite its shortcomings, remains the best mean of staging lymphomas and has been adopted by the

American Joint Committee on Cancer (AJCC) as well as Union for International Cancer Control (UICC) as the official system for classifying the extent of anatomic involvement and for staging of both HL and NHL.

THERAPY

Radiation therapy and/or combination chemotherapy is the current mainstay of treatment for both NHL and HL of the head and neck. Advances in molecular biology have led to the development of novel therapies for NHL such as monoclonal antibodies and radioimmunoconjugates. Although surgery does play a role in the management of lymphoma, particularly in localized gastrointestinal disease, its utility in the head and neck is typically limited to diagnostic biopsy.

Hodgkin Lymphoma

Initial therapy for early stage HL (I–IIA) may vary depending on the center instituting treatment. Extended-field radiation had been the standard of care for decades. However, with 5-year survival rates for patients with early-stage disease of 90% or higher, long-term complications from radiation therapy are not insignificant (53). Second malignancies such as breast cancer occur roughly 1% a year for at least 30 years after treatment (54). Other long-term side effects include mediastinal fibrosis, myelitis, and hypothyroidism (55). For favorable early-stage disease, short-term chemotherapy with doxorubicin, bleomycin, vinblastine, and dacarbazine (ABVD) alone or combined chemotherapy with involved-field radiation therapy to involved lymph nodes regions only is now recommended (56).

Tumor bulk, high erythrocyte sedimentation rate, multiple sites, age 50 or greater, and massive splenic disease have been identified as factors defining unfavorable disease in HL (57). Although the subject of ongoing debate, the usage of combination chemotherapy plus involved-field radiotherapy rather than extended-field radiation is a generally accepted protocol (58). For the rare nodular lymphocyte-predominant HL, with its improved prognosis, reduced intensity protocols have been advocated for early stage tumors (59).

In patients with advanced stage III to IV HL, the ongoing challenge involves developing regimens that maximize survival rates while limiting the development of long-term toxicities. The first combination chemotherapy used for these patients was the MOPP (mechlorethamine, vincristine, procarbazine, and prednisone) protocol. Developed in 1970 for patients with disease progression after radiotherapy, this regimen markedly improved survival rates (60). In 1975, the ABVD regimen was shown to have similar clinical activity (61). A regimen utilizing alternating cycles of ABVD and MOPP was later shown to have superior overall survival rates (62). More recently, a large multi-institutional trial established ABVD as the standard regimen for treatment of advanced HL, with the hybrid MOPP/ABV regimen associated with greater toxicity (63). Thus, the primary treatment strategy at many centers is ABVD combined with involved-field radiotherapy. Similar regimens are typically used for advanced stage nodular lymphocyte-predominant HL (64).

Indolent Non-Hodgkin Lymphoma

Indolent lymphoma comprises 40% of all NHLs, with follicular lymphomas the most common subtype. The majority of these patients are initially asymptomatic and typically present at advanced stage. Although these tumors have a long median survival, the majority of patients are incurable, with the exception of rare early stage disease (65). The goal of treatment should be complete remission but often is focused toward alleviating localized symptoms and compromised organ function. There is significant controversy in treatment options because despite the wide range of available therapeutic approaches, most patients ultimately relapse. However, despite some data suggesting that overall survival for these patients has not improved in the last several decades, recent studies have shown survival improvements, particularly from the introduction of biologic therapies (66).

Data from large prospective trials have shown no significant difference between observation and the initiation of immediate treatment in advanced indolent lymphoma patients (67). Watchful waiting, particularly in patients older than 70 years of age, is thus an accepted initial option. In symptomatic patients, combination chemotherapy and immunotherapy is considered to be standard therapy. The addition of the anti-CD20 monoclonal antibody rituximab with the standard CHOP (cyclophosphamide, doxorubicin, vincristine, and prednisone) regimen (R-CHOP) has shown significant improvement in outcome without additional major toxicity (68). The addition of rituximab has demonstrated clinical benefit as well for symptomatic elderly patients with relevant comorbidities (69). Rituximab as maintenance therapy is recommended for relapsed or refractory advanced disease (70). Radioimmunotherapy using monoclonal antibodies covalently bound to radionuclides such as Yttrium-90 ibritumomab tiuxetan and iodine-131 tositumomab has shown efficacy in both consolidation therapy and rituximab-refractory tumors, respectively (71,72).

Aggressive Non-Hodgkin Lymphoma

The majority of NHL cases are aggressive lymphomas, with DLBCL as the most common histologic subtype in the head and neck (73). Treatment has evolved over the last 30 years from the primary usage of radiotherapy to combination chemotherapy with immunotherapy. Current National Comprehensive Cancer Network (NCCN) guidelines provide oncologists with the option of utilizing either three

cycles of R-CHOP plus involved-field radiation therapy or six to eight cycles of R-CHOP with or without involved-field radiation therapy for both bulky and nonbulky early-stage disease (74). The addition of radiation therapy, however, is controversial, and the majority of oncologists utilize the extended combination chemotherapy protocol alone (75).

For advanced stage DLBCL, R-CHOP is considered to be the standard of care in the United States. Large prospective studies in both France and the United States have found significant improvement in both progression-free and overall survival with R-CHOP compared to CHOP in elderly patients over 60 years of age (76,77) These findings have been confirmed in both younger patients (age less than 60) and in a population-based study in British Columbia (78,79). However, as cure rates with R-CHOP range from 30% to 70%, treatment protocols continue to seek further refinement.

Highly Aggressive Non-Hodgkin Lymphoma

Highly aggressive lymphomas include lymphoblastic lymphoma and Burkitt lymphoma. These diseases are uncommon in adults and encompass roughly 5% of all NHL cases in the United States. Lymphoblastic lymphomas are treated with modified acute lymphoblastic leukemia (ALL)-type regimens including intensive multiagent induction therapy, consolidation, and maintenance therapy (80). Central nervous system (CNS) prophylaxis with intrathecal chemotherapy is widely accepted, as the incidence of CNS relapse in patients not receiving prophylaxis approaches 30% (81). Similar approaches with induction chemotherapy and CNS prophylaxis but without prolonged maintenance therapy are used for Burkitt lymphoma (82).

LYMPHOMA SPECIFIC TO THE HEAD AND NECK

Waldeyer Ring Lymphoma

Roughly half of all Waldeyer ring NHLs arise in the palatine tonsil, 20% of which are bilateral (83). In decreasing order, lymphomas in this region also arise from the pharyngeal tonsil, base of tongue or lingual tonsil, or involve multiple primary sites (84). Symptoms correspond with the location of disease. NHL of the tonsil and base of tongue typically present with unilateral odynophagia and dysphagia while nasopharyngeal NHL can manifest with nasal obstruction, eustachian tube dysfunction, persistent epistaxis, or cranial neuropathy. On physical examination, NHL lesions are mostly submucosal, unlike the ulcerated lesions seen with SCC.

The vast majority of patients present with early stage I or stage II disease, with B symptoms occurring in less than 15% of patients (85). The most common histologic subclassification in this region is by far DLBCL, which is present in up to 85% of cases (86). Although large prospective series are not available, combined chemoradiotherapy has consistently shown superior disease-free survival compared with chemotherapy or radiotherapy alone (85,87). Out-of-field recurrences are the primary pattern for failure, with up to a third of patients developing relapse in the gastrointestinal tract (88).

CT imaging of Waldeyer ring NHL commonly shows a large homogeneous mass of similar intensity to surrounding lymphoid tissue in either the lingual or palatine tonsil, or the nasopharynx (Fig. 128.3) (89). Unlike in nasopharyngeal carcinoma, skull base erosion from nasopharyngeal lymphoma is rare. Associated lymphadenopathy on the ipsilateral side of the lesion is common and usually nonnecrotic in imaging appearance.

Sinonasal Lymphoma

Sinonasal lymphoma is uncommon and represents less than 1% of overall NHL cases. Similar to Waldeyer ring NHL, DLBCL is the most common subgroup of disease found in this location (90). The vast majority of sinonasal DLBCL tumors involve the paranasal sinuses but not the nasal cavity. The next most common subgroup, NK/T-cell lymphoma, is more prevalent in Asia than in Western countries and is associated with EBV infection (91). Unlike DLBCL, NK/T-cell lymphoma nearly always arises from the nasal cavity. Most patients with sinonasal lymphoma present with early stage disease. In contrast to most large Asian studies, a recent clinicopathologic analysis of tumors from the United States showed that NK/T-cell lymphomas had a favorable prognosis with similar outcomes to patients with DLBCL tumors (92). On magnetic resonance imaging (MRI), sinonasal lymphomas are more homogeneous on T2 sequences and mildly enhance when compared with carcinoma. They may present with bony remodeling and/or erosion and can radiographically mimic destructive nasal lesions such as Wegener granulomatosis.

Low-grade sinonasal lymphomas present with obstructive symptoms while high-grade tumors can manifest with cranial neuropathies, pain, and epistaxis. DLBCL tumors have a propensity for soft tissue or osseous destruction near the orbit and can have ophthalmic symptoms such as proptosis. In contrast, true to their alternative name of lethal midline granuloma, NK/T-cell tumors are associated with nasal septal ulceration and destruction (93). Treatment includes combination chemotherapy, most commonly CHOP, and radiation therapy (94). Though uncommon, lymphoma should remain in the differential diagnosis of many sinonasal lesions; a high index of suspicion often must be maintained to make the diagnosis.

Salivary Gland Lymphoma

Between 2% and 5% of salivary gland neoplasms are primary lymphomas. Patients with this tumor typically present with an asymptomatic mass of their parotid or

submandibular gland. Pain and facial nerve paresis are very uncommon. Most of these tumors are early stage, and 70% to 80% of them arise from the parotid gland (95). Lymphoma is rarely suspected preoperatively, and many of these patients undergo invasive procedures such as superficial parotidectomy prior to obtaining a diagnosis of lymphoma. Histologic subtypes in this region include, in decreasing frequency, mucosa-associated lymphoid tissue (MALT) lymphoma, follicular lymphoma, and DLBCL (96). Lymphomas of the salivary glands have a favorable overall survival rate compared to other extranodal sites in the head and neck and are typically treated with primary radiotherapy (97).

There is controversy in the literature over the terms *primary*, *secondary*, *nodal*, and *extranodal* with respect to NHL of the parotid gland. Some investigators distinguish disease arising from the parenchyma and tumors of the periparotid and intraparotid lymph nodes. Other reports differentiate tumors arising in the background of known malignant lymphoma or in patients with established autoimmune disease (98). Compared with normal age-matched cohorts, patients with Sjogren disease have an over 40 times greater relative risk of developing NHL within the affected parotid glands (99). For patients with the Sjogren disease, there is an overall 4% prevalence of NHL (100).

CT imaging of salivary gland lymphomas shows homogeneity and mild enhancement (Fig. 128.3) (101). Aggressive tumors can exhibit infiltration of surrounding tissue with necrotic or cystic changes in the tumor itself (102). Ultrasound, an often used modality in the work-up of parotid

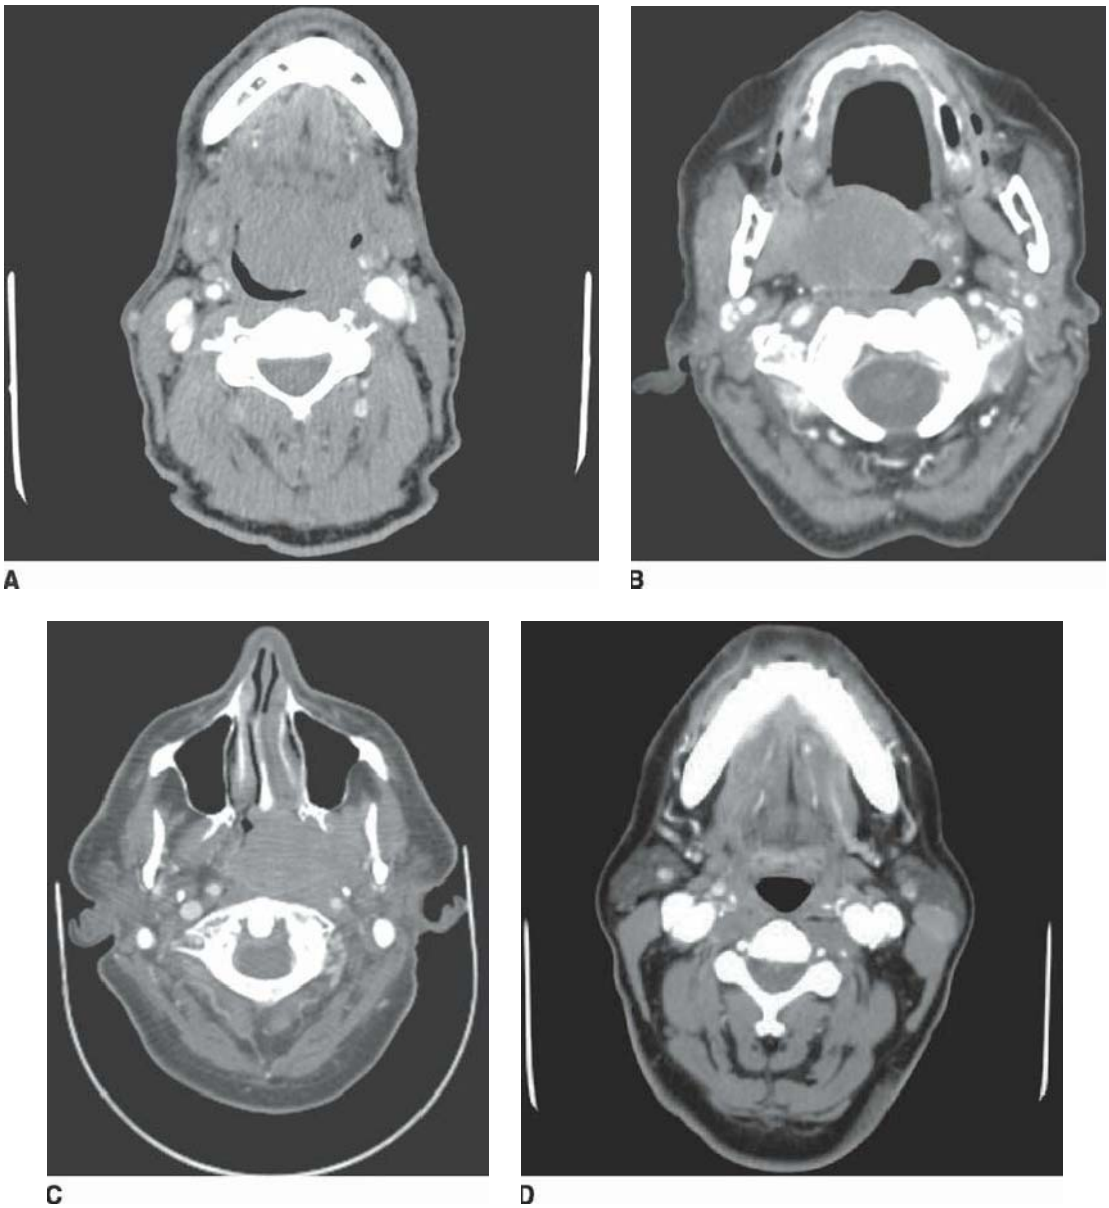

Figure 128.3 Contrast-enhanced axial CT images from patients with lymphoma of the (**A**) base of tongue, (**B**) left tonsil, (**C**) nasopharynx, (**D**) the left parotid gland.

masses, typically shows a well-circumscribed, hypoechoic mass with marked intratumoral vascularization (103).

Thyroid Lymphoma

Primary thyroid lymphoma is uncommon, comprising less than 5% of all thyroid malignancies (104). The most common presentation of disease is a rapidly growing thyroid mass. Patients with primary lymphoma of the thyroid are often younger than those with anaplastic thyroid cancer—the other major disease of concern for those presenting with a rapidly enlarging thyroid mass. Compressive symptoms including hoarseness, dysphagia, and stridor occur in roughly 30% to 50% of patients (105). Although not often on the differential diagnosis of a thyroid mass, prompt diagnosis of primary thyroid lymphoma is critical in that the disease has favorable rates of curability when confined to the thyroid itself. Five-year overall survival for stage I disease is higher than 80% while advanced stage disease (III or IV) has survival rates less than 35% (106). Because of a high relapse rate even for early stage MALT lymphomas, a combination of CHOP and irradiation is used in most centers for all primary thyroid NHLs (107).

The normal thyroid gland does not contain lymphoid tissue. Acquisition of lymphoid tissue in this organ is almost entirely found in patients with autoimmune thyroiditis (108). Chronic lymphocytic thyroiditis (Hashimoto's) has been estimated to confer a 40- to 80-times higher risk for developing thyroid lymphoma in comparison to the general populace (109). It takes an average of 20 to 30 years for lymphoma to develop after the onset of Hashimoto's (110). Most patients are euthyroid.

DLBCL is the most common histologic subtype, occurring in roughly 70% of cases (111). High-grade transformation to DLBCL from MALT lymphoma, the next most common subtype, has been seen on rare occasions (112). Similar to other extranodal lymphomas, most primary thyroid NHLs present in early stage I or stage II disease (113). Although open surgical biopsy has traditionally been required for diagnosis, FNA with modern immunotyping is reasonable for diagnosis in suspicious lesions, particularly for high-grade tumors (114). CNB may provide adequate tissue as well if the diagnosis of thyroid lymphoma is entertained.

Although imaging can be helpful in determining the extent of disease and monitoring treatment efficacy, it is difficult radiographically to distinguish primary thyroid lymphomas from other rapidly enlarging thyroid masses such as anaplastic carcinoma. On ultrasound, most tumors show a well-defined hypoechoic mass with low echogenicity (115). One series reports that nearly all thyroid NHLs have a characteristic asymmetric pseudocystic pattern on ultrasound (116). On CT imaging, a lack of necrosis and calcification in a rapidly growing thyroid mass is suggestive of lymphoma (117). A "donut sign" on CT has been described because of the propensity for the disease to encircle the trachea (118).

Laryngeal Lymphoma

Primary laryngeal lymphoma is an exceedingly rare disease, with less than 100 cases reported in the literature. Common symptoms include dyspnea, hoarseness, and stridor. Most cases manifest as a nonulcerated submucosal mass in the supraglottis, which is the location of organized lymphoid tissue in the larynx (119). Most cases on histology are either MALT lymphomas or DLBCL (120). Although these lesions are noted to be exquisitely radiosensitive, most centers utilize combined chemoradiotherapy for treatment (121). On CT imaging, characteristic features of laryngeal NHL include a uniformly enhancing supraglottic mass without necrosis, calcification, or cervical lymphadenopathy (122).

AIDS-Related Lymphoma

Nearly 500,000 Americans live with AIDS, with 50,000 new HIV infections diagnosed yearly in the United States (123). An estimated 40% of patients with AIDS will develop cancer during their lifetime (124). Cervical carcinoma, Kaposi sarcoma, and NHL constitute the three AIDS-defining malignancies (125). The development of AIDS increases the relative risk of developing lymphoma by 165-fold, with a roughly 4% incidence of NHL amongst those with the diagnosis of AIDS (126). There is evidence, however, to suggest that the overall incidence of AIDS-related NHL has declined since the introduction of modern highly active antiretroviral therapy (HAART) (127). HAART therapy though has not been shown to improve survival time for patients with NHL (128).

HIV-associated B-cell dysregulation secondary to immunodeficiency is considered to be the primary contributing factor to the development of lymphomas. As such, DLBCL is the most common subtype amongst AIDS-related NHL cases (129). Interestingly, although rituximab plus intravenous bolus chemotherapy is the standard of care for immunocompetent patients with aggressive B-cell lymphomas, prospective studies have suggested that R-CHOP has an unacceptable rate of toxicity for patients with AIDS (130). Infusional therapy is now being used in many centers as it has been demonstrated to have similar to greater efficacy while minimizing toxicity (131).

Posttransplant Lymphoproliferative Disorder

Given the increasing number of transplantation procedures being performed, the otolaryngologist must be familiar with the manifestations of PTLD and its manifestations in the head and neck. First described by Starzl in 1968, PTLD involves a spectrum of abnormal lymphoid proliferations that occur after either solid organ transplant or hematopoietic stem cell transplantation (132). PTLDs can be subclassified into four distinct categories: early lesions (plasmacytic hyperplasia), polymorphic disease,

monomorphic disease (B- and T-cell neoplasms), and classical HL (133). The majority of PTLD cases (roughly 70%) are associated with EBV infection (134). In patients receiving long-term immunosuppression therapy such as cyclosporine, T-lymphocyte suppression allows for unchecked proliferation of EBV-infected B cells. Thus, the primary risk factors for the development of PTLD include the EBV serostatus of both the donor and recipient as well as intensity of immunosuppression (135). The incidence of PTLD is highest in combined heart-lung transplants and small bowel transplants (roughly 20%) and lowest after kidney transplantation (less than 1%) (136). Extranodal involvement is seen in up to 85% of cases (137).

Head and neck manifestations of PTLD vary depending on the site of involvement. These can include constitutional B symptoms, enlargement of Waldeyer ring, and cervical lymphadenopathy. Most patients presenting with head and neck symptoms within 1 year of transplantation will present with a mononucleosis-like syndrome with rapid swelling of lymphoid tissue (138). Imaging reveals focal masses, particularly in Waldeyer ring, as well as a predilection for submucosal extension through fascial planes (139). Unlike with immunocompetent patients, central lymph node necrosis is commonly seen.

First described over 25 years ago, the initial therapeutic approach for the management of PTLD remains reduction of immunosuppression (RI) (140). The goal of this strategy is to allow the body to recover normal immune surveillance function. Independent prognostic factors associated with a poor response to RI include organ dysfunction, multiorgan involvement, and elevated LDH (141). However, the utility of RI in aggressive PTLDs has been questioned. A recent retrospective analysis of patients with aggressive PTLDs revealed a less than 10% rate of remission from RI alone (136). Another drawback in the usage of RI is the expected risk of organ rejection (142).

Although there is evidence supporting RI alone in the treatment of early stage PTLD, many centers now utilize rituximab-based therapy in patients who either fail or do not tolerate RI (143). In the largest prospective trial of PTLD patients to date, the usage of rituximab monotherapy followed by sequential cycles of R-CHOP demonstrated a complete response rate of roughly 70% (144). For patients receiving CHOP therapy, immunosuppression can continue to be withheld without increased risk for graft failure. It has been suggested that the inherent immunosuppressive activity of chemotherapy can compensate for any negative effects of RI (145).

CONCLUSION

The otolaryngologist is often the first physician to evaluate a patient with lymphoma given the propensity of the disease to present in the head and neck. A high index of suspicion must often be maintained, and recognition of the various manifestations of this diverse group of tumors is critical for facilitating prompt diagnosis and treatment. Communication with colleagues in the specialties of hematology/oncology, pathology, and, increasingly, infectious disease and transplant surgery is important as well.

With the development of novel diagnostic, staging, and therapeutic regimens, the outcome for individuals diagnosed with lymphoma will continue to improve.

HIGHLIGHTS

- Otolaryngologists will often be called upon to make diagnosis of lymphomas in the head and neck area.
- Lymphoma in the head and neck area presents most commonly as enlarged cervical lymph nodes or hypertrophic lymphoid tissues within the Waldeyer ring.
- Definitive biopsy requires tissue sampling for histologic examination and flow cytometry. Gold standard is excisional biopsy of involved lymph node. CNB may be appropriate also.
- CT with contrast is adequate for the initial evaluation of patients with suspected lymphoma in the head and neck area.
- The Ann Arbor staging system is the most widely used system for classifying the extent of anatomic involvement in lymphomas and for staging of both HL and NHL.
- The most common type of NHL is follicular lymphoma, which is often indolent and does not require active treatment.
- Radiation therapy and/or combination chemotherapy is the current mainstay of treatment for both NHL and HL of the head and neck. Advances in molecular biology have led to the development of novel therapies for NHL such as monoclonal antibodies and radioimmunoconjugates.

129 Neoplasms of the Nose and Paranasal Sinuses

Lee A. Zimmer *Ricardo L. Carrau*

EPIDEMIOLOGY

Malignant tumors of the sinonasal tract constitute about 3% of tumors arising in the upper respiratory tract. They occur most commonly in whites, and the incidence in males is twice the incidence in females (1). Exposure to industrial fumes, wood dust, nickel-refining processes, and leather tanning has been implicated in the carcinogenesis of certain types of sinonasal malignant tumors. Other industrial exposures associated with an increased incidence of sinonasal cancer include mineral oils, chromium and chromium compounds, isopropyl oils, lacquer paint, soldering and welding, and radium dial painting. A recent report demonstrates a higher incidence of nasal cancers in cigarette smokers (1).

EVALUATION

Diagnosis

Tumors of the sinonasal tract commonly present with symptoms similar to those caused by inflammatory sinus disease, such as nasal airway obstruction, epistaxis, headache, facial pain, and nasal discharge, and are frequently asymptomatic in 9% to 12% of patients, contributing to a delay in the diagnosis and advanced stage of disease. Regional and distant metastases are infrequent despite the advanced stage of the primary tumor. The incidence of cervical metastases on initial presentation varies from 1% to 26%, with most series reporting less than 10%. In one large series, the 5-year incidence of neck metastasis is 4.3% for primary ethmoid malignancies and 12.5% for primary maxillary malignancies (2). This number decreases in patients treated with radiation to the neck. The presence of distant metastasis on initial presentation is even less common, with most authors reporting an incidence of less than 7%.

The physical examination should be thorough, with emphasis on the sinonasal region, orbit, cranial nerves, and should include nasal endoscopy. Although not pathonogmonic, numbness or hypoesthesia of the infraorbital (V2) or supraorbital (V3) nerve strongly suggests malignant invasion. Other findings such as proptosis, chemosis, extraocular muscle impairment, mass effect in the cheek, gingiva or gingivobuccal sulcus (e.g., ill-fitting dentures), and loose dentition also suggest the presence of a sinonasal tumor. Table 129.1 provides a summary of diagnostic techniques.

Radiologic imaging is essential for staging. Plain films may demonstrate bone destruction; however, a significant number will be interpreted as normal. A screening computed tomography (CT) scan is more accurate than plain films to evaluate the bony framework of the paranasal sinuses and compares favorably with the cost of plain films. High-risk patients with a history of carcinogen exposure, severe persistent pain, cranial neuropathies, exophthalmos, chemosis, and sinonasal disease and those with persistent symptoms after adequate medical treatment should be evaluated with an axial and coronal CT scan with contrast or magnetic resonance imaging (MRI) with contrast. CT scanning is superior for the evaluation of the bony confines of the sinonasal tract and skull base. The use of contrast provides an estimate of the tumor vascularity and its relationship to the carotid artery.

MRI differentiates adjacent tumor from soft tissue, differentiates secretions in an obstructed sinus from a space-occupying lesion, demonstrates perineural spread, suffers less artifact effect with dental fillings, offers the advantage of imaging in the sagittal plane, and does not involve exposure to ionizing radiation. Coronal MRI images are superior for the evaluation of the foramen rotundum, vidian canal, foramen ovale, and optic canal. Sagittal images are most useful to demonstrate the replacement of the normal low-intensity signal of Meckel's cave and the high-intensity signal of fat in the pterygopalatine fossa (PtPF) by tumor signals similar to brain. MRI, however, is more expensive than CT scan, more prone to motion artifact, and less tolerated due to claustrophobia.

TABLE 129.1 DIAGNOSIS PARANASAL TUMORS TECHNIQUE

History and Physical	Risk Factors/Cranial Nerve Deficits, Nasal Mass
Imaging	
CT scanning	Evaluation of bony boundaries of PNS; not cost-effective
MRI	Evaluation of soft tissue invasion and perineural spread; differentiate retained secretions from tumor
PET	Routine evaluation for recurrent disease after primary treatment and distant metastasis; useful for SCCA; cost-effectiveness unknown
Biopsy	
Sinus lavage/cytology	
Fine needle aspiration	
Transnasal biopsy	Direct or endoscopic. Preferred modality

Positron emission tomography (PET) is commonly used for malignancies of the head and neck for staging and surveillance. The combined PET/CT scanner adds anatomical detail which aids in surgical planning by defining the extent of tumor. Although many reports have documented the use of PET in head and neck cancer, none have evaluated the use of this modality for malignant tumors of the nose and paranasal sinuses.

Angiography with carotid flow study is reserved for surgical candidates presenting with tumors that surround the carotid artery or when sacrifice of the vessel is anticipated to obtain clear margins. Balloon occlusion tests, used with SPECT, Xenon CT scan, or Transcranial Doppler, offer a reasonable estimate of the risk of ischemic brain infarction if the internal carotid artery is sacrificed. These tests, however, cannot predict ischemia at marginal ("watershed") areas or embolic phenomena.

A CT scan of the chest and abdomen is recommended for patients presenting with tumors that metastasize hematogenously, such as sarcomas, melanoma, and adenoid cystic carcinoma. Metastatic evaluation is important if an extensive resection is considered. A lumbar puncture, brain and spine imaging are recommended for tumors that invade the meninges or brain.

Pathology

The sinonasal tract pathology, with certain important exceptions, reflects the pathology found in other areas of the head and neck (Table 129.2). We provide a brief description of the most common histologic diagnoses.

Benign Epithelial Tumors

Papillomas arise from squamous or schneiderian epithelium. The keratotic papilloma of the vestibule (vestibular wart) behaves like other cutaneous counterparts. It is easily treated by simple excision or cauterization.

TABLE 129.3 PAPILLOMAS OF THE SINONASAL TRACT

	Inverted Papillomas	Fungiform Papilloma	Cylindrical Papilloma
Site of origin	Lateral wall	Septum	Lateral wall
Frequency	47%	50%	3%
Recurrence rate	27%–73%	22%–50%	25%–35%
Associated with malignancy	13%	3%–5%	15%

Adapted from Barnes EL. *Surgical pathology of the head and neck*, Vol. 1. New York: Marcel Dekker, 1985.

Papillomas of the nasal cavity may be classified in three distinct categories (Table 129.3). Fungiform papillomas arise from the nasal septum, while inverted and cylindrical papillomas typically arise from the lateral nasal wall. Although benign in nature, extension beyond their site of origin can destroy bone, recur when not excised completely, and may be associated with malignant tumors (3,4). They are most commonly diagnosed in white males during the fifth to seventh decades (mean 50 years). En bloc resection has been the gold standard for the treatment of these lesions (Table 129.4). MRI, CT scanning, and nasal endoscopy permit an accurate preoperative mapping of these lesions, allowing a more conservative resection through less invasive approaches. During the last decade, various endoscopic, transnasal techniques for the resection of inverting papillomas have been reported (4,5). Transnasal techniques avoid the use of incisions and usually require a shorter hospital stay than external approaches. The endoscopic approach provides superior visualization of the posterior ethmoid cells, especially those that extend lateral to the sphenoid sinus or around the optic nerve (Onodi cells). In expert hands, resection with an endonasal, medial maxillectomy approach has equal recurrence rates as traditional open, en bloc resections (Table 129.5) (5).

Adenomas of the sinonasal tract arise more commonly in the nasal septum. Most are found during the fourth to the seventh decade, occurring with an equal sex distribution. The recurrence rate is low following complete removal (10%).

Malignant Epithelial Tumors

Squamous cell carcinoma (SCCA) is the most common tumor of the sinonasal tract. It is most commonly reported in white males in their fifth to sixth decade. The prognosis is related to the extent of the tumor and the site of origin.

TABLE 129.4 OPEN MEDIAL MAXILLECTOMY RECURRENCE RATES FOR INVERTING PAPILLOMA

Authors	Lateral Rhinotomy-Medial Maxillectomy	Conservation Resection[a]
Benninger et al. (1991)	0% (0/20)	36% (5/14)

Minovi (2006)	10% (5/48)
Pasquini (2004)	3% (1/36)
Tomenzoli (2004)	0% (0/47)

Adenocarcinomas make up 4% to 8% of all sinonasal tumors. They originate most commonly in the ethmoid sinuses and nasal cavity and are associated with exposure to hardwood dust. Adenocarcinomas may be divided into low and high grades according to their histologic characteristics and behavior. Low-grade tumors present a uniform glandular architecture and cytologic characteristics, with rare mitoses and seldom perineural invasion or distant metastases. Low-grade adenocarcinomas tend to recur locally. High-grade adenocarcinoma has a solid growth pattern with poorly defined margins, prominent pleomorphism, and large number of mitoses. One-third of patients with high-grade adenocarcinomas will present with distant metastases. Approaches to adenocarcinomas of the paranasal sinuses include anterior craniofacial resection, lateral rhinotomy, and endonasal techniques with or without radiotherapy. The 5-year disease-specific survival for patients with adenocarcinoma of the nose and paranasal sinuses following surgery and radiation therapy is 100% for T1, 93% for T2, 60% for T3, and 0% for T4 lesions (6). Disease extension to the orbit, infratemporal fossa, frontal sinus and dura are poor prognostic indicators.

Adenoid cystic carcinomas of the sinonasal tract comprise 14% to 20% of all the adenoid cystic carcinomas arising in the head and neck. They are characterized by early spread to neurovascular structures, submucosal spread, and advanced stage at the time of diagnosis. Low-grade tumors are defined by histology with less than 30% solid architecture and include the cribriform and tubular patterns. High-grade tumors correspond to those with a histologic pattern with more than 30% solid cellular architecture. The incidence of perineural invasion is similar for both grades, but the incidence of local recurrence and metastases is higher in the solid type. High rates of recurrence (50% to 76%) are likely due to perineural spread and positive microscopic margins not identified at the time of surgery (7,8). The treatment of adenoid cystic carcinoma of the sinonasal tract is primarily surgical, although combined surgery and postoperative radiation therapy appear to yield better local control.

In the MD Anderson experience, among the 105 patients presenting with ACC of the sinonasal tract, most patients presented with locally advanced disease (8). Tumor extended to the skull base in 28% of patients and invaded the skull base and brain in 24%. Margins are difficult to clear even with extensive craniofacial resection due to the proximity to vital structures and the propensity for perineural spread, which in this series was 60% of patients. The survival rate at 2 years was 46% following primary treatment and 15% following salvage surgery. Patients recurred locally (31%), and 38% developed regional or distant recurrence. Overall 5-year survival was 50% for stage I to III and 20% for stage IV.

Melanoma of the sinonasal tract may be primary or metastatic. Although 20% of all melanomas originate in the head and neck, less than 1% arises from the sinonasal tract. They are most commonly found in the nasal cavity, followed by the maxillary sinus, ethmoid sinus, and frontal sinus, in descending order. Most patients present with disease confined to the site of origin but show a tendency toward early vascular and lymphatic invasion with a high incidence of local recurrence after surgical excision. Postoperative radiation therapy may be beneficial, although its impact on survival and local control has not been addressed in scientific trials. The median survival for patients presenting with sinonasal melanoma is 15 months with a 5-year overall survival of 23% (9). The most common cause of failure is local recurrence, whereas the most important factor in predicting survival is metastatic disease (9,10).

Olfactory neuroblastoma is a rare tumor arising in the olfactory epithelium. Patients often present with nasal obstruction and epistaxis. It has a bimodal frequency at 10 to 20 and 50 to 60 years of age, with a similar incidence in males and females. Its prognosis is related to the extent of disease and resectability on initial presentation. Most institutions have adopted combined therapies based on the Kadish staging system (Table 129.6). The UCLA classification (Table 129.7), however, provides better prognostication regarding local recurrences as factors such as intradural and orbital invasion are not considered in the Kadish staging system. The advent of open or endoscopic craniofacial resection with postoperative radiation to the primary site and neck has improved the therapeutic results (11). In a recent meta-analysis, the 5-year disease-free survival for all stages is 78% following combined surgery with radiotherapy and 47% for Kadish stage C (12).

TABLE 129.6 KADISH STAGING SYSTEM FOR OLFACTORY NEUROBLASTOMA

Stage A	Tumor confined to the nasal cavity
Stage B	Tumor in nasal cavity extending to paranasal sinus
Stage C	Tumor extending to orbit, base of skull, cranial cavity or with cervical/distant metastasis

TABLE 129.7 UCLA STAGING SYSTEMS FOR OLFACTORY NEUROBLASTOMA

Stage	Description
T1	Tumor involving the nasal cavity and/or paranasal sinuses (excluding sphenoid), sparing the most superior ethmoidal air cells
T2	Tumor involving the nasal cavity and/or paranasal sinuses (including the sphenoid) with extension to or erosion of the cribriform plate
T3	Tumor extending into the orbit or protruding into the anterior cranial fossa
T4	Tumor involving the brain

Sinonasal undifferentiated carcinomas are usually composed of small and medium-sized cells and must be differentiated from rhabdomyosarcomas, melanoma, olfactory neuroblastoma, lymphoma, and SCCA. The progression of symptoms is very rapid, and they usually present with very advanced stage involving multiple sinuses. Treatment includes trimodal therapy employing chemotherapy (cyclophosphamide, doxorubicin and vincristine), radiation therapy, and, in appropriate cases, surgery. Patients with intracranial disease fared poorly despite aggressive combination therapy.

Benign Nonepithelial Tumors

Fibro-osseous lesions, including osteomas, fibromas, and chordomas, are the most common benign tumors of the sinonasal tract. Their growth is usually slow and self-limited. Simple surgical excision is recommended when a histologic diagnosis is needed or to relieve obstructive symptoms.

Fewer than 4% of benign peripheral nerve sheath tumors of the head and neck arise in the nose and paranasal sinuses. They present as polypoid, slow-growing masses, reaching a very large size and often causing facial deformities and local destruction of adjacent structures. Ninety percent of the nerve sheath tumors show a benign histology. Two-thirds of these tumors are schwannomas and one-third neurofibromas. Unlike other regions, schwannomas of the nose and paranasal sinuses often lack tumor encapsulation, with neoplastic cells undermining adjacent respiratory mucosa (13). Treatment is by complete surgical excision, or partial removal for massive neurofibromas involving vital areas.

Malignant Nonepithelial Tumors

Neurogenic sarcomas are rare in the head and neck and commonly associated with neurofibromatosis. Neurogenic sarcomas are locally aggressive and frequently present with distant metastases. Surgery plays a primary role in their therapy; radiation and chemotherapy are usually reserved for incomplete removal, inoperable cases, or recurrences (14). The 5-year survival rate is 60% although sarcomas associated with neurofibromatosis behave more aggressively, yielding a 5-year survival rate of 30% (14).

Rhabdomyosarcomas arise in the head and neck in 35% to 45% of cases. In 10% of patients, they originate in the paranasal sinuses (15). These tumors may assume the morphology of any of the developmental stages of striated muscle, hence the classification into embryonal, alveolar, and pleomorphic types. There is a bimodal distribution pattern in childhood, with the embryonal occurring in the first decade and the alveolar type in adolescents. Rhabdomyosarcomas have a less favorable outcome in adults, with a 5-year survival rate of only 35% (16). The head and neck region is less involved in adults, with the viscera and extremities the most common sites of presentation.

Rhabdomyosarcomas of the sinonasal tract are classified as nonorbital parameningeal and behave more aggressively than those arising in other locations. Systemic and regional metastases are common. In 1987, the Intergroup Rhabdomyosarcoma Study I reported the use of intensive radiation and chemotherapy on patients with nonorbital parameningeal rhabdomyosarcoma showing an improvement of the survival rate from 51% to 81%. In 2002, Intergroup Rhabdomyosarcoma Study IV reported further improvements in survival for those patients with cranial parameningeal involvement (17). Patients with cranial parameningeal sarcomas, but without meningeal invasion, require multiagent chemotherapy followed by radiation therapy. High-risk tumors defined as intracranial tumors, tumors that eroded the base of skull or that caused a cranial neuropathy were treated with triple intrathecal chemotherapy, whole brain radiation, and spinal radiation. At 5 years, 73% of patients were alive, compared with 45% in IRS I. Overall survival for patients with paranasal sinus involvement was 76% for the low-risk group and 57% for the high-risk group. Failure-free survival was 57% for the low-risk group and 52% for the high-risk group. Aggressive initial surgical therapy was not warranted. These results, however, have never been confirmed in adults. Adult rhabdomyosarcoma is usually treated by wide surgical excision. Radiation is recommended for positive margins or inoperable or recurrent disease. Chemotherapy has a palliative role that must be weighed against its possible morbidity.

Fibrosarcoma is a tumor arising from fibroblasts, thus, the term encompasses a spectrum of malignancies that ranges from low-grade fibromatosis to high-grade tumors. Misdiagnosis is very common. Radiation and trauma have been implicated as possible etiologic factors. The treatment of choice is wide surgical excision for previously untreated tumors. Radiation is recommended for involved margins or recurrent or inoperable tumors.

Hemangiopericytoma is a very rare, highly vascular tumor arising from the pericapillary pericytes of Zimmerman. Histologic examination reveals oval- and spindle-shaped pericytes. Benign and malignant varieties

have been described. Malignant tumors are distinguished by increased mitotic activity, high cell density, and necrotic and hemorrhagic zones. They invade locally and metastasize in 10% to 15% of cases. Hematogenous metastases involve lung, liver, and bone. Sixteen percent are found in the head and neck, with about 50 reported cases arising in the sinonasal tract (18). Their prognosis relates to the size of the lesion, number of mitoses, and metastases. The primary treatment is surgical excision.

Osteogenic sarcoma is the most common primary tumor of bone in the United States, with an estimated incidence of one case per 100,000. Those originating within the jaws constitute 7% to 10% of all osteosarcomas. Etiologic factors include ionizing, radiation, fibrous dysplasia, trauma, Paget disease, and the gene associated with retinoblastoma. The most effective therapy is surgical excision. However, during the past decade, several reports have suggested that adjunctive radiation and chemotherapy may improve survival. A multi-institutional review and meta-analysis demonstrated a 2- and 5-year disease-free survival for maxillary osteosarcomas of 65% and 38%, respectively (19). Adjuvant therapy, including radiation, chemotherapy, or combination therapy, failed to improve outcome. Nonetheless, these authors acknowledge a selection bias and therefore the role of adjuvant therapy remains unresolved.

Chondrosarcomas are slow-growing tumors that usually arise from cartilaginous structures. These tumors have been graded from I to III on the basis of the rate of mitoses, cellularity, and nuclear size. Size of the tumor and grading correlates with the rate of metastasis, local aggressiveness, and ultimate survival. Surgical removal with wide margins is the treatment of choice. Gross total removal with postoperative radiation is recommended for those involving vital structures.

Although the metastatic potential and oncologic outcome of sarcomas arising in the sinonasal tract is variable among the different histologic types, the local behavior of sarcomas is similar. Sarcomas are infiltrative, usually advancing to areas farther than what is appreciated by the naked eye; thus, they are often incompletely resected and therefore recur locally. Wide excision improves the local control, but this is difficult to perform when dealing with the sinonasal tract, which is adjacent to important if not vital structures. Cranial base surgery may improve the local control of sarcomas of the sinonasal tract.

Lymphoma of the sinonasal tract accounts for only 0.17% of all lymphomas. T-cell lymphomas are more common in Asian populations, while B-cell lymphomas are more common in Western populations. The primary sites of occurrence in the sinonasal tract are the maxillary sinus (79%) and nasal cavity (20%) (20). The treatment includes radiation therapy for localized lesions and chemotherapy to prevent systemic recurrence. The biologic behavior is remarkably different in the pediatric and adult populations. Adults suffer frequent relapses, commonly involving the abdomen, and show a 5-year survival rate of around 45%. Distant metastases are often associated with failure to treat with chemotherapy in the primary setting (20). In children, complete remissions are more common, involvement of the gastrointestinal tract is rare, and the 5-year survival rate is close to 75%.

Eighty to ninety percent of patients with extramedullary plasmacytoma have involvement of the head and neck region, 40% arise in the sinonasal tract. It is more common in the sixth to seventh decades. It tends to spread locally, and can be found in the cervical nodes in less than 25% of the cases. The prognosis is unpredictable, and a variable number of the patients will be diagnosed with multiple myeloma. It is of utmost importance to rule out this diagnosis on the initial presentation. Most of these lesions will respond to radiation therapy in doses of 4,000 to 5,000 cGy administered over 4 to 5 weeks.

Metastatic Tumors

Metastatic tumors to the sinonasal tract produce symptoms similar to those of primary tumors. More than 100 cases have been reported, metastasizing to the maxillary, ethmoid, frontal, and sphenoid sinus in descending order. The most common primary sources are the kidneys, breasts, and lungs. The treatment is palliative, using radiation, surgery, or chemotherapy to relieve obstructive and compressive symptoms or pain.

STAGING

A staging system provides a guide to define the extent and prognosis of a tumor and also serves as a communication tool, allowing different institutions to compare their experience with the use of different therapeutic modalities. The American Joint Committee on Cancer (AJCC) TNM staging system of the nose and paranasal sinuses is provided (Table 129.8). The AJCC recommends a different system for soft tissue sarcomas. This system includes a histologic grading system that differs from the system used for epithelial tumors. Grading is thought to be the most significant prognostic factor in patients with mesenchymal tumors and is based on the number of mitoses, degree of cellularity, amount of stroma, degree of maturation, nuclear pleomorphism, and presence or absence of necrosis.

PRINCIPLES OF TREATMENT

Surgery

Diagnostic (Biopsy)

Tissue sampling may be performed using endoscopic sinus surgery instruments or through open transcutaneous or transoral procedures (e.g., Caldwell-Luc antrostomy, external ethmoidectomy, rhinotomy). The former is preferred since it provides good access and hemostatic control with less morbidity, and does not contaminate other soft tissues.

TABLE 129.8 MAXILLARY SINUS TNM STAGING FOR PRIMARY TUMOR (T)

TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis	Carcinoma *in situ*
T1	Tumor limited to maxillary sinus mucosa with no erosion or destruction of bone
T2	Tumor causing bone erosion or destruction including extension into the hard palate and/or middle nasal meatus, except extension to posterior wall of maxillary sinus and pterygoid plates
T3	Tumor invades any of the following: bone of the posterior wall of the maxillary sinus, subcutaneous tissues, floor or medial wall of orbit, pterygoid fossa, ethmoid sinuses
T4a	Tumor invades anterior orbital contents, skin of cheek, pterygoid plates, infratemporal fossa, cribriform plate, sphenoid or frontal sinuses
T4b	Tumor invades any of the following: orbital apex, dura, brain, middle cranial fossa, cranial nerves other than maxillary division of trigeminal nerve (V2), nasopharynx, or clivus

American Joint Committee on Cancer. *Manual for staging of cancer*, 6th ed. New York: Springer-Verlag, 2002:61.

Drainage/Debridement

An adequate drainage port (e.g., nasoantral window) should be opened in patients presenting with secondary bacterial sinusitis and in patients who will require radiation therapy as primary treatment.

Resection

Surgical resection is usually recommended with curative intent. Palliative excision may be considered to alleviate intractable pain, to provide rapid decompression of vital structures, or to debulk a massive lesion, thus freeing the patient from social embarrassment. Surgery as a single treatment modality for malignant tumors of the sinonasal tract has yielded 5-year survival rates from 19% to 86%. Figures 129.1 through 129.6 demonstrate the most common surgical approaches and techniques.

With recent advances in preoperative imaging, intraoperative image guidance systems, endoscopic instrumentation, and materials for hemostasis, endonasal techniques for the removal of nasal and paranasal sinus tumors may be a viable alternative to the traditional open techniques. Endoscopic approaches can access and visualize tumors in the nasal cavity, ethmoid, sphenoid, medial frontal, and medial maxillary sinuses. Frozen sections must be utilized as the tumor is often removed in a piecemeal fashion. Improvements in functional recovery and long-term survival, however, are yet to be described. A recent review of 134 patients undergoing endoscopic resection of sinonasal malignancies revealed a 5-year disease-free survival rate 91% and a 59% survival rate for open procedures (21). Unfortunately, the data were not stratified by stage.

Rehabilitation

The main goals of postsurgical rehabilitation are primary wound healing, preservation or reconstruction of the facial contour, and restoration of oronasal separation, thus facilitating speech and swallowing. Functional considerations take precedence over aesthetics. Rehabilitation after surgical resection may be achieved with a dental prosthesis or reconstructive flaps, such as temporalis muscle flaps with and without the inclusion of cranial bone, pedicled or microvascular free myocutaneous flaps (e.g., pectoralis major, latissimus dorsi, trapezius), and cutaneous flaps (e.g., forehead, scalp, deltopectoral). Flaps are recommended to replace resected skin, to provide support for the orbit or brain, or to isolate the cranial cavity from the upper aerodigestive tract.

A total maxillectomy defect should not be obliterated at the initial operation; an open cavity facilitates cleansing and direct visual inspection during the follow-up period. Patients requiring a craniofacial resection, especially those needing an orbital exenteration deserve special consideration, since a recurrence after an adequate craniofacial resection is uniformly lethal. From the functional standpoint, patients require immediate separation of the cranial cavity from the upper aerodigestive tract and support of the brain. A pericranial flap and transfer of a temporalis muscle flap achieves these goals. The temporalis muscle, however, is often devascularized after an infratemporal fossa dissection or its bulk may be inadequate to obliterate the dead space. Under these circumstances, the maxillectomy cavity may be obliterated with a free microvascular flap, offering immediate palliation and oronasal separation without the need for a prosthesis.

Radiation Therapy

The response of sinonasal tract tumors to radiation varies with the stage and histology of the tumor. Radiation may be used as a single modality, as an adjunct to surgery, or as palliative therapy. Recent reports indicate that postoperative radiation improves local control but not cause specific or absolute survival (22). Radiation therapy is the primary

treatment for lymphoreticular tumors, for patients who are poor surgical candidates and for those patients who refuse surgery. Preoperative and postoperative radiation therapy seems to produce similar results. We and others favor postoperative radiation since there is a smaller volume of tumor cells to kill, the margins of the nonradiated tumor can be better defined during surgery and the postoperative wound healing is more predictable.

Chemotherapy

The role of chemotherapy for the treatment of tumors of the sinonasal tract is usually palliative, using its cytoreductive effect to relieve pain, obstruction, or to debulk a massive external lesion. Nevertheless, the failure of combination therapy, including surgery and radiation, to achieve local control, the need for deforming procedures,

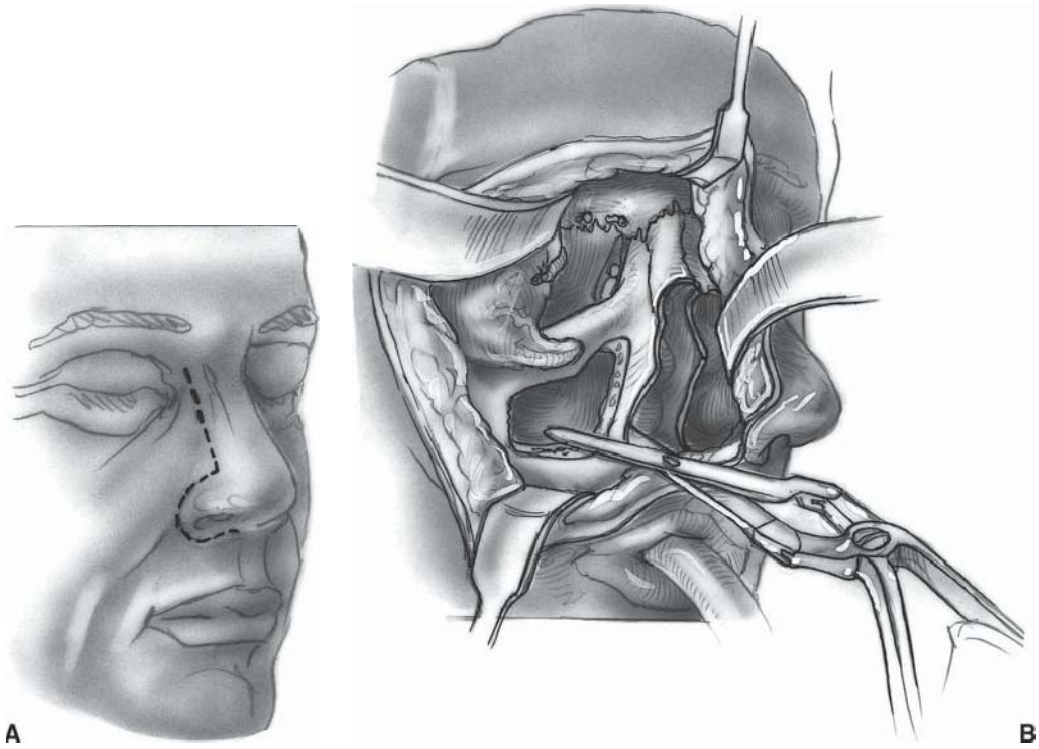

Figure 129.1 Medial maxillectomy. Lateral rhinotomy: **A:** The skin incision begins beneath the medial aspect of the eyebrow and continues 4 to 5 mm anterior to the medial canthus and over the nasal bone along the deepest portion of the nasomaxillary groove and following the alar crease. A lip-splitting extension of the incision is not necessary. To expose the surgical area, the cheek flap is elevated subperiosteally over the maxilla and around the infraorbital nerve. The periorbita is elevated over the lamina papyracea, and the frontoethmoid suture is identified and followed posteriorly until the anterior and posterior ethmoid arteries are identified. The anterior wall of the antrum is penetrated at the canine fossa using a 4-mm chisel. The antrostomy is enlarged with a Kerrison rongeur around the infraorbital nerve and superiorly toward the inferior orbital rim. **B:** Bone is removed across the orbital rim, including the lacrimal fossa. The nasolacrimal duct is divided and the lacrimal sac is opened and marsupialized (**C**). **D:** Osteotomies and removal of the specimen. The first osteotomy involved in the actual removal extends through the piriform aperture at the level of the nasal floor, directed posteriorly until the osteotomy perforates the posterior wall of the antrum. The orbit is retracted laterally, and a second osteotomy is performed at the frontoethmoid suture, extending posteriorly to a point 2 to 3 mm posterior to the posterior ethmoid artery (i.e., anterior to the optic foramen). **E:** The thin bone of the medial floor of the orbit is sawed following a line that joins the lacrimal fossa with the superior osteotomy. The final bone cut involves three steps. First, a 2-mm osteotome is introduced through the anterior antrostomy and directed through the medial posterior antral wall. The osteotome is advanced superiorly to reach the level of the superior osteotome and is then pushed medially. Second, a wide osteotome, introduced through the nose, is impacted into the anterior wall of the sphenoid sinus, and then pushed laterally. Heavy right-angle scissors (e.g., upper-lateral-cartilage scissors) are guided through the inferior osteotomy with one blade in the nose and the other in the antrum to start the posterior cut, behind the turbinates. **F:** Heavy curved scissors are then introduced with one blade in the nasal cavity and the other in the superior osteotomy, directed through or along the posterior attachments of the turbinates. The specimen is removed by anterior and inferior traction. Hemostasis is achieved by direct clamping or cautery. The bony edges are smoothed with a rongeur. Residual ethmoid mucosa is removed with ethmoid forceps, and a wide sphenoidotomy is opened with Kerrison rongeurs. The cavity is covered with Gelfoam for hemostasis. The medial canthal tendon is sutured to the periosteum of the nasal bones. The wound is closed using a meticulous layered closure. AEF, anterior ethmoidal foramen; OF, optic foramen; PEF, posterior ethmoidal foramen.

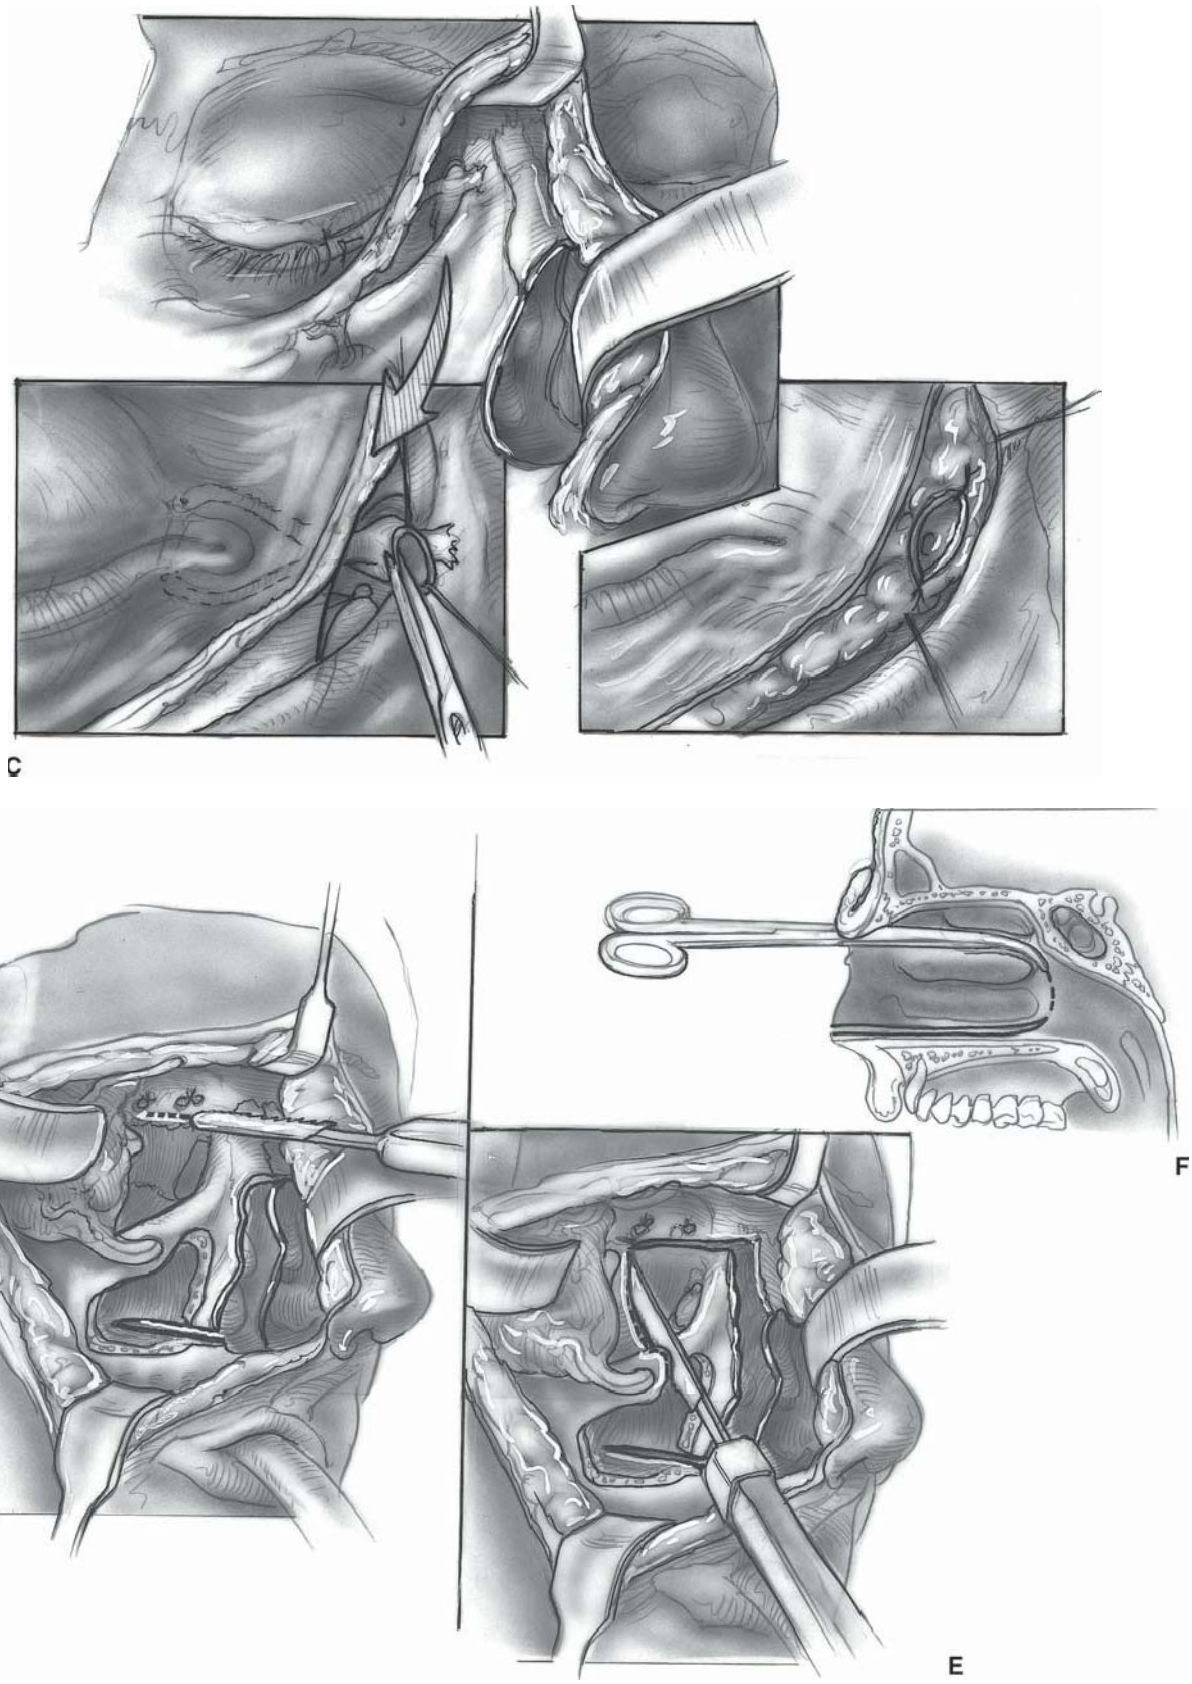

Figure 129.1 *(Continued)*

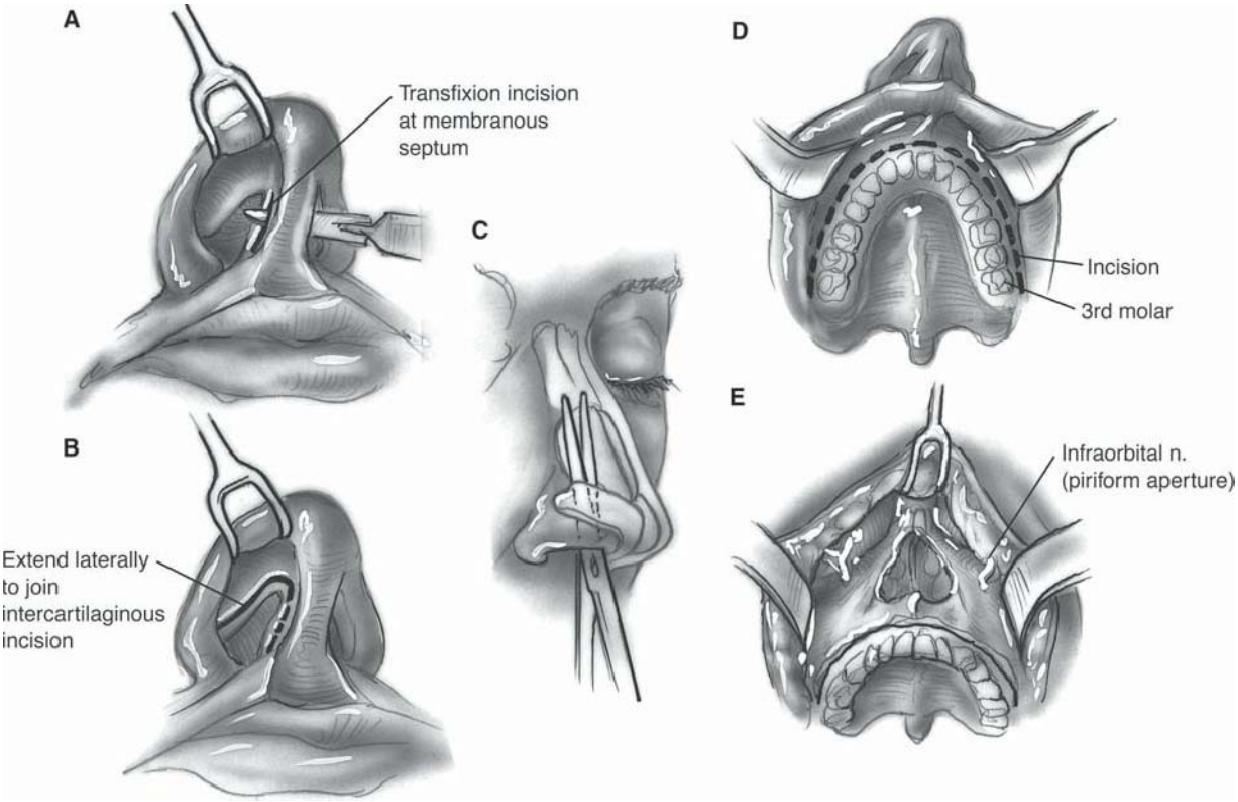

Figure 129.2 **A,B:** Mid-face degloving. A transfixion incision is performed at the membranous septum and is extended laterally to join a transcartilaginous incision. **C:** A gingivobuccal incision is performed, extending laterally from the midline to the maxillary tuberosities. **D:** In exposing the surgical area, tenotomy scissors are introduced through the transcartilaginous incisions to dissect the skin from the nasal skeleton. The dissection over the maxilla is carried out in a subperiosteal plane. This dissection joins the nasal degloving using sharp dissection over the piriform aperture attachments. The dissection is extended superiorly exposing the mid-face skeleton. **E:** The exposure is limited by the infraorbital neurovascular bundles. The osteotomies, removal of the specimen, reconstruction, and closure are performed as described for the lateral rhinotomy.

or the shifting of cause of failure to distant metastases spearheaded the use of systemic and even topical chemotherapy in multimodal therapy protocols. These reports, however, are very limited in nature, including small number of patients, and the studies are usually nonrandomized. Recent reports have shown a survival advantage for patients undergoing concurrent chemoradiation followed by definitive surgery. Samant et al. (22) in 2004 reported the use of high-dose intra-arterial cisplatin with concomitant radiation in patients with carcinoma of the paranasal sinuses. The overall and disease-free survival rates at 5 years were 53% (Table 129.9). Patients who represent a poor surgical risk and those who refuse surgery, should be considered for enrollment in protocols that include combinations of radiation and chemotherapy.

Treatment by Site of Origin

This section discusses the treatment of SCCA by site of origin. The management of other epithelial and mesenchymal malignancies was discussed in the pathology section.

Nasal Cavity

SCCA is the most common malignant tumor, constituting more than half of the tumors in this area. Tumors arising at the floor, lateral wall, and septum are all amenable to surgical excision. Tumors extending to the paranasal sinuses, those larger than 2 cm, and those associated with positive surgical margins have been associated with a poor prognosis for which postoperative radiation should be administered. Most series report a 5-year survival rate of above 60%.

Maxillary Antrum

The maxillary sinus is the most common site of origin for malignancies of the sinonasal tract. Early-stage SCCA may be treated by surgery or radiation. However, SCCA is usually diagnosed at advanced stages for which combination therapy seems more successful. Survival diminishes with the stage of the tumor, and complete surgical resection is required for success. The overall 5-year survival rate in large series range between 40% and 50%.

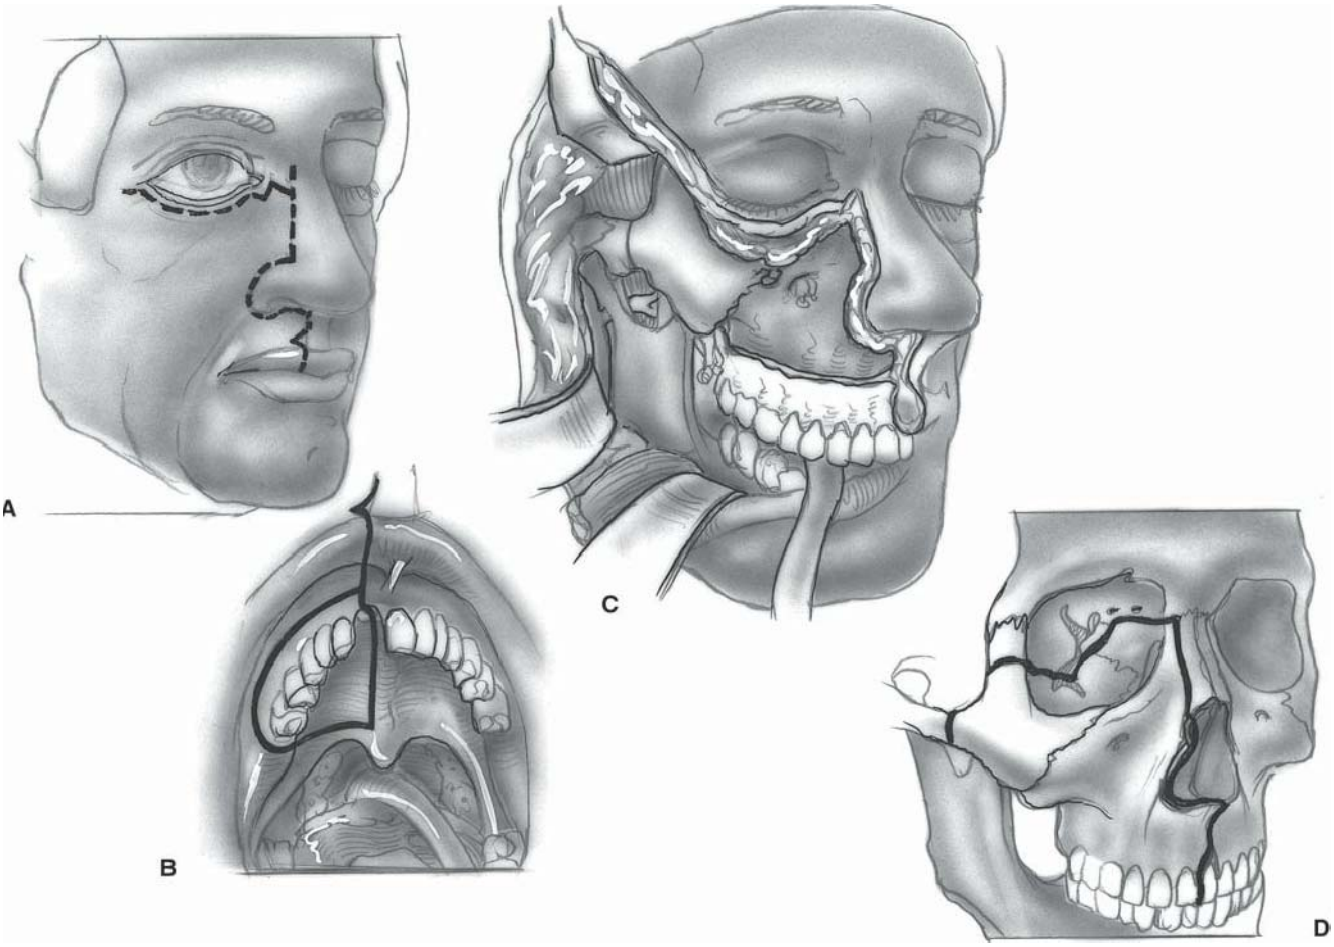

Figure 129.3 Total maxillectomy. A total maxillectomy with preservation of the orbit can be performed using incisions identical to lateral rhinotomy incisions with a lip-splitting extension. Alternatively, a lateral rhinotomy incision may be combined with an ipsilateral degloving approach. **A**: If increased exposure is necessary, the facial incisions may be modified. The superior incision begins at the lateral canthus and extends medially, passing 3 to 4 mm below the ciliary line. The eye is protected by a temporary tarsorrhaphy stitch. This incision may be substituted by a transconjunctival incision. The subciliary limb is joined to a lateral rhinotomy incision. The orbicularis oculi muscle is incised with an inferiorly directed slant, exposing the orbital septum. The gingivobuccal incision is extended laterally to the ipsilateral maxillary tuberosity. **B**: The soft palate is incised at the junction with the hard palate, and its attachments are sharply transected. The mucoperiosteum of the hard palate is incised following a paramedian line ipsilateral to the lesion. The paramedian strip of mucosa will be later imbricated over the bony edge of the hard palate to facilitate the fitting of a prosthesis. **C:** The orbital contents are dissected from the medial inferior and lateral walls, exposing the lacrimal sac, the anterior and posterior ethmoid arteries, and the infraorbital fissure. These are managed as described for a medial maxillectomy (Fig. 129.1). Osteotomies and removal of the specimen. **D:** The body and frontal process of the zygoma are divided with the saw. The maxilla is severed from the nasal bones with the saw, and the osteotomy is extended superiorly to the frontoethmoidal suture. A superior osteotomy is carried out posteriorly to a point 3 to 4 mm posterior to the posterior ethmoid artery. An osteotomy is performed connecting the lateral and medial wall osteotomies across the inferior orbital fissure. The hard palate is transected with a Gigli or sagittal saw. The maxilla is detached from the skull by tapping a chisel placed into the pterygomaxillary fissure in a posterosuperior direction. The superior attachments of the turbinates are sharply severed, as for a medial maxillectomy (Fig. 129.1). The specimen is removed by anteroinferior traction. Remnants of ethmoid sinus mucosa are removed in a piecemeal fashion. The coronoid process of the mandible is removed to avoid displacement of the prosthesis when opening the mandible. *(Continued)*

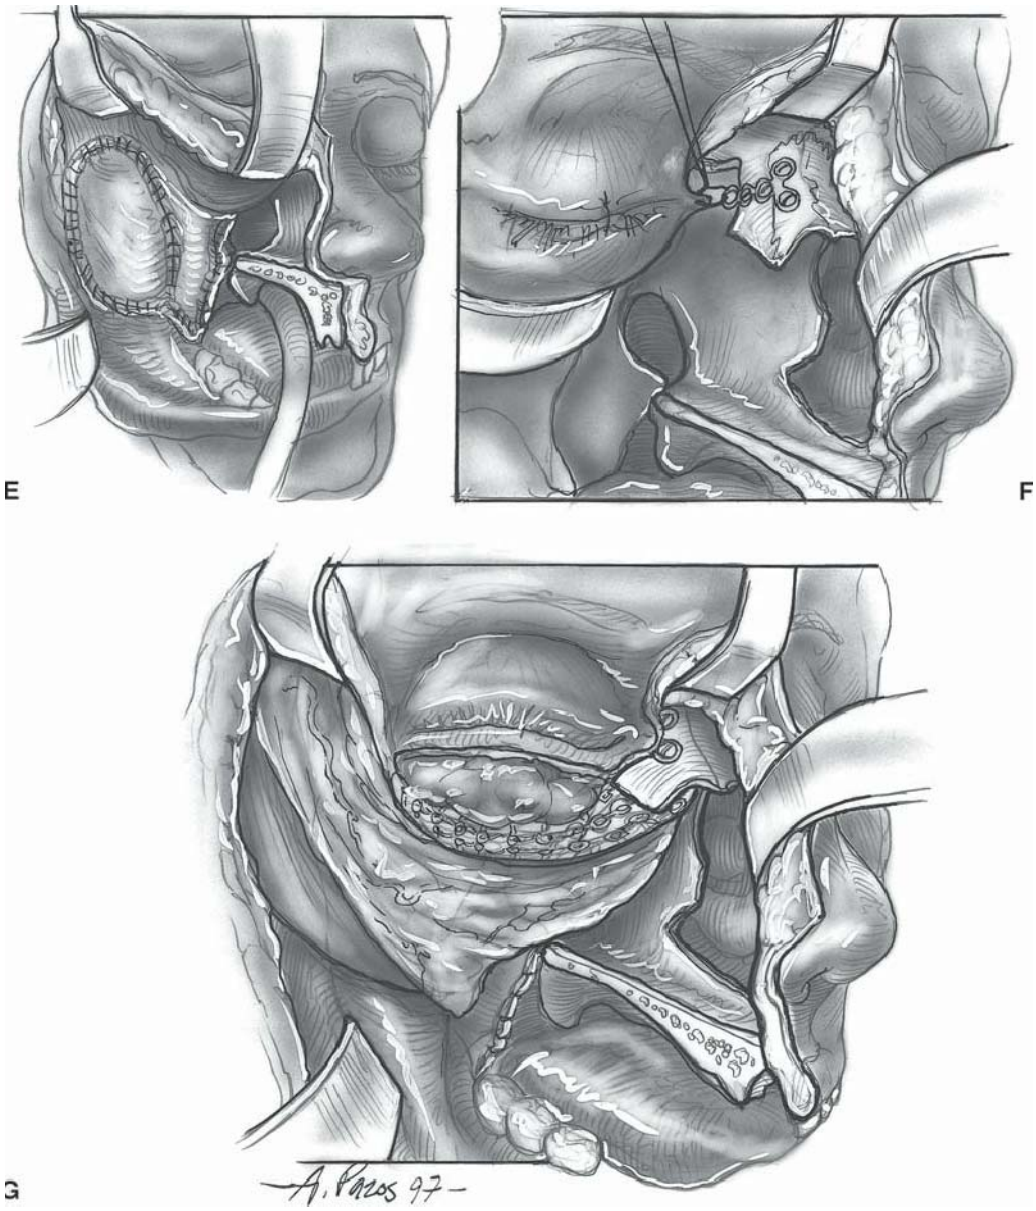

Figure 129.3 *(Continued)* **E:** The exposed facial and pterygoid muscles and periorbita are lined with a split-thickness skin graft that is 0.35 to 0.45 mm thick. The obturator or denture is wired to the remaining dentition or suspended from the zygomatic arch and piriform aperture or leg screwed to the remaining hard palate. **F:** A medial canthopexy, using a Y-shape titanium plate fixed to the nasal bones. A figure-8 nonabsorbable suture is used to medialize the medial canthal tendon. **G:** The floor and medial walls of the orbit are reconstructed with titanium mesh. This is then covered by a vertically split temporalis muscle flap. The anterior half is used for the reconstruction, and the posterior half is transposed to the anterior temporal fossa to obliterate the defect.

Ethmoid Sinus

Tumors originating in the ethmoid sinuses produce symptoms at early stages, leading to earlier diagnosis and better prognosis. SCCA continues to be the most common histologic diagnosis, but adenomatous carcinomas are more common than at other areas. Improved imaging techniques and the use of anterior craniofacial resection (see the discussion below on "Management of Advanced Tumors" of the base of skull) have improved the prognosis of previously unresectable tumors. Smaller tumor, T1 or T2, may be considered for endoscopic resection. Combined therapy with radiation is recommended for advanced stages, positive surgical margins, and recurrent tumors. The overall 5-year survival rate is 50% to 60%.

Sphenoid Sinus

Primary malignancies of the sphenoid sinus are extremely rare, making up less than 1% of malignant sinonasal tumors. En bloc surgical resection is technically difficult due to the anatomical relationships of the sphenoid

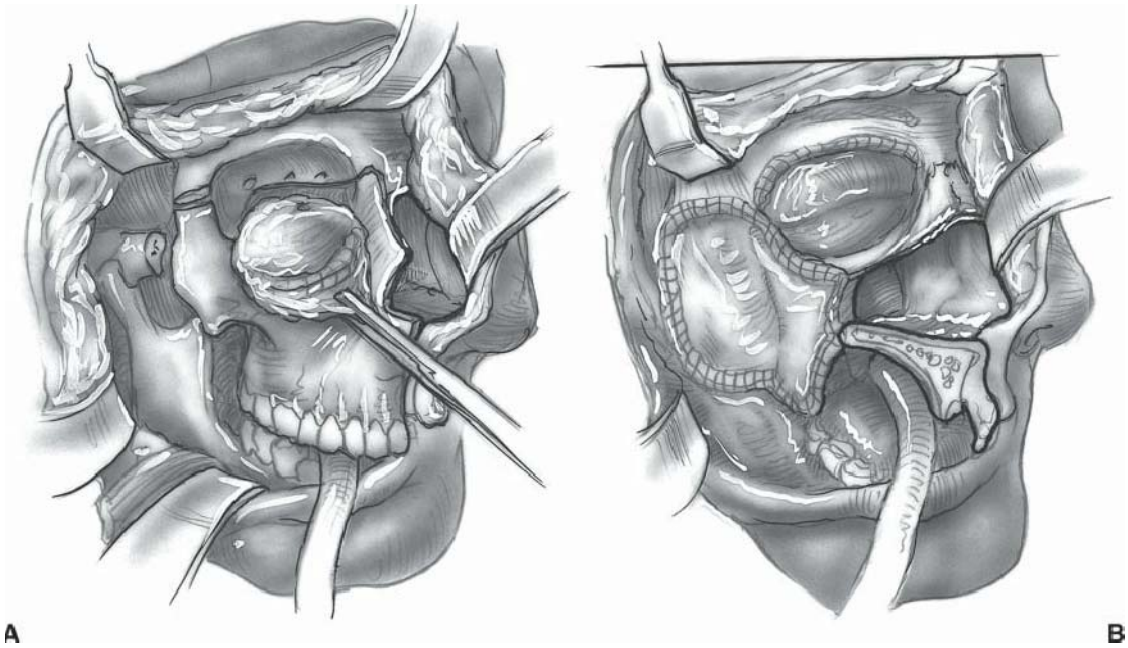

Figure 129.4 Orbital exenteration. **A**: Incisions for orbital exenteration include those described in Figure 129.3 and a supraciliary incision along the upper eyelid. These incisions allow the preservation of the lids, which can be used to line the remaining orbital cavity. If the eyelids are involved by the tumor, the incisions are modified to include their resection en bloc. The exposure proceeds as previously described (Fig. 129.3), omitting the dissection of the orbit from the inferior wall. The upper eyelid is retracted superiorly, and the periorbita is incised over the superior orbital rim. The orbit is dissected from the superior wall, identifying optic foramen and superior orbital fissure. These are infiltrated with lidocaine to block the autonomic innervation and prevent cardiac arrhythmias. The neural and vascular structures traveling through these foramina are transected after hemostasis with bipolar cautery or clamping. Inferior traction on the globe allows further visualization of the orbital floor and inferior orbital fissure. Lateral and medial wall osteotomies are connected as in Figure 129.3C. Other osteotomies are identical to Figure 129.3C. The roof of the orbit may be lined with a skin graft or left to granulate and mucosalize. Alternatively, the cavity may be filled with a temporalis muscle flap. It should be remembered that squamous epithelium tolerates trauma (e.g., prosthesis) better than mucosa. **B**: In exposing the surgical area, the facial flap is elevated subperiosteally. In the case of extension through the anterior wall of the antrum, the facial flap may be elevated in a subcutaneous plane, including the facial musculature in the specimen. The skin may also be resected en bloc, to address direct invasion by the tumor. The dissection is carried out along the lateral wall of the maxilla and the internal maxillary artery is identified at the pterygomaxillary fissure and clipped.

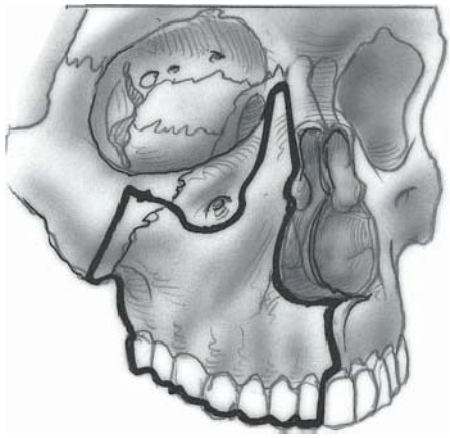

Figure 129.5 Inferior maxillectomy. Tumors confined to the floor of the antrum may be managed by partial maxillectomy. It differs from total maxillectomy on the preservation of the orbital floor and, in selected cases of the infraorbital nerve. Bilateral maxillectomy. The procedure is performed bilaterally as in Figure 129.4. The nasal septum may be sacrificed or preserved for suspension of the prosthesis or reconstructive flaps.

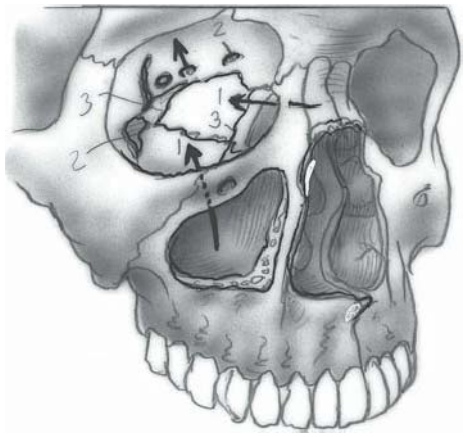

Figure 129.6 Pathways of invasion include (*1*) direct bony erosion (e.g., medial wall or floor), (*2*) perivascular or perineural invasion (e.g., infraorbital or ethmoidal neurovascular bundles), and (*3*) preformed pathways (e.g., infraorbital fissure, nasolacrimal duct).

TABLE 129.9 TREATMENT TUMORS OF THE SINONASAL TRACT

Modality	Indications
Surgery	Mainstay treatment
Radiation	Unresectable or lymphoreticular tumors, poor surgical candidates. Usually requires surgical drainage/debridement
Combination therapy	(+) margins, perineural, perivascular invasion (+) lymph nodes, recurrent tumor
Chemotherapy	Palliative role Clinical research (controlled protocols)

sinus. Gross total removal and postoperative radiation therapy is the treatment of choice for most of these tumors. Although the benefits of surgical debulking are debatable, at the very least it will provide a wide sphenoidotomy for drainage and debridement during radiation therapy. The overall prognosis at 5-year follow-up varies from 5% to 25%.

Frontal Sinus

Tumors arising in the frontal sinus, like sphenoidal tumors, are rare. The anatomical site, however, is more amenable to surgical resection. These tumors may be managed similarly to ethmoidal tumors.

MANAGEMENT OF ADVANCED TUMORS

Orbital Invasion

Sinonasal tract tumors may extend to the orbit by invasion or erosion of the bony walls, by perineural or perivascular invasion, or by following preformed pathways (Fig. 129.6). As great as 26% of patients with sinonasal malignancies have orbital invasion at the time of presentation (23). Patients with orbital invasion rapidly develop ocular symptoms, such as proptosis, diplopia, decreased visual acuity, diminished motility, chemosis, lid edema, and epiphora. CT scanning provides evidence of bony erosion, but it is not reliable in ascertaining invasion of the soft tissues. MRI better identifies soft tissue invasion, but invasion must be confirmed during surgery.

Bone erosion does not constitute an absolute indication for orbital exenteration (24). The prognosis of patients with invasion of the periorbita is dismal; therefore, palliation is a more realistic goal (Table 129.10). Adjunctive radiation therapy, before or after surgery, does not seem to yield an improved prognosis.

Resection of the medial and inferior orbital walls produces severe enophthalmos and hypophthalmos, which is aggravated by resection of the periorbita. Rigid reconstruction of the bony orbit using titanium mesh with or without calvarial bone grafts is recommended; which is then covered with local, regional, or microvascular flaps. To better restore the orbital anatomy and to prevent lagophthalmos, due to ectropion, the lateral canthus should be reattached to the corresponding anatomical site of insertion. Ectropion may still occur due to fibrosis. The medial wall is usually resected as part of the oncologic surgery, requiring that the medial canthus be reattached to a titanium plate, as illustrated in Figure 129.5.

Cervical Metastasis

The incidence of nodal metastasis on initial presentation varies from 3% to 16%. Nodal metastases at initial presentation indicate a grim prognosis. The low incidence of nodal metastasis from sinonasal malignancies does not justify the use of elective neck dissection or radiation. Recurrence in the form of cervical metastasis ranks second after local

TABLE 129.10 META-ANALYSIS OUTCOME: INVASION OF ORBIT (NED)

	Sparing	Exenteration	Significance
Som et al. (1971)	—	3/27 (11%)	
Perry et al. (1988)	1/2 (50%)	2/4 (50%)	
Xuexi et al. (1995)	8/23(35%)	24/88 (27%)	
Carrau et al. (1996)	5/9 (56%)	6/12 (50%)	
Total	**14/34 (41%)**	**35/131 (27%)**	**p > 0.05**

This table demonstrates the lack of statistically significant difference in the survival rate of those patients in whom the orbit was preserved when compared with patients whose orbit was exenterated. The trend toward worst survival in those patients who required exenteration illustrates the aggressiveness of tumors that invade the periorbita.
Adapted from Carrau RL, Segas J, Nuss DW, et al. Squamous cell carcinoma of the sinonasal tract invading the orbit. *Laryngoscope* 109:230–235, 1999.

recurrence as a cause for treatment failure. However, an isolated recurrence to cervical nodes is rare; usually it is accompanied by recurrent disease at the primary site.

Pterygopalatine Fossa

The incidence of PtPF invasion by sinonasal tract malignancies varies from 10% to 20%. The presence of tumor in this area is considered a risk factor for local recurrence. Despite the difficulty of an en bloc resection of this area, several authors have designed approaches with sound oncologic principles, obtaining variable results. Radical surgical resection in combination with radiation therapy, however, is advised for patients with PtPF invasion.

Infratemporal Fossa and Skull Base

The skull base may be involved by tumor by direct invasion and bone erosion, by preformed pathways (e.g., cribriform plate, superior orbital fissure, foramen lacerum), or by following neural or vascular structures (e.g., V2, V3). The overall incidence of skull base invasion by sinonasal malignancies appears to be about 15%. The anterior or anterolateral craniofacial resection is a well-established procedure for sinonasal tumors invading the anterior skull (Fig. 129.7). The anterior craniofacial resection may be extended laterally to join a temporal craniotomy to include the pterygoid plates, the PtPF, the infratemporal fossa, and the floor of the middle cranial fossa en bloc. Absolute contraindications for craniofacial resection are medical or nutritional problems that would eliminate the patient as a surgical candidate, presence of distant metastases, invasion of the prevertebral fascia, invasion of the cavernous sinus by a high-grade malignancy, involvement of the carotid artery in a high-risk patient (as determined by carotid flow studies), and bilateral invasion of the optic nerves or optic chiasm. Resection of these areas is associated with an unacceptable morbidity and mortality rate, offers no significant palliation, and does not appear to improve survival. Relative contraindications include invasion of the dura and intracranial involvement of neural structures. These situations have a poor prognosis, but in selected cases craniofacial resection may offer significant palliation or local control.

Improvements in the preoperative mapping of tumors with CT scan and MRI and the use of more reliable vascularized flaps for the reconstruction of the skull base have improved the surgical mortality and morbidity. However, the overall 5-year survival rate appears unchanged at 50% to 60%.

COMPLICATIONS

Surgical

The nasolacrimal duct is sacrificed during the performance of a maxillectomy, and subsequent stenosis of the lacrimal sac opening may lead to epiphora. A dacryocystorhinostomy at the time of definitive resection is an effective way to prevent this complication. Cannulation of the lacrimal canaliculi for 12 weeks is recommended.

Limitation of movement of the extraocular muscles may occur after trauma to the muscle or its motor innervation or upon entrapment in the craniofacial osteotomies. The latter complication should be managed by urgent surgical release. Limitations of extraocular muscle movement due to edema or neuromuscular contusion should be managed expectantly. Diplopia may be alleviated by alternating eye patching.

The optic nerve may be compressed during the mobilization of the specimen or during craniofacial resection. High-dose steroids and emergent surgical decompression are recommended.

Enophthalmos or hypophthalmos usually develop due to the loss of the inferior orbital and/or medial support. Reconstructive techniques were previously discussed.

Radiation Therapy

The incidence of radiation complications in patients with orbit preservation is close to 100% (Table 129.11). The field included in the radiation portals for sinonasal tract tumors usually includes the anterior and posterior orbital segment. When the orbit is involved by the tumor, irradiation of the entire eye is usually necessary. Complications of the anterior globe are common with full eye irradiation. A dry eye will decompensate rapidly, leading to severe keratitis, panophthalmitis, and blindness within 1 year. Enucleation is recommended for uncontrolled panophthalmitis or a painful eye.

If the anterior segment can be spared, patients will most likely experience delayed (3 to 5 years) loss of vision secondary to post-radiation retinopathy or optic neuropathy. Although the retina and optic nerve are radio resistant, their microvasculature is not. Chemotherapy, diabetes mellitus, and atherosclerosis may have an additive effect on radiation complications. The incidence of these complications is related to total dose and fractionation. The tolerance limit seems to be around 5,000 cGy with fractions of 200 cGy. Although they are rare below 3,500 cGy, their incidence is 50% to 65% with 6,000 to 7,000 cGy and above 85% with 8,000 cGy. Nevertheless, the degree of visual impairment cannot be accurately predicted and has been reported with doses considered within the safe limits. The incidence of unilateral blindness can range around 35%, while the incidence of bilateral blindness, although rarely reported, may be as high as 8% and is related to the irradiation of the contralateral posterior segment. Blindness is felt to be due to ipsilateral radiation retinopathy and contralateral optic neuropathy. However, the dose should not be compromised to diminish the complication rate if the attempted goal is cure. Conformal radiation therapy reduces the percentage of radiation received by normal tissue and may decrease the incidence of optic nerve and optic chiasm complications.

Wound Complications

Wound complications include bleeding, infection, and loss of reconstructive flaps or skin grafts (Table 129.12). Osteoradionecrosis can occur in up to 10% of patients. The most common site of osteoradionecrosis is the maxilla. Severe osteoradionecrosis can be secondary to poor dentitia or recently extracted dentitia. We recommend the routine extraction of poor dentitia with time to recover prior to postoperative radiation to avoid this complication.

Postoperative infection is rare. Cellulitis should be treated with antibiotics providing broad-spectrum coverage adjusted to the culture and sensitivity results. Venous retrograde seeding, or even direct spread in the presence of a CSF fistula can lead to meningitis or intracranial abscess. A CT scan followed by a lumbar puncture is indicated if

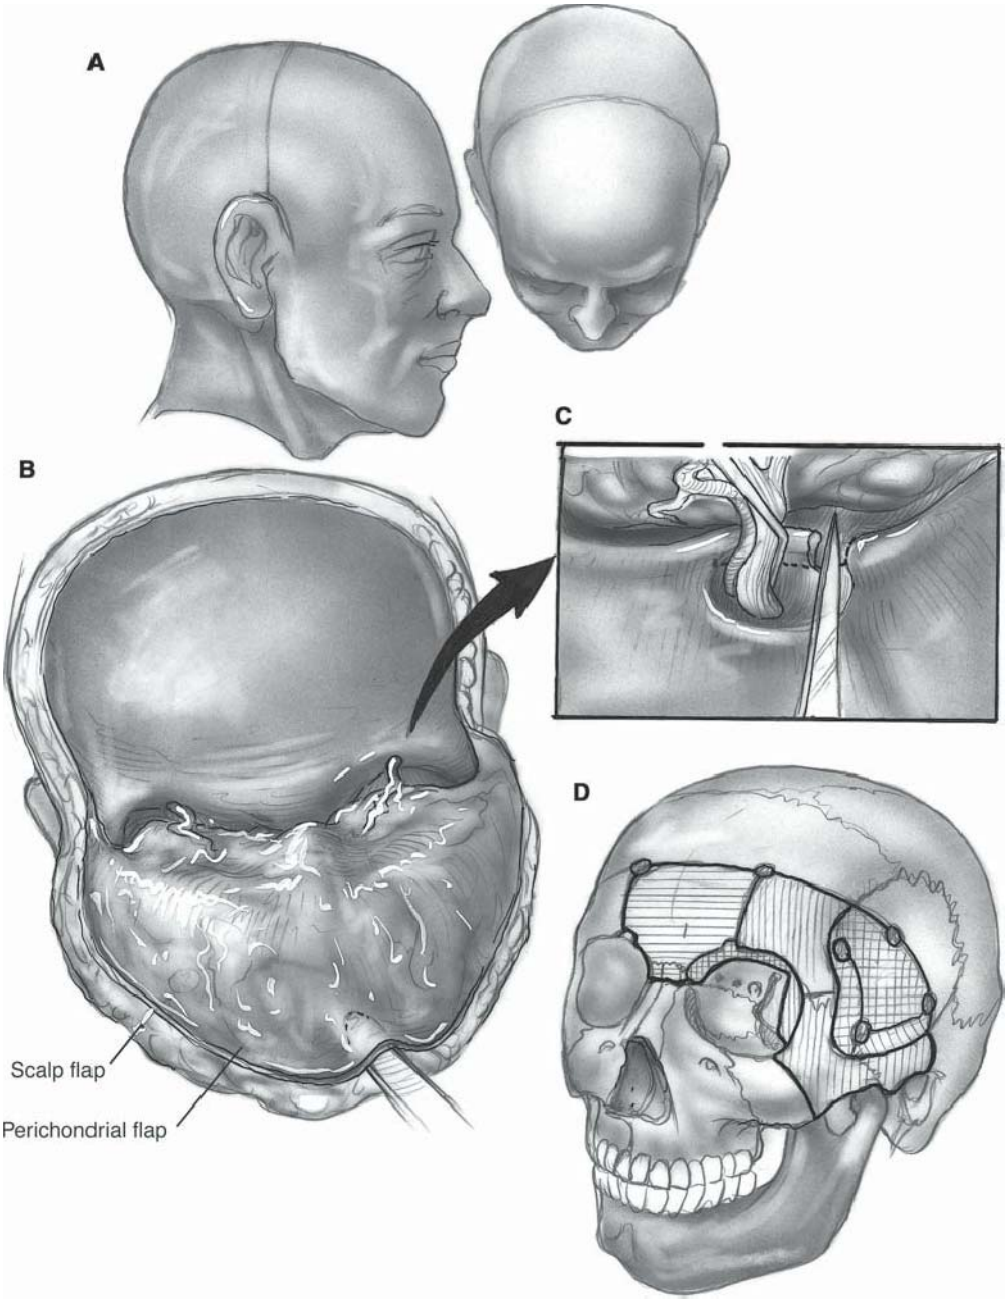

Figure 129.7 **A:** Bicoronal flap incision. **B:** The scalp flap is dissected anteriorly in a subperiosteal plane and laterally just above the superficial layer of the deep temporal fascia. Leaving the pericranial flap attached to the scalp flap prevents desiccation of the flap during the procedure. **C:** In order to expose the supraorbital rim, superior orbital cavity and nasal bones, the supraorbital neurovascular bundle is mobilized from its notch or foramen. **D:** Orbital, cranial, and zygomatic osteotomies are performed according to the required exposure. The tumor is resected en bloc with the anterior or middle fossa skull base. *(Continued)*

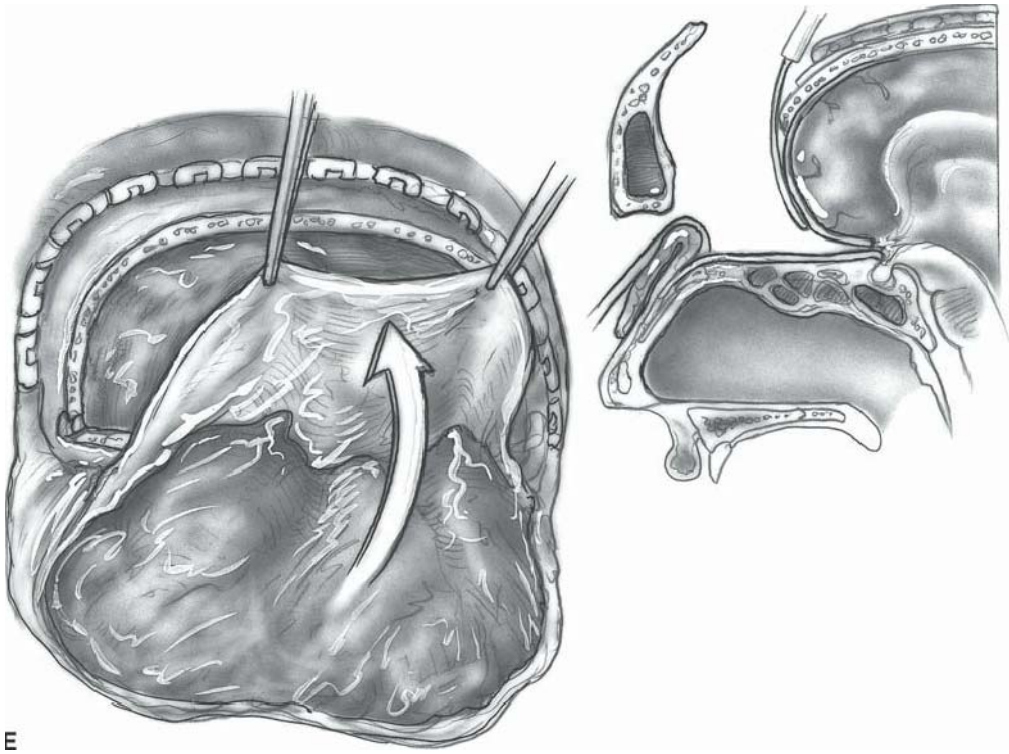

Figure 129.7 *(Continued)* **E:** A pericranial flap is elevated and placed under the dura of anterior lobe and over the remaining bone of the anterior fossa. The craniotomy and orbital bone grafts are replaced above the pericranial flap which separates the cranial cavity from the upper aerodigestive tract.

meningitis is suspected. Formation of crusts within the nasal cavity is a common problem and may lead to infection. Frequent irrigations with normal saline solution help with nasal hygiene.

The loss of a reconstructive flap is accompanied by necrosis and overgrowth of bacteria and is best treated by debridement and aggressive local care. A secondary reconstruction must be postponed until the defect is free of infection. However, flaps providing coverage to vital areas (e.g., carotid artery, brain) must be replaced by another vascularized flap as soon as possible. Loss of minor areas of a skin graft is usually of no consequence, since secondary epithelialization occurs rapidly. Loss of the entire skin graft, however, may lead to scarring and contraction of the cavity, healing by mucosalization, and problems in fitting a prosthesis. Treatment of local infection and debridement of necrotic tissue, followed by regrafting with internal and external splinting of the skin graft may remedy this problem.

TABLE 129.11 EFFECTS OF RADIATION ON THE EYE

Tissue	Effect	Latency	Dose
Lacrimal gland	Atrophy	>6 mo	>5,000 cGy/5–6 wk
Conjunctiva	Hyperemia	1–3 wk	≥5.000 cGy/5 wk
	May lead to secondary infection		
Cornea	Edema	1–3 wk	4,000–5,000 cGy/2–3 wk
	Chronic ulceration	Several months	>6,000 cGy/5–6 wk
	Perforation	4–12 mo	>6,000 cGy/5–6 wk
Retina	Edema	Several weeks	2,000–3,500 cGy/3–4 wk
	Retinopathy	>1 y	5,000–6,000 cGy/5–6 wk
Lens	Cataract	1–20 y	≥200 cGy

TABLE 129.12 COMPLICATIONS SINONASAL TRACT TUMORS

Problem	Treatment
Orbital	
Surgical	
Epiphora	DCR
Diplopia	Observe, release EOM if entrapped
Blindness	Perform optic nerve or orbital decompression
Enophthalmos/ hypophthalmos	Support globe with bone grafts and/or titanium mesh
Radiation	
Wound	
Bleeding	Packing, arterial ligation, or embolization
Infection	Antibiotics/debridement
Loss of reconstructive flaps or skin grafts	Debridement
Skull base	
CSF leak	Observation, bed rest Reconstructive flap for persistent leak
Meningitis	Antibiotics, correct CSF leak
Pneumocephalus	Aspiration if at tension
Osteomyelitis	Antibiotics, debridement, HBO
Other	
Serous otitis media	Ventilation tube (rule out CSF leak)

Skull Base Complications

Skull base complications include CSF leak, meningitis, intracranial abscess, tension pneumocephalus, and osteomyelitis. These complications are most commonly the result of technical errors (e.g., loss of a reconstructive flap) and are surprisingly uncommon, considering that skull base resection involves exposure of the cranial cavity to aerodigestive tract flora. Treatment includes empiric intravenous antibiotics with broad spectrum coverage, including the skin and aerodigestive flora. The antibiotics are later adjusted to the culture and sensitivity results. Further contamination or exposure of the intracranial contents to the sinonasal tract should be curtailed by the use of vascularized flaps. Free bone grafts that become infected during the early postoperative period should be removed. Late osteomyelitis or osteoradionecrosis may be managed with antibiotics and debridement limited to the affected bone. Hyperbaric oxygen treatment may be beneficial in patients with osteoradionecrosis. Intracranial abscess requires open drainage and intravenous antibiotics.

Tension pneumocephalus is treated by percutaneous aspiration and diversion of the nasal airway. The latter may be accomplished with the use of an endotracheal tube, nasal trumpets, or a tracheotomy.

EMERGENCIES ASSOCIATED WITH SINONASAL TUMORS

Bleeding

Friable or vascular tumors may lead to profuse bleeding when traumatized (e.g., biopsy), or bleeding may occur spontaneously after desiccation and breakdown of the blood vessels in the tumor (Table 129.13). Mild to moderate bleeding is managed using the principles of treatment for anterior and posterior epistaxis. Cauterization or packing is recommended. In the case of a massive tumor that completely occludes the nasal passages, angiography and embolization should be considered. This technique is also useful in vascular tumors, providing prompt hemostasis and facilitating surgical removal. If circumstances preclude the use of this technique, a transantral ligation of the internal maxillary artery and transorbital ligation of the ethmoidal arteries may control the bleeding. Ligation of the external carotid artery, although not as effective as internal maxillary artery ligation, may be necessary if the transantral approach is impossible. One should remember, however, that ligation of the external carotid artery will eliminate the possibility of embolization. A combination of these techniques may be required to prevent exsanguination. Uncontrollable hemostasis from a known malignancy may require emergency maxillectomy.

Vision Impairment

Sinonasal tumors may lead to blindness due to compression or stretching of the optic nerve, its arterial supply, or its venous drainage. Emergent treatment of the tumor with radiation or surgery may be necessary to prevent blindness, although it will be a moot point if the eye is going to be ultimately sacrificed.

Infection

Tumors of the sinonasal tract may obstruct sinus drainage and lead to acute bacterial sinusitis and possible orbital and intracranial complications. Secondary sinus infections must be treated with antibiotics providing broad aerobic

TABLE 129.13 EMERGENCIES SINONASAL TRACT TUMORS

Problem	Treatment
Bleeding	Cauterization/packing Arterial ligation/embolization Emergency extirpative surgery
Visual impairment	Decompression of orbit or optic nerve Radiation for lymphoreticular tumors
Infection	Antibiotics and drainage/debridement
CSF leak/ pneumocephalus	Definitive surgery, reconstructive flap

and anaerobic coverage. Surgical drainage by endoscopic or open technique is usually required.

CSF Leak

CSF leak may occur after destruction of the skull base and disruption of the dura mater (e.g., cribriform plate). CSF leaks are less likely to resolve spontaneously under these circumstances and therefore should be managed by prompt craniofacial resection, dural grafting, and a pericranial flap. Patients must be kept on bed rest while awaiting the operation. The use of prophylactic antibiotics is controversial. They may seem indicated in the presence of a necrotic tumor, but prolonged treatment may lead to colonization with resistant flora that will be more difficult to eradicate in case of meningitis.

HIGHLIGHTS

- The most common clinical presentation of sinonasal tumors includes symptoms that are undistinguishable from inflammatory sinus disease, namely, nasal airway obstruction, pain, and epistaxis. Abnormal V1 and/or V2 sensation strongly suggest the possibility of a tumor.
- CT or MRI is an essential component of evaluation, establishing the extent and vascularity of the tumor and its relationship to neurovascular structures.
- An understanding of the variable natural history of tumors of the sinonasal tract is crucial to patient counseling and treatment planning. A wide variety of histologies may be encountered, although SCCA is most common.
- Rehabilitation after surgical resection may be accomplished by the use of prosthodontics or reconstructive flaps.
- Radiation is a common adjuvant to surgery for patients with SCCA. The response of sinonasal tract tumors to radiation therapy varies with the stage and histology of the tumor.
- Combined intra-arterial cisplatin chemotherapy and radiation therapy before surgical resection offers a survival advantage in advanced SCCA of the paranasal sinuses.
- Bony erosion of the orbital walls does not constitute an indication for orbital exenteration.
- Patients with tumor involvement of the skull base, either in the infratemporal fossa or at the fovea ethmoidalis and cribriform plate, should be considered for craniofacial resection.
- Complications, such as CSF leak, meningitis, intracranial abscess, and tension pneumocephalus, although uncommon, are potentially devastating and need to be addressed in an emergent fashion.

Orbital Tumors 130

Neda Esmaili *Michael E. Stadler* *Adam M. Zanation*

INTRODUCTION

In this chapter, we provide the reader with a cursory overview of orbital pathology as it may relate to the practicing Otolaryngologist. This chapter outlines the most common categories of orbital tumors and other common orbital pathologic processes. We discuss various classifications of the pathologies presented, as well as the most common associated signs/symptoms, radiographic findings, and recommended workup and treatment for these lesions. We only briefly discuss secondary lesions affecting the orbit, as these are covered in greater depth in the rhinology and skull base sections of this text. We also specifically discuss the surgical approaches that can be utilized in addressing these pathologic processes.

Classification

Orbital tumors are rare, yet constitute a wide range of lesions. They are often classified based on their origin. Primary orbital tumors originate within the bony orbit, while secondary tumors extend into the orbit from the paranasal sinuses, skin, and/or intracranial compartment. Primary tumors can further be classified based on their anatomic location, with intraconal lesions being confined within the extraocular muscle cone, and extraconal lesions occurring outside of these muscles. Lastly, metastatic orbital tumors originate from distant tissues and spread to the orbit through lymphovascular and/or hematogenous spread.

Primary orbital tumors can originate from the tissues that are present within the orbit, including vascular, lymphoid, nervous, and mesenchymal structures. Lacrimal gland tumors of epithelial and/or lymphoid origin can also present as orbital tumors. In a 40-year study of orbital tumors at the Mayo Clinic, Henderson (1) found that the five most common primary tumors of the orbit were hemangioma, non-Hodgkin lymphoma, inflammatory tumors, meningioma, and optic nerve glioma. Similarly, in a study of 1,264 patients from the Wills Eye Institute, Shields et al. (2) showed again that there is a very wide range of pathologic types of orbital tumors and that the five most common categories of orbital lesions in their series were vasculogenic (17%), inflammatory (11%), lymphoid/leukemic (10%), lacrimal gland (9%), and optic nerve or meningeal lesions (8%).

In another large series out of MD Anderson, Shinder et al. (3) found that the five most common lesions were lymphoproliferative (25%), lacrimal (10%), inflammatory (8%), vascular (7%), and mesenchymal (7%). In a meta-analysis of five large series, Wilson and Grossniklaus (4) evaluated a total of 4,563 orbital lesions and found that the most common primary orbital tumors were meningiomas, cavernous hemangiomas, and lymphomas. While some series have shown that secondary orbital tumors can account for 33% to 45% of all orbital neoplasms (1), more recent series have found that only 11% to 26% of all orbital tumors are secondary in nature (2,3). This could be due to improved recognition and treatment of the primary processes that most often cause secondary lesions of the orbit, mainly paranasal sinus mucoceles, squamous cell carcinomas (SCCs) of the paranasal sinuses, meningiomas of the cranial base, vascular malformations, and basal cell carcinomas (BCCs) of the skin. Metastatic disease to the orbit has been found to account for anywhere between 2% and 10% of orbital tumors (1–3). (See Tables 130.1 and 130.2 for the most common orbital tumor percentages and the most common metastatic lesions.)

Interestingly, Shields et al. found that malignant lesions comprised 36% of the tumors in their series, while Shinder et al. found that 63% of their tumors were malignant (2,3). Obviously, the type of high volume referral centers where series such as these are put together largely determines the types and distribution of lesions seen, treated, and reported. Not surprisingly, the rates of malignant lesions,

TABLE 130.1 OVERALL PREVALENCE OF ORBITAL LESIONS

Type of Lesion	% of Orbital Tumors	Type of Lesion	% of Orbital Tumors
Metastatic:	**5%–8%**	**Cysts:**	**6%–12%**
Breast	2%–4%	Dermoid	2%–7%
Lung	<1%	Epithelial inclusion cysts	1%
Prostate	<1%	**Mesenchymal:**	**6%–11%**
Neural:	**9%–17%**	Rhabdomyosarcoma	2%–3%
Glioma	1%–4%	Fibrous dysplasia	<1%

as a percentage of all orbital tumors, increase significantly as age increases. Most pediatric tumors are benign, with most series reporting between 10% and 30% of all pediatric orbital tumors being malignant (1,2). However, some cancer centers treat a larger proportion of pediatric malignant orbital tumors, with the MD Anderson group reporting 68% of their pediatric tumors being malignant (3).

Presentation

The volume of the orbit is roughly 30 mL, and therefore, mass occupying lesions have scant room for expansion before signs and symptoms arise. Proptosis is the cardinal clinical sign of an orbital space-occupying lesion. Direction and laterality of the proptosis are important factors that aid in the identification of the location, origin, and ultimate diagnosis of the lesion. Axial proptosis often occurs with lesions that exist within the intraconal space, while nonaxial proptosis tends to occur in tumors occupying an extraconal location. The timing of the proptosis also can help differentiate various processes, with acute proptosis developing over hours to days favoring inflammatory and infectious processes. Malignant tumors tend to present in a subacute time frame, while benign tumors tend to have a more indolent progression of symptoms. Age of onset can also help narrow the differential in consideration.

Diplopia and ocular motility disturbances are also common findings in patients with orbital tumors. Lesions may cause displacement of the globe with resultant diplopia. Similarly, infiltrative processes may affect the extraocular muscles and associated nerves, causing gaze restriction and diplopia. Deterioration of a patient's visual acuity, including the rate and extent, is also of importance when distinguishing between various etiologies. For example, optic nerve gliomas or meningiomas may cause significant visual acuity changes, while secondary processes affecting the nerve often cause mild symptoms related to compressive effects. Orbital pain is most often a symptom of inflammatory and/or infectious processes. However, aggressive malignant tumors and metastatic lesions can also present in this manner. Slower growing lesions more often cause a sensation of pressure rather than pain. Pupillary changes can be found when tumors invade or compress the sympathetic or parasympathetic fibers supplying the iris dilator and

TABLE 130.2 COMMON METASTATIC ORBITAL LESIONS

- Breast (adenocarcinoma): 29%–59%
- Lung (bronchogenic carcinoma): 8%–15%
- Prostate: 3%–10%
- Cutaneous melanoma: 5%–8%
- Renal cell carcinoma: 5%–7%

- Gastrointestinal: 2%–5%
- Sarcomas: 1%–2%
- Thyroid carcinoma: <1%

pupillary sphincter. Finally, while not part of the practicing otolaryngologist's clinical exam, fundus changes within the globe are common ophthalmologic exam findings and may include optic atrophy or edema, optociliary shunt vessels, retinal venous dilation, and choroidal folds (5).

Anatomy of the Orbit

Detailed knowledge of the anatomy of the orbit and periorbital structures is critical in developing effective surgical technique and minimizing surgical complications while operating in the tight orbital space. The following is a brief overview of orbital and eyelid anatomy.

The bony orbit (Fig. 130.1) is composed of the frontal, zygomatic, sphenoid, maxilla, lacrimal, palatine, and ethmoid bones. The adult orbit has a volume of approximately 30 mL and measures 35 mm in maximal height, 40 mm in width, and 45 mm in medial wall length. The orbital walls lie adjacent to all four paranasal sinuses: the orbital apex is located just anterolateral to the sphenoid sinus, the medial lamina papyracea borders the ethmoid sinuses, the orbital floor is adjacent to the maxillary sinus, and the roof of the orbit often forms the floor of the frontal sinus. The orbit is also intimately associated with the skull base, as the orbital roof borders the anterior cranial fossa and the orbital apex borders the middle cranial fossa. The orbit communicates with the middle cranial fossa via the superior orbital fissure and optic canal. It is contiguous with the pterygopalatine and infratemporal fossae via the inferior orbital fissure (6).

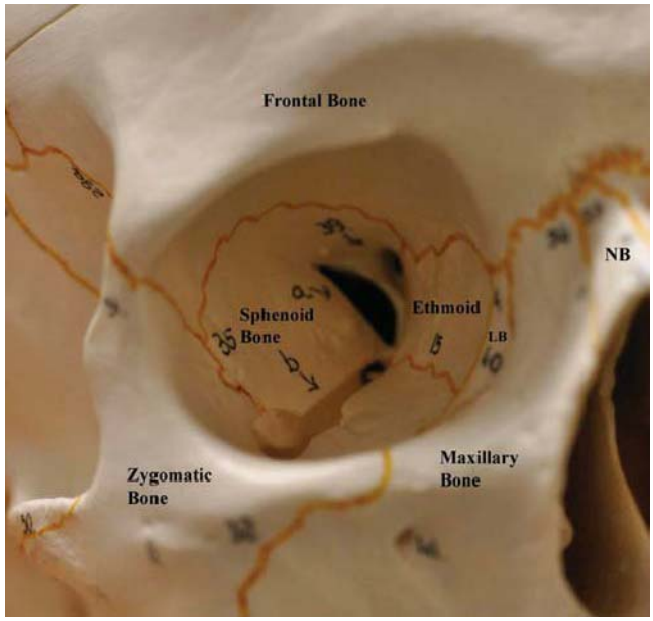

Figure 130.1 Orbital anatomy. Seven bones articulate to form the orbital vault. Six are listed; the palatine bone is not shown. LB is the lacrimal bone, and NB is the nasal bone (which is listed but does not form the orbit). The *arrow* in the apex of the orbit is pointing to the Optic Canal and "a" is the Superior Orbital Fissure and "b" is the Inferior Orbital Fissure.

The majority of the nerves of the orbit pass through the sphenoid bone. The superior orbital fissure lies between the greater and lesser wings of the sphenoid bone, with the optic canal located in the lesser wing. The annulus of Zinn, a tendinous ring at the orbital apex from which the rectus muscles arise, encircles the optic canal and separates the superior orbital fissure into two compartments at the origin of the lateral rectus muscle. The superolateral portion transmits the lacrimal, frontal and trochlear nerves, as well as the superior ophthalmic vein and occasionally the orbital branch of the middle meningeal artery. The medial portion outside of the optic canal transmits the upper and lower divisions of the oculomotor nerve (CN III), the nasociliary branch of CN V, and the abducens nerve (CN VI).

The intraorbital optic nerve is approximately 30 mm in length and passes through the optic canal along with the ophthalmic artery and sympathetic nerve fibers. The dura mater surrounding the nerve is continuous with the periosteum of the optic canal. The extraocular muscles are responsible for the movement of the eye and eyelid. All four rectus muscles (superior, medial, inferior, and lateral recti) originate posteriorly in the annulus of Zinn. The superior oblique muscle arises outside of the annulus, just superomedial to the optic canal, and courses anteriorly to the cartilaginous trochlea prior to inserting on the globe. The levator muscle originates superior to the annulus on the lesser sphenoid wing. The inferior oblique arises in the anterior orbital floor just inferolateral to the lacrimal sac fossa and travels posterolaterally to insert onto the globe (7).

Orbital fat lies posterior to the orbital septum as intraconal and extraconal fat. The fat pads of the eyelids are anterior extensions of the extraconal fat and lie anterior to the levator aponeurosis in the upper lid and capsulopalpebral fascia in the lower lid. In the upper lid, there is a medial and central fat pad; the lacrimal gland lies laterally and may be mistaken for a third fat pad. In the lower lid, there is a medial, central, and lateral fat pad.

The arterial supply of the orbit arises primarily from the internal carotid artery, which gives rise to the ophthalmic artery. The ophthalmic artery lies inferolateral to the optic nerve in the optic canal, and in the majority of patients, it passes over the nerve to reach the medial orbit. As it courses anteriorly through the orbit, it gives off several branches including those to the optic nerve and retina (central retinal artery, posterior ciliary arteries), extraocular muscles, and lacrimal gland. Anteriorly it forms anastomoses with the external carotid arterial system to provide a rich blood supply to the eyelids and face. Venous blood is drained primarily by the superior ophthalmic vein, which originates in the superomedial orbit and travels posterolaterally to enter the cavernous sinus via the superior orbital fissure.

The eyelids provide a barrier for the globe against desiccation and trauma and thus play an important role in the preservation of vision. Eyelid skin is the thinnest skin of the body and lacks subcutaneous fat. Beneath the skin lies the orbicularis oculi muscle, which is responsible for

voluntary and involuntary closure of the eyelids. The orbital septum separates the eyelid anatomy from the deeper orbital contents and originates from the periosteum along the orbital rim. The orbital fat pads mentioned earlier are located posterior to the orbital septum and anterior to the upper and lower lid retractors. The main retractor of the upper lid is the levator palpebrae, which becomes the levator aponeurosis after it passes through Whitnall suspensory ligament. The capsulopebral fascia and Lockwood ligament are the analogous retractor and suspensory ligament of the lower lid. The conjunctiva is a mucous membrane that constitutes the posterior-most layer of the eyelids. The canthal tendons, which help maintain the horizontal stability of the eyelids, are fibrous bands that originate from the bony orbital walls and fuse with the upper and lower tarsal plates; the medial canthal tendon arises from the anterior and posterior lacrimal crests medially and the lateral canthal tendon originates at the lateral orbital tubercle (8).

VASCULAR TUMORS

Vascular tumors are among the most common orbital lesions in children and adults, and the majority are benign. In a recent large, 30-year series of 1,264 patients referred to an ocular oncology service for suspected orbital neoplasm, vascular tumors were the most common type of orbital lesion encountered, with an overall incidence of 17%. Of the vascular tumors, cavernous hemangioma, lymphangioma, and capillary hemangioma were the most common (2).

Capillary Hemangioma

Capillary hemangiomas are benign hamartomatous proliferations of endothelial cells. They represent 3% of all orbital lesions and are the most common orbital vascular tumors in infants (2). Lesions appear shortly after birth and rapidly enlarge for the first 6 to 12 months of life. Spontaneous involution often occurs, with 75% of lesions resolving over the following 4 years (7).

Periocular lesions occur most frequently in the superomedial quadrant of the orbit and medial upper lid, and are commonly associated with hemangiomas in other regions of the body. Periocular hemangiomas may be superficial or deep. Superficial lesions involve the skin, producing a reddish discoloration and dimpled texture known classically as the "strawberry nevus." Deeper lesions produce a bluish discoloration and may not involve the overlying skin. They are largely extraconal in location, and may even extend intracranially through the optic canal or superior orbital fissure (9).

These lesions may cause significant morbidity due to interference with visual, orbital, and facial development. Eyelid lesions may cause strabismus, anisometropia, ptosis, and subsequent amblyopia (decreased vision due to incomplete development of the visual system). Orbital lesions may lead to proptosis, globe displacement, strabismus, amblyopia, optic atrophy, and bony deformities of the orbit and face.

Diagnosis is usually made based on clinical features and orbital imaging. Since capillary hemangiomas are nonencapsulated, computed tomography (CT) shows a lobulated and diffusely infiltrating mass. Enhancement with contrast is seen on both CT and magnetic resonance imaging (MRI). MRI may demonstrate fine intralesional vascular channels separated by thin septa, as well as high blood flow from fine feeder vessels (9). Expansion of the bony walls due to mass effect can occur. Biopsy may be required in atypical cases in which malignancy is suspected. Histologically, lesions are composed of endothelial sheets that develop into capillary-caliber vascular channels.

Treatment is indicated for lesions affecting visual or orbital development. Options include topical, oral, or intralesional corticosteroid therapy. Surgical debulking can be performed for anteriorly located and well-circumscribed lesions, although complete surgical removal is generally not possible. Other treatment modalities such as interferon therapy, radiation, and pulsed-dye laser carry serious side effects and are thus reserved for life-threatening or refractory cases (7). Most recently, nonselective beta-blockers have demonstrated rapid and dramatic success in decreasing the size and symptoms of cutaneous and orbital lesions (10,11).

Cavernous Hemangioma

Cavernous hemangioma is the most common benign tumor of the orbit in adults, representing 6% of all orbital lesions (2). It occurs most frequently in middle-aged women. These lesions tend to enlarge slowly and do not involute. Patients typically present with slowly progressive, painless proptosis, although abrupt proptosis during puberty or pregnancy can occur. The lesions are often discovered incidentally on neuroimaging for symptoms such as headache. Cavernous hemangiomas tend to be isolated lesions and are often located in the lateral retrobulbar intraconal space. They may cause vision loss if located at the orbital apex, which may occur in up to 10% of cases (9).

Diagnosis can usually be made by characteristic features on orbital imaging (Fig. 130.2). CT shows a well-encapsulated, round to ovoid, hyperattenuating mass. Microcalcifications and bony remodeling may occasionally be seen (9). MRI demonstrates small intralesional vascular channels with low arterial blood flow (Fig. 130.2). Histologically, these lesions consist of large, blood-filled vascular channels lined with flattened endothelium and separated by fibrous septa containing smooth muscle. Surgical excision of the tumor and its pseudocapsule is performed if vision is threatened or proptosis results in unacceptable cosmesis. Recurrences are rare even with incomplete resection.

Lymphangioma

Lymphangiomas are benign vascular malformations that account for 4% of all orbital lesions (2). Lesions may involve the conjunctiva, eyelids, and orbit. Their origin

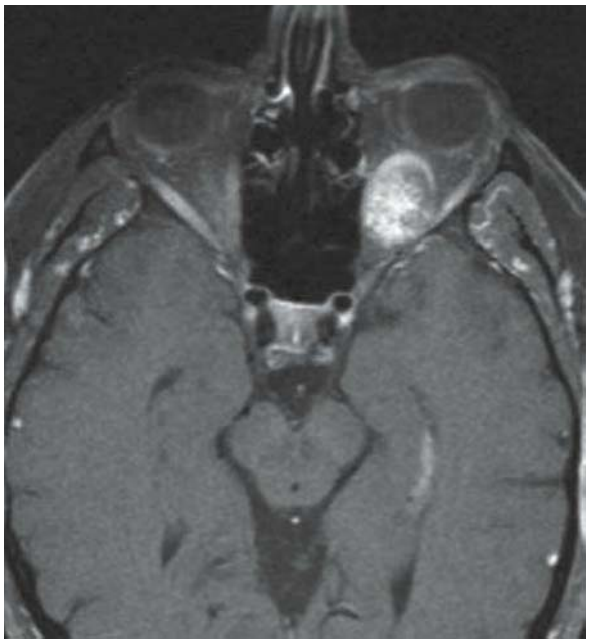

Figure 130.2 Orbital cavernous hemangioma. T1 with contrast axial MRI showing a well-circumscribed enhancing orbital lesion.

remains unclear, but they are thought to arise from embryonal elements capable of differentiating into both venous and lymphatic tissue. Histologically, these lesions are composed of endothelial-lined vascular spaces filled with lymphatic or proteinaceous fluid and a fibrotic interstitium containing follicles of lymphoid tissue.

Patients typically become symptomatic in the first decade of life. Lesions of the orbit and eyelid may present as a soft mass with bluish discoloration. Sudden proptosis may occur due to intralesional hemorrhage from fragile interstitial capillaries. This may result in significant globe displacement, strabismus, cosmetic deformity, or vision loss secondary to amblyopia, compressive optic neuropathy, or corneal exposure. These hemorrhages may occur spontaneously or after minor trauma. Hemorrhage can also occur during an upper respiratory tract infection, presumably due to the activity of lymphoid tissue in the lesions. "Chocolate cysts" refer to the subsequent collection of loculated blood breakdown products after hemorrhage (9).

MRI is the preferred imaging modality, and demonstrates characteristic findings of multiloculated cystic lesions. The presence of fluid–fluid levels due to intralesional hemorrhages is virtually pathognomonic. The lesions are isolated from the systemic circulation and thus do not enhance with IV contrast. This feature aids in distinguishing lymphangiomas from other vascular malformations such as orbital varices and arteriovenous malformations, which are distinct clinical entities requiring different management (12).

Management of lymphangiomas is challenging given their poorly circumscribed and highly infiltrative nature. As it is common for the blood-filled cysts to spontaneous resorb, observation is recommended unless vision is threatened by optic nerve compression or exposure keratopathy. When surgical intervention is required, the cysts may be decompressed with needle aspiration or via an open surgical approach. Surgical excision may be performed on more circumscribed lesions; however, complete surgical resection is usually not possible. Recurrent hemorrhages are common, and multiple partial excisions may be required. In cases of highly infiltrative lesions with a high likelihood of a difficult and incomplete surgical excision, orbital decompression to address proptosis and globe displacement may instead be performed (7).

Multiple adjuncts to surgical resection are available and include bipolar cautery and laser ablation with carbon dioxide and Nd:YAG. These techniques may provide intraoperative hemostasis and induce shrinkage of unresectable portions of the lesion. Intralesional injections of sclerosing agents and steroids have also been utilized. Recent reports have documented benefits of intralesional fibrin glue injection, which helps delineate the walls of the lesion for more complete surgical resection and may inhibit recurrences of intralesional hemorrhages (13).

HEMATOPOIETIC TUMORS

Lymphoid Tumors

Lymphoproliferative lesions are relatively common, with an overall incidence of 20% of all orbital lesions (7). They encompass a continuum of entities of varying morphology and clinical grade, from benign reactive hyperplasia to malignant lymphoma. Non-Hodgkin lymphoma accounts for up to 90% of these lesions and is the most common orbital neoplasm in the older age group. The most common subtype is mucosa-associated lymphoid tissue (MALT) lymphoma. Other common low-grade lesions include follicular center lymphoma and small B-lymphocytic lymphoma. The most common high-grade type is diffuse large B-cell lymphoma (14).

Lymphoproliferative lesions often present as gradual painless proptosis or a slowly enlarging mass or swelling, occurring over several months. Pain and inflammation are usually minimal. Lesions may involve the orbit, lacrimal sac, eyelids, or conjunctiva. A lesion beneath the conjunctiva often gives rise to the classic salmon patch appearance on slit lamp examination. Within the orbit, the lacrimal gland, extraocular muscles, or orbital space may be involved. Whether benign or malignant, these lesions tend to mold around existing orbital structures rather than invade them. As a result, lesions may reach a large size without causing vision loss or diplopia. Imaging features on CT include indistinct margins and moderate IV contrast enhancement. Bony erosion is typically absent except in aggressive lesions. MRI shows a poorly circumscribed lesion with moderate hyperattenuation on T1- and T2-weighted images and moderate enhancement with gadolinium (15).

Once a lymphoproliferative lesion is suspected based on clinical history and imaging, an open biopsy should be performed to establish the diagnosis. Fresh tissue is analyzed with immunohistochemical, molecular genetics, and flow cytometry studies to identify monoclonal (i.e., malignant) proliferations. All patients with hypercellular lymphoproliferative lesions (including benign reactive hyperplasia) should be referred to an oncologist for evaluation of possible systemic dissemination. Evaluation may include complete blood count (CBC); bone marrow biopsy; CT scans of the chest, abdomen, and pelvis; and regular periodic follow-ups. Approximately 20% to 30% of patients with periocular lymphomas will have disseminated disease at diagnosis, and an additional 30% will develop it over 5 years. Bilateral periocular involvement confers a greater risk of systemic spread, as do certain locations; the risk is lowest with conjunctival lesions, greater with orbital lesions, and highest with eyelid lesions (7).

Low-dose radiation therapy is the treatment of choice for primary orbital lymphomas and achieves local control in most cases, with a 5-year survival rate of 90% to 100%. Surgical cure is usually not possible given the infiltrative nature of the lesions. For secondary orbital lymphomas, systemic treatment with chemotherapy is used alone or in combination with orbital radiotherapy. Recent studies have suggested an interesting link between chronic *Chlamydia psittaci* infection and orbital MALT lymphomas, based on the theory that these lesions are antigen-driven. A similar link has been previously noted in gastric MALT lymphomas and *Helicobacter pylori* infection. Treatment of orbital MALT lymphomas with doxycycline has shown to induce partial to complete response. However, other studies of orbital lymphomas have failed to detect chronic chlamydia infection, and thus suggest a possible geographic distribution of this association (15).

Leukemia

Leukemia is the most common malignancy of childhood. Leukemic infiltrates may involve the orbit, and are more common with myelogenous leukemias than lymphocytic ones. Granulocytic sarcoma (chloroma, myeloid sarcoma) is a primary tissue mass form of acute myeloid leukemia. The tumor mass is composed of granulocytic precursor cells with varying degrees of differentiation. These lesions may occur prior to the development of systemic leukemia in up to 88% of cases, with systemic involvement usually occurring within 1 year (16).

These lesions typically occur in children during the first decade of life, with a mean age of 7 years. The most common presenting clinical sign is proptosis from a rapidly enlarging mass. Eyelid swelling and ecchymosis may also occur. Lesions may involve the orbital soft tissue, lacrimal gland, and subperiosteum of the orbital bones, with a predilection for the lateral and medial walls (17).

CT scan shows a large irregular mass with possibly bony erosion. As these features may not distinguish these lesions from other pediatric orbital malignancies in cases presenting prior to systemic leukemic involvement, biopsy is often required. A greenish appearance of these lesions on biopsy has been reported in up to 70% of cases (hence the term chloroma) and is due to the exposure of myeloperoxidase to ultraviolet light (16). Touch preparations may be performed on the tissue to stain for cytoplasmic esterase (Leder stain) and myeloperoxidase. Treatment consists of local radiotherapy and systemic chemotherapy.

Langerhans Cell Histiocytosis (Histiocytosis X)

Langerhans cell histiocytosis (LCH), formerly known as Histiocytosis X, is the accumulation of proliferating monocytes and dendritic histiocytes (epidermal macrophages). The exact histogenesis is unclear, but it is thought to result from mononuclear phagocyte dysregulation. LCH encompasses a spectrum of diseases. Eosinophilic granuloma is the most common and benign entity and is characterized by unilateral, usually solitary, osseous lesions. The intermediate clinical form is called Hand-Schüller-Christian disease and classically presents as the triad of diabetes insipidus, proptosis, and multifocal lytic bone lesions. Letterer-Siwe disease is the disseminated, most aggressive form of the disease.

LCH is a rare disease, with an estimated annual incidence ranging from only 0.5 to 5.4 cases per million persons per year. The disease occurs in children and teens, with a peak incidence between 5 and 10 years of age. There is a male predilection, with male-to-female ratio of 2:1. Orbital involvement occurs in up to 20% of cases, most frequently presenting as a lytic defect of the superolateral orbit (frontal, zygomatic, or greater sphenoid bones), and causing relapsing episodes of superolateral inflammation with eyelid swelling and erythema that may initially mimic infectious orbital cellulitis. Proptosis may also occur from the enlarging bony lesion.

CT scan shows a punched-out, osteolytic bone lesion with sharp borders. Treatment of isolated orbital bone lesions consists of surgical excision, which may be curative. Intralesional steroid injection or low-dose radiotherapy may be used as adjuncts to surgery. Spontaneous remission has also been reported after biopsy. Patients with disseminated disease receive aggressive chemotherapy treatment. Prognosis depends on the degree of involvement, with unifocal disease carrying an excellent prognosis, and disseminated disease carrying a 50% mortality rate (7).

NEURAL TUMORS

Optic Nerve Gliomas

Optic nerve gliomas (juvenile pilocytic astrocytoma) are cytologically benign tumors that occur most often in childhood, with peak age of onset between 2 and 6 years. Up

to 50% are associated with neurofibromatosis, and may be bilateral in this setting. Patients typically present with slowly progressive, painless, axial proptosis and profound vision loss. Eye exam findings include an afferent pupillary defect, optic atrophy, optic nerve edema, and strabismus.

Although these tumors are generally self-limited or progress slowly, some show aggressive growth. They may extend along the length of the optic nerve but typically do not invade the adjacent dura. Intracranial extension may lead to hypothalamic and pituitary dysfunction. Cystic degeneration can lead to sudden tumor enlargement and subsequent vision loss, but does not represent true tumor growth. Spontaneous improvement has also been observed but is rare (7). Characteristic orbital imaging findings are usually sufficient to establish diagnosis. Fusiform enlargement of the optic nerve is seen, with kinking or tortuosity commonly seen. Calcifications are rare. Contrast enhancement is variable on CT, and moderate to marked on MRI (18).

Treatment includes observation, resection, and radiation therapy. Close observation is indicated when the tumor remains isolated to the orbit and vision is intact. Surgical excision with free margins is indicated in cases of aggressive growth in order to prevent chiasm, contralateral optic nerve, or life-threatening intracranial extension. Radiation or chemotherapy can be used to retard growth of lesions already affecting the chiasm. Given its adverse effects on childhood development, chemotherapy is preferred over radiation.

Orbital Meningiomas

Orbital meningiomas represent up to 4% of all orbital lesions. They are the fifth most common orbital tumor (2). Meningiomas are derived from meningothelial cells of the arachnoid villi. Primary optic nerve sheath meningiomas are much less common than secondary orbital meningiomas, which arise intracranially and extend to the orbit through the optic canal, superior orbital fissure, or bone (17).

Primary optic nerve sheath meningiomas (Fig. 130.3) occur most frequently in women in the third to fourth decade of life. Slowly progressive vision loss occurs over years. Gaze-evoked transient visual obscurations, axial proptosis, and ocular motility restriction are possible. An afferent pupillary defect and visual field disturbance can be detected on exam. Ophthalmoscopic examination typically demonstrates optic nerve edema or atrophy. Optociliary shunt vessels are visible on fundus exam in up to a third of patients; these collaterals permit retinal venous outflow through the choroidal circulation and thus bypass central retinal vein obstruction secondary to tumor compression. Lesions occurring in childhood are often associated with neurofibromatosis.

Secondary meningiomas occur in a slightly older population, typically in the fifth decade of life, and also with a female preponderance. Lesions involving the greater sphenoid wing and lateral orbital wall cause proptosis, temporal fossa swelling, and lower eyelid swelling. Tumors involving the lesser sphenoid wing may lead to early vision loss and visual field defects due to optic nerve involvement (19).

Diagnosis can often be established on the basis of characteristic imaging features. Primary optic nerve meningiomas show diffuse tubular enlargement with marked contrast enhancement on both MRI and CT. Globular enlargement occurs less frequently and is the result of tumor invasion of the adjacent dura. CT demonstrates focal calcifications in 20% to 50%. Contrast-enhanced axial CT often reveals a linear central hypointense optic nerve surrounded medially and laterally by a hyperintense nerve sheath—a well-known finding termed "tram-tracking." Bony remodeling can be seen with expansive, long-standing lesions. Secondary orbital meningiomas produce bony hyperostosis. The presence of a dural tail on contrasted MRI helps distinguish meningioma from fibrous dysplasia (18). Most meningiomas are histologically benign, with aggressive forms occurring most commonly in younger patients.

Surgery is indicated for secondary meningiomas when compression of surrounding structures causes significant visual, cosmetic, or intracranial morbidity. Treatment of primary optic nerve sheath meningiomas is dictated by the degree of vision loss and the presence of intracranial extension, which occurs in up to 15% of patients. If vision loss is only moderate, patients are often observed because of the tumor's slow growth. If vision loss is progressive, vision function can be improved with radiation therapy. Surgical excision is performed when intracranial extension threatens the optic chiasm or contralateral optic nerve, or when the tumor has caused marked vision loss and significant proptosis (7).

Schwannoma (Neurilemoma)

Schwannomas are uncommon benign tumors of the peripheral nerve sheath. They arise due to proliferation of the myelin-producing Schwann cells and rarely undergo malignant transformation. They occur most commonly in adults between 20 and 60 years of age and are most often found in the superior or intraconal orbit. They can cause slowly progressive proptosis, and location at the orbital apex may cause progressive vision loss. Histopathologically, these lesions are well-encapsulated and are divided into Antoni A type (solid tissue with spindle cells arranged in whorls or palisades) or Antoni B type (loose myxoid tissue containing stellate cells). CT scan shows a dense, well-circumscribed, ovoid, or fusiform mass that enhances with contrast. Long-standing lesions may demonstrate bony remodeling, lower density areas of mucinous cystic degeneration, and calcification. Treatment consists of complete surgical excision of the tumor and capsule (17–19).

INFLAMMATORY TUMORS

Idiopathic Orbital Inflammation

Idiopathic orbital inflammation (IOI), also known as orbital pseudotumor, is a nongranulomatous inflammatory disorder with a heterogeneous clinical presentation. It can occur in children and adults, and accounts for up to 11% of all orbital lesions (2). Almost any orbital structure may be involved, including one or more extraocular muscles (orbital myositis), the sclera and posterior tenons (sclerotenonitis), or the optic nerve sheath (inflammatory optic neuritis). Patients may also present with a more diffuse process involving the orbital fat, multiple orbital structures, or with extension into the sinuses or intracranial cavity.

As the anatomic site of involvement dictates the signs and symptoms, the clinical presentation of IOI is varied. Patients commonly experience deep, boring periocular pain. Ocular motility restriction, diplopia, proptosis, conjunctival inflammation, and eyelid erythema and edema may also occur. Myositis may cause pain on eye movement. Decreased vision may be seen when the optic nerve, sclera, or posterior tenons are involved. Children often present with systemic signs such as fever, emesis, abdominal pain, and lethargy. Bilateral disease is seen in up to 30% of children with IOI. In contrast, bilateral involvement in an adult signals an underlying systemic vasculitis (7).

Diagnosis is usually clinical, and often confirmed with orbital imaging. CT shows an ill-defined, heterogeneous infiltrate that enhances with contrast during the acute phase. Laboratory findings include an increase in erythrocyte sedimentation rate, peripheral blood eosinophils, and cerebrospinal fluid (CSF) pleocytosis.

First-line treatment consists of oral corticosteroids (1 mg/kg/day). A rapid and dramatic response is typically observed within a few days, and steroids are tapered slowly over several weeks to prevent rebound inflammation. Biopsy may be required in patients with atypical symptoms, imaging features, treatment failure, or recurrence off steroids. This is especially true for lacrimal gland lesions, as an aggressive malignancy may also present with inflammation. Biopsy-confirmed refractory cases may respond to low-dose radiation therapy or immunosuppressants. A sclerosing variant has been found to be less responsive to systemic steroids and radiation, and may respond to intraorbital steroid injection (20).

Orbital Vasculitis

Orbital vasculitis is an inflammatory disorder that is associated with multiple systemic vasculitides. Giant cell arteritis, polyarteritis nodosum, Wegener granulomatosis, and connective tissue disorders such as systemic lupus erythematosus, dermatomyositis, and rheumatoid arthritis may involve orbital vessels. The pathogenesis involves a type III hypersensitivity reaction to circulating immune complexes with deposition of inflammatory cells in the vessel walls and subsequent orbital ischemia. Patients may present with painful proptosis and symptoms of systemic vasculitis. In patients with no known history or symptoms of systemic disease, the presentation may be confused with IOI. For this reason, failure of corticosteroid treatment in cases of presumed IOI should prompt biopsy (7).

Thyroid-Associated Orbitopathy

Although not considered an orbital lesion, thyroid-associated orbitopathy (TAO) is a common cause of orbital inflammation and is the most common cause of unilateral and bilateral proptosis in adults. The thyroid status of patients presenting with TAO varies: 90% are hyperthyroid, 6% are euthyroid, 3% have Hashimoto thyroiditis, and 1% are hypothyroid. Smoking exacerbates the disease, with severity being dose-dependent on the number of cigarettes smoked per day. The pathogenesis of TAO involves circulating autoantibodies to thyroid-stimulating hormone receptor (TSH-R) and insulin-like growth factor receptor (IGF-1R), which cross-react with orbital fibroblasts and stimulate them to differentiate into adipocytes and produce glycosaminoglycans, with resulting increase in orbital soft tissue volume.

The most common presenting sign is eyelid retraction, often with lateral temporal flare of the palpebral fissures. Proptosis, lagophthalmos, conjunctival chemosis and hyperemia over the rectus muscle insertions, extraocular muscle restriction, and optic neuropathy may also be observed. CT scan demonstrates the classic finding of fusiform extraocular muscle enlargement, which, unlike orbital myositis, spares the tendinous muscle insertions. Treatment of the active phase of TAO is aimed at establishing a euthyroid state, which can be accomplished with radioactive iodine ablation, antithyroid medications, or total thyroidectomy. A transient worsening of TAO may be noted after radioactive iodine ablation and total thyroidectomy, likely due to the release of TSH-R antigens. Vision-threatening optic nerve compression or exposure keratopathy may be temporized with corticosteroids and/or orbital radiation therapy. Total thyroidectomy may provide further control if not already performed. Definitive treatment most often requires orbital decompression. Recent studies have shown beneficial effects of immunomodulatory agents in treating vision-threatening TAO (21).

CYSTS

Cystic lesions of the orbit are uncommon, representing only 6% of all orbital lesions (2). The majority of these lesions are dermoid cysts and epithelial inclusion cysts. Histologically, dermoid cysts and epithelial inclusion cysts

are lined by epithelium and contain a central lumen filled with the secretory products of this lining. They are thought to arise from epithelial and subepithelial tissue that becomes entrapped within bony sutures during embryogenesis or becomes implanted in the orbit as the result of surgical or nonsurgical trauma.

Dermoid Cysts

Dermoid cysts are lined by keratinized stratified squamous epithelium and contain dermal appendages, such as hair shafts, sebaceous glands, and even sweat glands, in their walls. Their central lumens are filled with a mixture of keratin, oil, and occasionally hair shafts. Approximately 5% of dermoid cysts arise from conjunctival epithelium (nonkeratinized stratified squamous epithelium with goblet cells).

They are often found in the anterior superolateral orbit at the frontozygomatic suture, but can be found superomedially at the frontoethmoidal suture, or at any other bony suture. Patients often present in the first decade of life with a slowly progressive, painless, subcutaneous mass. It is typically firm to palpation, and may be freely mobile or fixed to bone. Deep orbital dermoid cysts typically present later in adulthood with proptosis and globe displacement. Dermoid cysts may also present as orbital inflammation, which is caused by an intense granulomatous reaction incited by cyst leakage. In younger patients, it is important to distinguish medial dermoid cysts from encephaloceles, mucoceles, or dacryoceles (22).

CT scan shows a round to ovoid, well-defined cystic structure with a thin wall that may contain calcifications. A dumbbell configuration may be seen with cysts that extend through the suture into the temporalis fossa, sinuses, or cranial vault. Bony remodeling or erosion may occur in long-standing cases. Fat-fluid levels may be seen on CT or MRI. Contrast may cause mild enhancement of the rim but not the lumen (18).

Treatment consists of complete surgical excision in symptomatic patients. It is important to avoid intraoperative cyst rupture. If rupture does occur, copious irrigation should be performed to avoid marked inflammatory reaction. For lesions that traverse a bony suture, complete excision may be difficult. Recurrence can occur after incomplete excision.

Epithelial Inclusion Cysts

Epithelial inclusion cysts differ from dermoid cysts in that they do not contain dermal appendages in their walls and are filled with keratin and epithelial debris. They may arise from cutaneous, conjunctival, respiratory, or apocrine gland epithelium. They may occur at any age, and are found most commonly on the eyebrow and eyelid. Orbital lesions are less common, and may represent posterior extension or a primary lesion. Unlike dermoids, epithelial inclusion cysts typically do not demonstrate fat content or rim calcifications on CT. The clinical presentation and management of these lesions is similar to that of dermoid cysts (22).

MESENCHYMAL TUMORS

Rhabdomyosarcoma

Rhabdomyosarcoma (RMS) is the most common primary malignancy of the orbit in the pediatric population. Four types have been described, including embryonal, alveolar, pleomorphic, and botryoid types. Embryonal is the most common subtype, alveolar is the most malignant subtype, and the pleomorphic subtype carries the best prognosis. Nearly half of the primary sites of occurrence for RMS lie within the head and neck, and orbital RMS accounts for roughly one-third of these (23). Orbital RMS does not arise from the extraocular muscles, but rather from the primitive undifferentiated mesenchymal cells within the orbit, particularly within the superomedial quadrant. Metastasis does occur via hematogenous spread, mainly to the lung and bones.

The disease is nonhereditary and presents at a median age of 8, with 90% of cases being diagnosed in patients prior to the age of 13 (23). Rarely, it may occur in older adults. Males are predominantly affected with a 5:3 male-to-female ratio. Patients usually present progressive proptosis over days to weeks, with one in three children presenting with ptosis and a palpable mass. There is often marked eyelid edema and discoloration. Downward globe displacement may be observed, reflecting the predilection of this tumor for the superomedial quadrant. However, the tumor may occur in any quadrant. The alveolar subtype tends to occur more frequently in the inferior orbit.

On CT imaging, the tumor typically shows moderately well-defined to ill-defined margins and an irregular shape with moderate contrast enhancement. In roughly 40% of cases, bony destruction is also seen. It appears isointense to muscle on T1- and hyperintense to muscle on T2-weighted MRI images (23). Definitive diagnosis is usually obtained via open biopsy or CT-guided fine needle aspiration (FNA) for deeper lesions. Evaluation for systemic spread should be performed, including bone marrow biopsy, chest radiographs, CBC, liver function tests, and lumbar puncture. Once a diagnosis is confirmed by biopsy, treatment consists of primary chemoradiation therapy. With the advent and widespread use of these treatment modalities, survival rates have been found to be over 90% in most series (24,25).

Fibrous Dysplasia

Fibrous dysplasia was found to account for roughly 1% of all orbital tumors in a recent series (2). Fibrous dysplasia is a rare, nonhereditary disease of the bone that is thought to be due to hamartomatous malformations of immature

bone and osteoid that replaces the normal bone with fibrous tissue. The disease may be restricted to only one site of the skeleton (monostotic) or may affect multiple skeletal areas (polyostotic). It is thought that roughly one in five cases of fibrous dysplasia involve the craniofacial bones. Most of the lesions found in the orbit are monostotic, with the orbital roof being the most common site of involvement (26). However, craniofacial involvement may accompany orbital disease in patients with McCune-Albright syndrome, which consists of a triad of polyostotic fibrous dysplasia, sexual precocity, and skin pigmentation occurring more frequently in women. Malignant transformation of this condition is quite rare but when it does occur, it is usually associated with prior irradiation (26).

While the disease has traditionally been considered a disease of childhood, it has also been found to occur well into adulthood. Lesions are usually noticed within the first two decades of life, but can remain asymptomatic and undiagnosed for extended periods of time. The clinical presentation depends upon the orbital bones involved, with most patients presenting with facial asymmetry, orbital dystopia, and proptosis. Epiphora may result from involvement of the nasolacrimal duct. Progressive narrowing of the foramina of the orbital apex can cause multiple motor and sensory cranial neuropathies, as well as vision loss from optic nerve compression in up to 50% of patients (18).

On CT imaging, the affected bone appears hyperostotic and thickened, with multiple areas of lytic spaces intermixed with "ground-glass"-like sclerotic areas (Fig. 130.4). CT imaging characteristics may resemble those of sphenoid wing meningiomas, and the lack of dural enhancement of these lesions on MRI can often be useful in further distinguishing the two. Fibrous dysplasia lesions often show an area of low-to-intermediate signal intensity and moderate to marked enhancement of contrast on MRI. Surgical treatment involves local resection or curettage and is indicated in patients with pain, marked deformity, or malignant transformation.

Solitary Fibrous Tumor

Solitary fibrous tumor (SFT) is a relatively new pathologic entity/classification. In a recent large series of 41 fibroblastic tumors with overlapping morphologic features originally diagnosed as hemangiopericytomas, fibrous histiocytomas, mixed tumors, or giant cell angiofibromas, reclassification using modern-day pathologic evaluation techniques showed that all cases were rediagnosed as SFTs (27). It is an uncommon spindle cell tumor that rarely occurs in the orbit. Previous to this recent series and likely due to previous designations, there had been only 53 cases reported worldwide since it was first described in the orbit in 1994 (28). The mean age of onset is 40 years, and patients present with proptosis and diplopia. A palpable mass with or without pain has also been observed.

SFTs are hypervascular lesions with CT scan findings of a well-circumscribed mass with moderate contrast enhancement and possible calcification and bony remodeling. On MRI, these lesions appear as an intermediate intensity mass on T1-weighted images with moderate contrast enhancement. Histologically, SFTs consist of densely arranged spindle-shaped cells in a storiform pattern with numerous

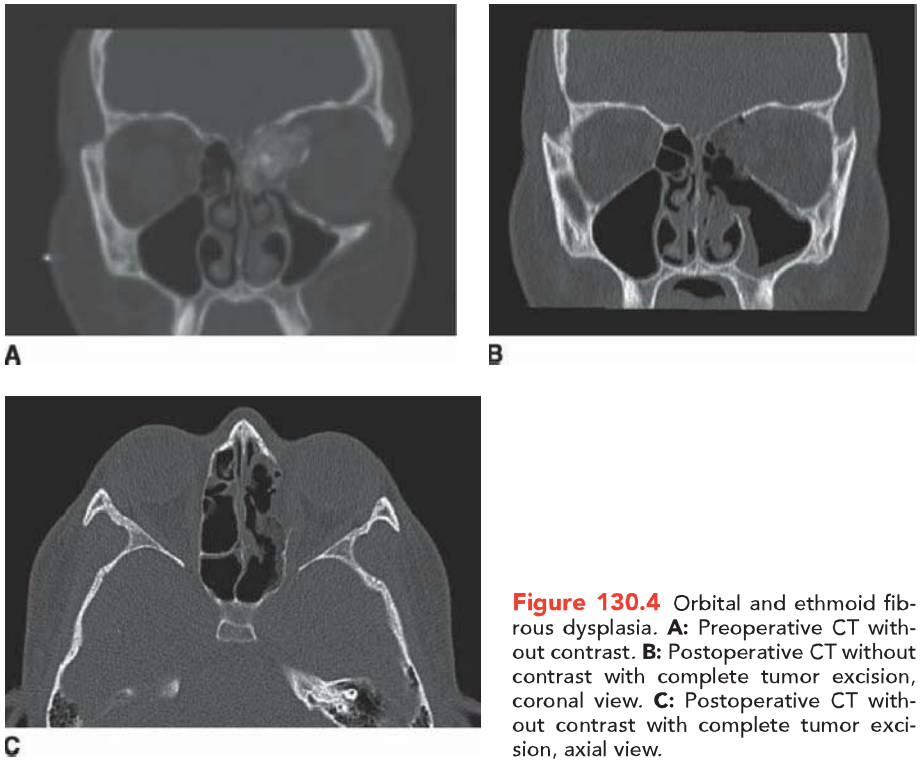

Figure 130.4 Orbital and ethmoid fibrous dysplasia. **A:** Preoperative CT without contrast. **B:** Postoperative CT without contrast with complete tumor excision, coronal view. **C:** Postoperative CT without contrast with complete tumor excision, axial view.

vascular channels (28). They share histologic similarities to fibrous histiocytoma and hemangiopericytoma lesions. However, immunohistochemical studies can differentiate between them and can be utilized to confirm the diagnosis, as SFTs stain positively for CD34. Treatment includes en bloc tumor resection, although residual tumor has been found to remain stable for some time.

Osteoma

Primary bone tumors of the orbit constitute roughly 1% of all orbital tumors and in most series, a third to a half of these lesions are benign osteomas (2,26). These lesions are often secondary orbital tumors as well, originating in the adjacent frontal, sphenoid, and/or ethmoid paranasal sinuses. The roof of the orbit is most commonly affected in primary osteomas of the orbit. These lesions are most commonly unilateral and present in adulthood. CT scan or plain films show a sessile or pedunculated smooth, rounded mass with density similar to normal cortical bone. Patients presenting with multiple lesions must be considered for Gardner syndrome, a hereditary disease associated with multiple osteomas, other soft tissue tumors, and colon polyps with nearly 100% malignant transformation. Symptoms vary depending on the location and size of the osteoma. These lesions can often be followed conservatively, while symptomatic lesions are usually resected with recurrence being rare.

Sarcomas

Malignant mesenchymal lesions such as osteosarcoma, fibrosarcoma, chondrosarcoma, and liposarcoma are exceedingly rare in the orbit, but have been reported and are known to occur in the orbit as primary malignancies. Children with a history of retinoblastoma have been shown to be at higher risk for sarcomas of the orbit even if they have not undergone treatment with radiation (7). All of these sarcomatous lesions have a very poor prognosis due to their highly malignant nature.

LACRIMAL TUMORS

Mass lesions that affect the lacrimal gland most often produce signs of proptosis and inferomedial displacement of the globe. Most lacrimal gland masses are due to idiopathic orbital inflammatory disease and are accompanied by other signs and symptoms associated with these processes. These often include lateral upper eyelid swelling, erythema, and warmth. One such diagnosis is acute dacryoadenitis, caused by either viral or bacterial infection of the lacrimal gland. Offending agents can include herpesvirus, mumps, mononucleosis, staphylococcal and/or streptococcal microorganisms. Shields et al. (2) found in their series of 1,264 patients that lacrimal gland lesions represented 9% of all space-occupying orbital lesions, with roughly 20% of these being lesions of epithelial origin. It has been said that another 20% to 30% of lacrimal gland lesions are caused by lymphoproliferative disorders with the remaining 50% to 60% of lesions being caused by inflammatory and/or infectious causes. Lymphoid lesions of the lacrimal gland include atypical and benign reactive lymphoid hyperplasia, leukemias, and malignant lymphomas.

Of the epithelial lesions, roughly 50% to 60% have been shown to be benign in nature, the vast majority of which are pleomorphic adenomas (benign mixed tumors). These usually present with slowly progressive painless proptosis with inferomedial globe displacement over a period of months to years. Upper eyelid edema may also be a presenting finding. Radiographic findings usually reveal a round well-circumscribed mass at the superolateral orbit with enlargement of the lacrimal fossa, but no bony destruction. While complete surgical excision with an intact capsule is always the goal, recent data have shown that recurrence rates remain low even when there is violation of the tumor capsule and/or when complete excision is carried out after previous incomplete excision (29).

The remaining 40% to 50% of epithelial lesions are malignant carcinomas. Of this subgroup, adenoid cystic carcinoma (ACC), carcinoma ex-pleomorphic, adenocarcinoma, and mucoepidermoid carcinoma are the most common in descending order. In ACC, the most common presenting signs are globe ptosis, dystopia, and proptosis (29). Rapidly developing pain and/or hypoesthesia are ominous signs of an aggressively behaving tumor. A basiloid histopathologic pattern has a much poorer survival when compared to nonbasaloid patterns (29). Recently, improvement in prognosis has been shown in patients with ACC that are treated with intra-arterial cytoreductive chemotherapy as an adjunct to conventional treatment of surgery and adjuvant radiation therapy, although this has not yet become standard of care (29). Other common malignant epithelial lesions include carcinoma ex-pleomorphic (aka malignant mixed cell carcinomas), adenocarcinomas, and mucoepidermoid carcinomas. All of these lesions tend to present with progressive proptosis, pain, and/or numbness in the periorbital region, and imaging findings suggest bony destruction and expansion of the lacrimal fossa. Mortality for most of these carcinomas is greater than 50%. Biopsy is indicated to establish a definitive diagnosis and if feasible, complete surgical excision of the lesion should be the primary modality of treatment, often including exenteration with excision of adjacent orbital bone and periorbital soft tissues. Adjuvant radiation therapy is nearly universally recommended as well.

SECONDARY LESIONS

With the orbit's anatomic proximity and shared borders, it is of no surprise that the majority of secondary orbital tumors arise from paranasal sinus, eyelid and periorbital skin, and intracranial primary processes. However, primary processes of the globe and conjunctiva can cause secondary orbital tumors as well. Secondary tumors accounted for roughly 44% of all tumors in Henderson Mayo Clinic series

(Henderson), while more recent large series have shown slightly lower rates of 11% to 26% (2,3). In the Mayo series, the most common secondary lesions affecting the orbit were: mucoceles, SCCs, meningiomas, BCCs, and vascular malformations (1). More recent data have shown that malignant melanomas of the skin, conjunctiva, and uvea/choroid have increased in prevalence, accounting for 45% of all secondary tumors (2). It should be noted that mucoceles were not included in this series. Regardless, primary skin lesions such as BCC, SCC, and melanoma of the eyelid and periorbital skin are an increasingly common secondary orbital lesion encountered by the modern-day physician.

Paranasal mucoceles, mainly of the frontoethmoid and sphenoid sinuses, continue to be prominent lesions secondarily involving the orbit. Similarly, the relatively rare invasive processes of the paranasal sinuses, including SCC, inverting papilloma, adenocarcinoma, ACC, mucosal melanoma, sinonasal undifferentiated carcinoma, and esthesioneuroblastoma, all have the high anatomic potential to encroach upon and invade the orbital space. Intracranial processes, most commonly meningiomas of the sphenoid ridge, also account for a substantial portion of secondary tumors of the orbit. Regardless of origin, the primary process requires treatment, often in conjunction with addressing the orbital involvement, often with a multidisciplinary team approach.

METASTATIC TUMORS

Orbital metastasis represents approximately 7% of all orbital tumors, and is therefore an important entity to consider in the differential diagnosis. Metastasis to the orbit is reported to occur in approximately 2% to 4.7% of patients with systemic cancer (30,31). Orbital metastasis may be the presenting sign of malignancy in up to 25% of patients.

The vast majority of orbital metastases are carcinomas. Breast carcinoma is the most common, accounting for 50% of metastatic orbital lesions, followed by prostate and lung carcinomas (2,30–32). Other less common metastases include gastrointestinal carcinoma, renal cell carcinoma, thyroid carcinoma, and malignant melanoma. Orbital metastasis is predominantly a condition of adulthood, with greater than 90% of cases occurring in patients aged 40 years or older. Bilateral disease is unusual, with more than 90% of cases occurring unilaterally.

The onset of symptoms is usually rapid and progressive, occurring over weeks to months. The most common presenting signs and symptoms include pain, proptosis, diplopia, decreased vision, ptosis, inflammation, and ocular motility restriction. The extraocular muscles are a common site of metastasis due to their rich blood supply. The bone marrow space of the sphenoid bone is also commonly involved given its high volume of low-flow blood, and lytic destruction of this part of the lateral orbital wall is highly suggestive of metastatic disease (7). Paradoxical enophthalmos has been well documented in metastatic scirrhous breast carcinomas due to the fibrosis and secondary contracture of orbital contents.

The most common metastatic tumor of childhood is neuroblastoma. Neuroblastoma metastasizes to the orbit in 15% of cases, presenting with the abrupt onset of unilateral or bilateral proptosis and ischemia-induced lid ecchymosis. The mean age of onset of neuroblastoma is 2 years, and metastasis often occurs late in the disease when the primary tumor can be detected in the abdomen, mediastinum, or neck (24).

Orbital imaging with CT and MRI may offer important clues to diagnosis. Metastatic lesions typically enhance on contrasted MRI. CT findings suggestive of breast carcinoma include a diffuse, infiltrative orbital mass extending along the extraocular muscles with possible bony destruction. Gastrointestinal and thyroid carcinomas may have both bony and soft tissue involvement. Prostatic carcinoma is known to metastasize to bone and produce hyperdense osteoblastic bone lesions, although osteolytic lesions may also be seen. Neuroblastoma frequently causes bony destruction of the lateral orbital wall and sphenoid marrow. Definitive diagnosis is made with tissue diagnosis by fine-needle aspiration biopsy or orbitotomy.

In general, orbital metastasis is associated with a poor prognosis (31). The goal of treatment is palliative and consists mainly of local radiation therapy. When orbital metastasis is the initial presentation of breast cancer, the orbital biopsy specimen should be analyzed for estrogen receptor expression in order to determine whether hormonal therapy would be beneficial (7,30).

SURGICAL APPROACHES

The approach that one chooses needs to be dictated by the anatomic location of the lesion, and to a lesser extent, the pathology of the lesion. An understanding of the anatomy of the orbit and the ability to correlate this with radiographic findings is also extremely important when striving to preserve form and function of the eye.

The choice of surgical approach to access orbital lesions depends on the location of the lesion, the extent of exposure required, and the goal of the surgery (biopsy, surgical debulking, or complete excision). A variety of transcutaneous and transconjunctival incisions can be used to provide transseptal, transperiosteal, or sub-Tenon's access to the extraconal and intraconal orbital space.

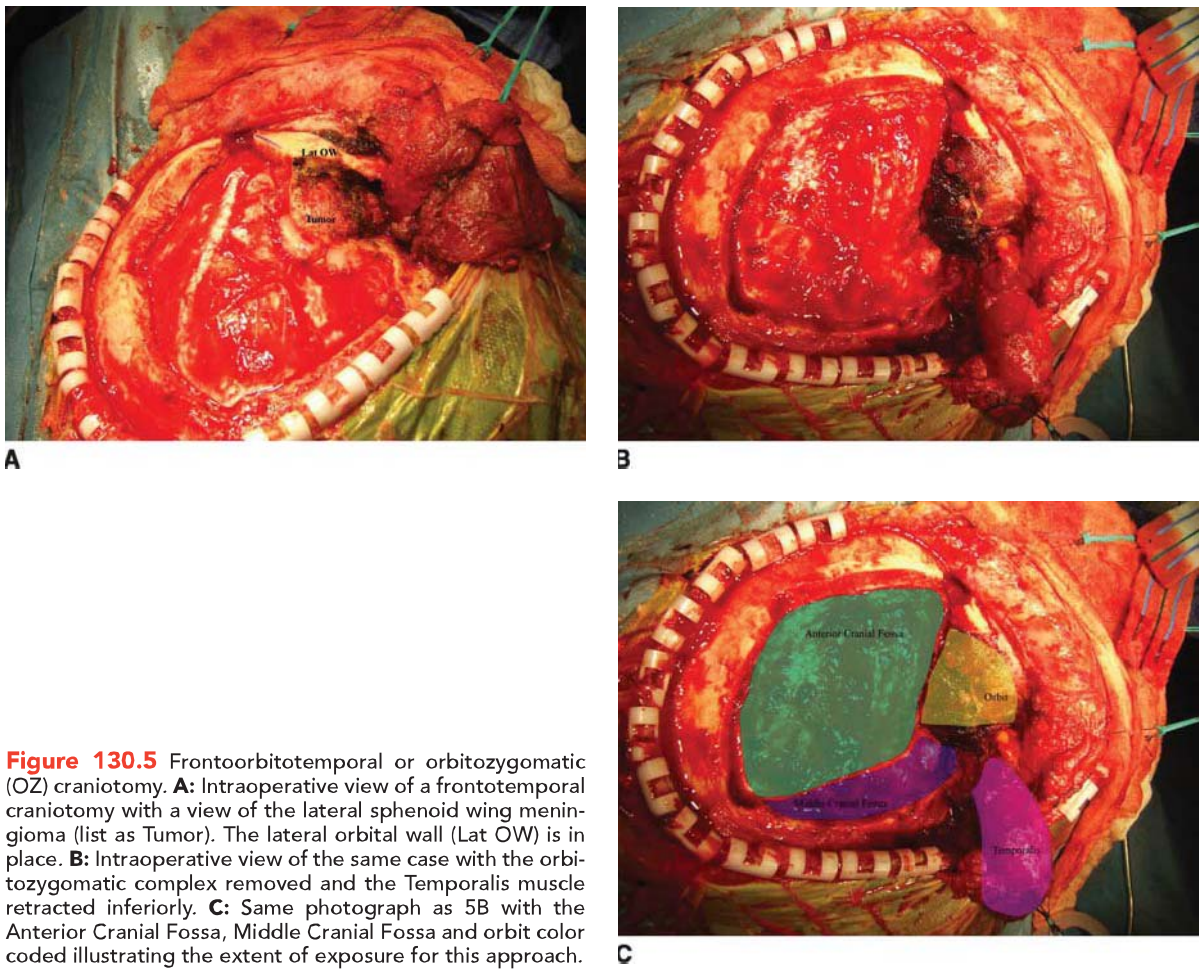
An anterior orbitotomy approach is used for lesions located anterior to the posterior aspect of the globe. Transcutaneous or transconjunctival incisions can be utilized to access lesions in the superior, lateral, inferior, or medial space around the eye. In the superior anterior orbit, an upper lid crease incision can be extended transseptally or subperiosteally, and provides better cosmesis than a subbrow incision. Inferiorly, a subciliary blepharoplasty incision, lower lid crease incision, or transconjunctival incision can be used. The transconjunctival approach has become the preferred approach for inferior orbitotomy, and is accomplished with an incision through the inferior palpebral conjunctiva and lower lid retractors. Access to the medial anterior orbit can

be achieved through a transcutaneous frontoethmoidal (Lynch) incision, bulbar transconjunctival incision, or transcaruncular incision. Laterally, an upper lid crease incision may be combined with a lateral canthotomy incision.

Deeper extraconal lesions, intraconal lesion, and the optic nerve can be accessed via the incisions listed above with additional modifications to provide enhanced exposure. In the case of medial lesions, detachment of the medial rectus can provide access to the intraconal space. For better visualization of the posteromedial orbit, a medial orbitotomy can be combined with a lateral orbitotomy to allow lateral rotation of the globe. A full thickness vertical incision of the upper lid can also provide access to the superomedial intraconal space. In this lid-splitting technique, the incision is made at the junction of the medial and central lid and transects the tarsus and levator aponeurosis (33). The transcaruncular incision has gained popularity for access to posteromedial lesions given its improved cosmesis compared to a skin incision. The transcaruncular technique provides wide subperiosteal access to the medial wall posteriorly to the orbital apex. When combined with a transconjunctival inferior fornix incision, additional inferior and inferolateral exposure can be achieved (34). Deep inferior orbital lesions can be exposed using a Caldwell-Luc incision to access the maxillary sinus. In this approach, an incision through the gingiva exposes the anterior wall of the maxillary sinus, an opening is created in the sinus, and the posteroinferior floor is removed (33).

A lateral orbitotomy approach provides access to the posterolateral intraconal and extraconal spaces and the optic nerve. Briefly, an upper eyelid crease or lateral canthotomy incision is used to mobilize the temporalis muscle and fascia and expose the lateral orbital wall. The bony lateral wall is removed with an oscillating saw in one piece to expose the underlying periorbita, which is excised. The lateral rectus can be retracted for intraconal access, and the bone sutured or plated back into position once excision is complete (35). Wide exposure to the posterior orbit and skull base can be achieved with extension of the bone removal to the posterior orbital wall or greater wing of the sphenoid bone. Superior extension of the bone removal provides greater access for larger lacrimal fossa lesions.

Lesions at the orbital apex, superior orbital fissure, or those that expand from the orbit into the cranial vault can be safely approached only by superior orbitotomy with frontal craniotomy. This approach requires a combined effort with neurosurgery. A frontotemporal or frontoorbitotemporal (Fig. 130.5) approach may also be used (36).



A B C

The lateral orbital wall (Lat OW) is in place. **B:** Intraoperative view of the same case with the orbitozygomatic complex removed and the Temporalis muscle retracted inferiorly. **C:** Same photograph as 5B with the Anterior Cranial Fossa, Middle Cranial Fossa and orbit color coded illustrating the extent of exposure for this approach.

Endoscopic skull base surgery is based upon the principle that an endonasal approach gives the operative surgeon direct access to lesions of the anterior and ventral skull base without the morbidity classically associated with approaches that traverse neurovascular boundaries. The same principle is utilized in endoscopic approaches to the orbit. The structure that needs most attention is the optic nerve, with tumors extending lateral and superior to the nerve are relatively inaccessible via the endonasal route. Conversely, lesions that are located inferomedially provide the most direct route for an endoscopic approach.

For nearly all cases, standard image guidance registration is performed, with the surgeon(s) reviewing the operative plan for that particular case. The approach first includes standard endoscopic rhinologic procedures. The uncinectomy and maxillary antrostomy are widely opened and the floor of the orbit is found. The ethmoids are traversed and the sphenoid is then opened for visualization of the carotid artery, optic nerve, planum, and sella. Dissection then proceeds anteriorly along the skull base to address the bony septations along the skull base and lamina. If orbital apex or intraconal work is required, it is best to utilize a binaural approach previously described. The ipsilateral middle turbinate, posterior septum, and the contralateral sphenoid are opened as well.

Three corridors for endoscopic endonasal intraorbital surgery for orbital tumors have previously been described (37). These include: an inferomedial approach for extraconal lesions, a transmaxillary approach for lateral extraconal lesions and a medial intraconal approach with displacement of the rectus muscles and intraconal dissection between the rectus muscles (37). The medial/inferior extraconal approach is the approach also used for endoscopic orbital and/or optic nerve decompression procedures. The medial/inferior intraconal approach utilizes a corridor between the medial and inferior rectus muscles (Fig. 130.6). This approach is best utilized after external identification, isolation, and retraction of the muscles as they insert on to the globe. This allows for a greater ease of dissection within the proposed corridor.

Transorbital neuroendoscopic surgery (TONES) is a recently described approach to lateral anterior skull base lesions, as well as to paramedian lesions that cross neurovascular structures (38). Utilization of the TONES techniques has allowed for the safe and effective repair of CSF leaks, optic nerve decompressions, repair of cranial base fractures, and removal of skull base tumors. The precaruncular (to access medial quadrant of the orbit), preseptal lower eyelid (inferior quadrant), superior eyelid crease (superior quadrant), and the lateral retrocanthal (lateral quadrant) approaches have all been described (38).

Regardless of the approach to the orbit, basic principles must be followed. First and foremost, it is critical to avoid crossing the optic nerve and ophthalmic artery. Therefore, tumors isolated to the superolateral orbit should not be approached endoscopically. Second, entry through the lamina papyracea should occur below the level of the ethmoidal foramina; therefore, limiting the risk of damage to the ethmoid arteries. Third, the extraocular muscles must be respected and handled with delicate caution. Lastly, team preoperative evaluations and planning and team surgery provides the best care for these complex lesions.

GENERAL OPERATIVE PRINCIPLES AND POSTOPERATIVE CARE

The surgeon who chooses to operate within the orbit must have a flawless knowledge of the intricate anatomy of this region. They must also utilize meticulous and deliberate technique. Respecting the delicate anatomic structures such as the vast neurovascular network within the orbit, the optic nerve and globe itself, and the extraocular muscles, is imperative. Avoiding excessive traction on these structures, while also striving for meticulous hemostasis with use of biploar cauterization, is required. Properly utilizing dependent, and even suction, drains postoperatively is also needed. The use of the proper equipment that allows for delicate handling and dissection of tissues is needed when operating within the compact anatomy within and around the orbit. Principles such as traction/countertraction, exposure, hemostasis, and patience need to be followed at all times. Recognition of potential complications and urgent situations, both intraoperatively and postoperatively, is also important for every surgeon operating in this area. For example, realizing that extreme post-op pain, especially in association with chemosis, decreased acuity, and elevated intraocular pressures indicates a possible retroorbital hemorrhage, which can lead to permanent ischemic injury to the optic nerve. Postoperatively, head elevation and the use of ice compresses also tend to help limit the edema that is often appreciated. Also, the use of ophthalmologic-specific medications, such as bacitracin ophthalmic ointment, is also required. Similarly, if any conjunctival incisions are made, whether bulbar or palpebral, a combination steroid-antibiotic drop should be prescribed prophylactically for a week's time.

CONCLUSION

Tumors and mass lesions affecting the orbit are overall quite rare, but an awareness of the extensive array and broad scope of pathologies potentially involved is imperative for clinicians treating patients with these problems. Common presenting signs and symptoms of orbital tumors include: proptosis, diplopia, visual acuity changes, and pain/pressure. The direction of proptosis is key in helping to determine the location, and often the most likely potential pathologies, of the lesion. Imaging of the orbit plays a crucial role in the appropriate preoperative workup of patients with orbital tumors, with specific imaging characteristics often leading to a confident preliminary diagnosis prior to a true tissue diagnosis. Surgical approaches to the

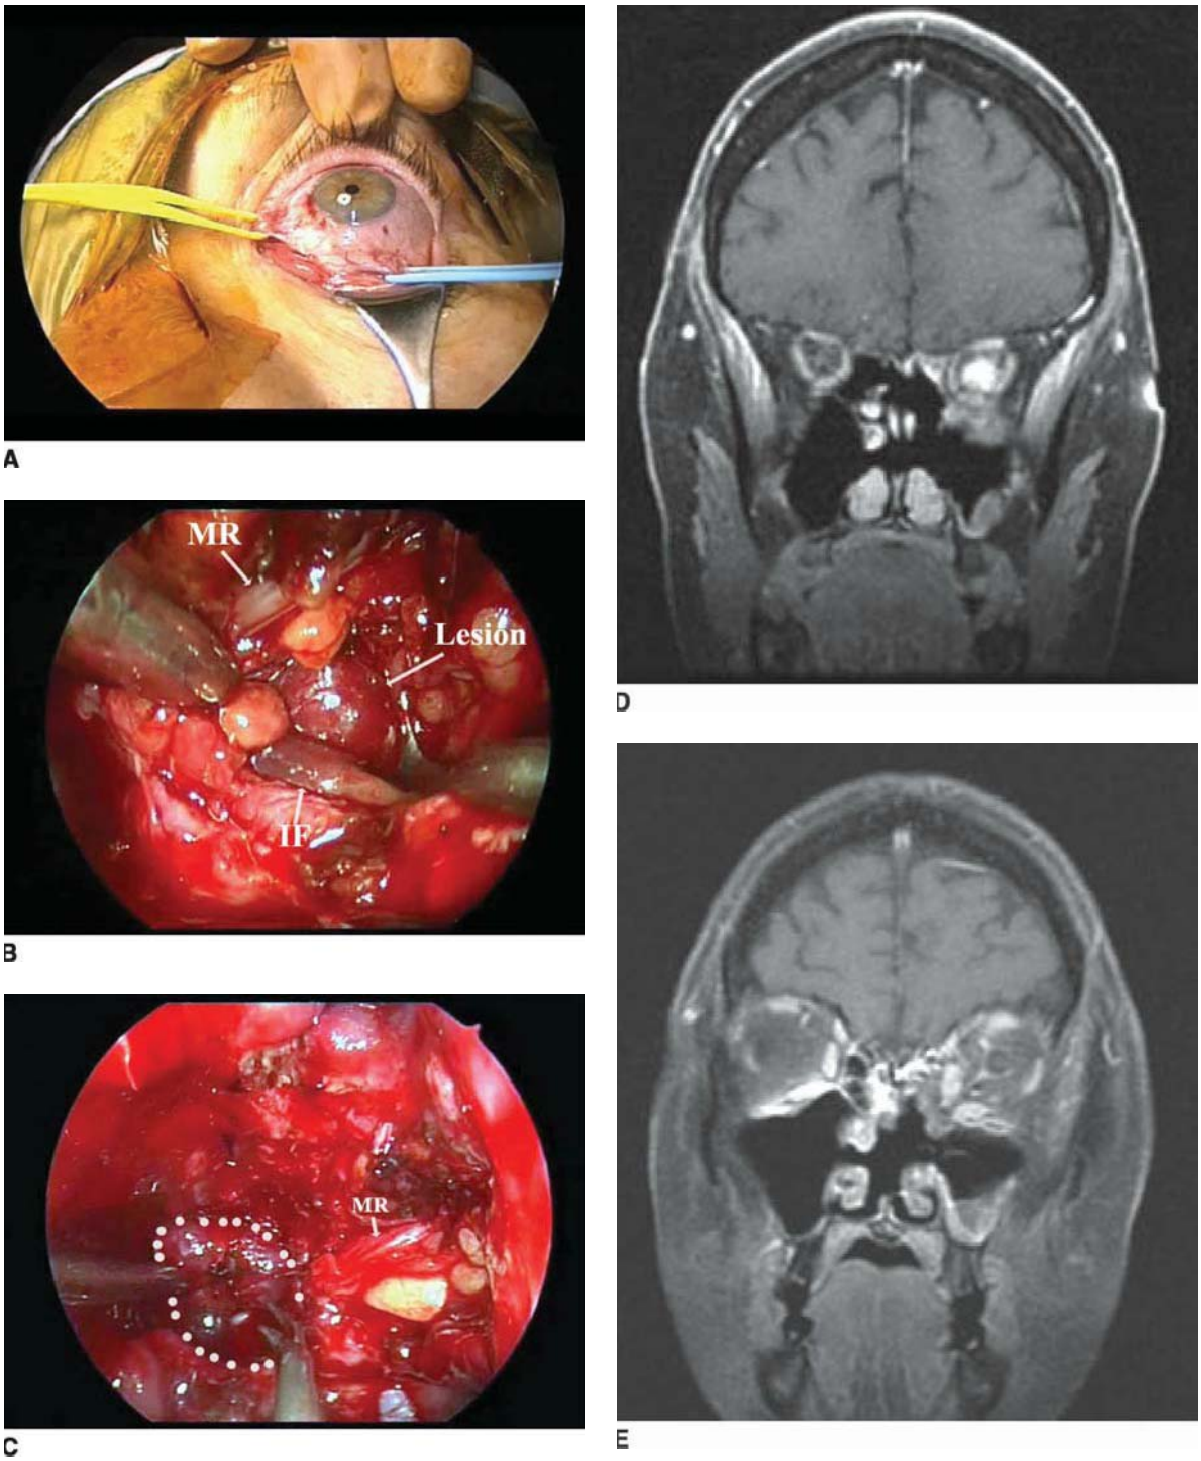


Figure 130.6 Endoscopic endonasal approach for an intraconal orbital tumor. **A:** External view of the left extraocular muscles identified and vessel looped for control. **B:** Intraconal identification and dissection of the hemangioma. MR, medial rectus, IF, inferior rectus. **C:** Lesion removed en bloc from the intraconal space. **D:** Preoperative MRI with contrast. **E:** Postoperative MRI with contrast with complete tumor excision.

orbit can be classified based on the location of the orbit that requires access. Extraorbital, transcranial, and endoscopic approaches have all been utilized in the treatment of these lesions. The choice of approach depends not only on the location of the lesion but the suspected or known pathology of the tumor, functional status of the orbit, and surgeon preference as well.

While uncommon, orbital tumors and associated diseases may present to the practicing otolaryngologist. While appropriate recognition and workup is important, if an otolaryngologist decides to treat patients with these pathologic processes, multidisciplinary teams are a tremendously important part of successful outcomes. The rarity and complexity of these cases often require Oculoplastic surgeons, Neurosurgeons, and Otolaryngologists to work together to safely and effectively treat patients. Early identification, thoughtful workup, multidisciplinary approach, meticulous technique, and appropriate postoperative care can, in some cases, prolong life and cure disease, as well as preserve or restore form and function of the orbit.

HIGHLIGHTS

- The most common benign tumors of the orbit are hemangiomas and meningiomas.
- The most common malignant tumor of the orbit is non-Hodgkin lymphoma.
- RMS is the most common primary malignancy of the orbit in the pediatric population.
- Proptosis is the initial and cardinal sign of an orbital lesion.
- Visual acuity loss is a late finding of advanced disease or a finding of a space-occupying lesion within the optic canal.
- The orbital vault is made of seven bones: frontal, zygomatic, sphenoid, maxilla, lacrimal, palatine, and ethmoid bones.
- Consideration for orbital metastases should be given for infiltrative and rapidly progressing orbital tumors. The most common primary site for metastasis in women is breast and for men is lung or prostate.
- Surgical approach needs to be dictated by the anatomic location of the lesion, the pathology of the lesion, and the primary goal for surgery (e.g., biopsy vs. resection).
- That extreme post-op pain, especially in association with chemosis, decreased acuity, and elevated intraocular pressure, indicates a possible retroorbital hemorrhage, which can lead to permanent ischemic injury to the optic nerve.
- There are several options for surgical care of orbital tumors; however, for any of these approaches team planning and surgery usually provides the best outcome.

QUESTIONS

1. A 35-year-old woman presents with a 3-month history of progressing double vision. On exam you note normal acuity but a left cranial nerve 6 palsy. What is the next step?

A. Obtain an MRI and CT	KEY
B. EMG of lateral rectus	Distracter
C. Serial clinical exam in 2 weeks	Distracter
D. Begin high dose steroids	Distracter

2. Which of these orbital bones contributes to the orbital rims?

A. Sphenoid	Distracter
B. Zygomatic	KEY
C. Palatine	Distracter
D. Lacrimal	Distracter

3. What is the main lower eyelid retractor?

A. Whitnall ligament	Distracter
B. Capsulopalpebral fascia	KEY
C. Inferior oblique muscle	Distracter
D. Orbicularis oculi	Distracter

4. A 3-year-old child presents with hypoglobus and a lesion on exam in the superior orbital rim. An FNA in clinic reveals dendritic histiocytes consistent with LCH. What is the next step in management?

A. Surgery with conservative removal	Distracter
B. Surgery with radical removal	Distracter
C. Bone survey	KEY
D. Radiation therapy	Distracter

5. Eight hours after an uneventful lateral orbitotomy for biopsy of an orbital tumor, your patient notes progressive unrelenting pain and chemosis. What must be considered as a cause for this pain?

A. Retrobulbar hematoma	KEY
B. Intraoperative traction on the inferior orbital nerve	Distracter
C. Transection of the superior orbital nerve	Distracter
D. Infection at the site of mini-plate repair	Distracter

Cranial Base Surgery

131

Carlos D. Pinheiro-Neto *Carl H. Snyderman* *Paul A. Gardner*

The cranial base is a complex anatomical region encompassing important neurovascular structures. The diversity and complexity of pathologies arising in the cranial base often require multidisciplinary evaluation and management. The collaboration between surgeons of different specialties (otolaryngology/head and neck, neurosurgery, ophthalmology, plastic and reconstructive surgery) is paramount to achieve an appropriate surgical plan. Frequently, the preoperative evaluation should include consultation with neuroradiology, radiation oncology, and medical oncology. Contributions from skilled and experienced anesthesiologists, pathologists, critical care physicians, dentists, nurses, speech pathologists, physical therapists, and other professionals are required during the intraoperative and postoperative period in order to establish good outcomes. The most effective scenario for the treatment of skull base pathologies occurs when members of these different fields are all integrated to form a skull base team.

The aim of this chapter is to provide an overview of the fundamentals of cranial base surgery. The evolution of the field in past decades is outlined. An anatomical review with clinical correlations and the evaluation and management of patients with skull base pathology are discussed. The surgical approaches for different regions of the cranial base with a discussion of complications are presented.

HISTORY

As a unique anatomical region and interface between surgical specialties, surgeries addressed to the cranial base began as sporadic procedures performed by otolaryngologists/head and neck surgeons, plastic/reconstructive surgeons, and neurosurgeons working separately. In the first decade of the 20th century, two pioneering neurosurgeons (Schloffer and Cushing) and an otorhinolaryngologist (Oskar Hirsh) were the first to reach the cranial base through the facial structures. They performed a transnasal approach to the pituitary fossa (1,2). Sixty years later, in 1967, Hardy first used the operating microscope in transsphenoidal pituitary surgery.

In 1941, Dandy (3) resected an orbital tumor using an approach through the anterior cranial fossa and ethmoid sinus. This is considered the beginning of modern craniofacial surgery (1). During the subsequent years, isolated reports were published regarding resection of cranial base lesions using intracranial and transfacial approaches. Pioneering efforts by Tessier (4) for craniofacial anomalies (e.g., orbital hypertelorism) also provided a foundation for cranial base surgery. In 1963, Ketcham et al. (5) were the first to report a series of 19 patients with sinonasal malignancies treated with anterior craniofacial resection.

In the field of lateral skull base surgery, House (6) advanced the subspecialty of neuro-otology by performing an acoustic neuroma resection via a middle fossa approach in 1961. House partnered with the neurosurgeon Doyle to form one of the first skull base teams. In the 1970s, Fisch described the resection of glomus jugulare tumors utilizing an approach through the infratemporal fossa.

The following years were characterized by the cooperation between otolaryngologists/head and neck surgeons and neurosurgeons for the development of cranial base surgery as a well-established subspecialty. A subspecialty society, the North American Skull Base Society, was established in 1989. In combination with this cooperation, advances in surgical technology especially in operative visualization, neuroimaging, powered instrumentation, anesthetic techniques, and intraoperative monitoring resulted in the incredible progress of cranial base surgery observed in the last few decades.

The introduction of endoscopes during microscopic transsphenoidal surgeries as a tool to improve visualization occurred in the late 1970s and early 1980s. In the 1990s, different groups around the world reported the use of the pure endoscopic transsphenoidal technique
